Several of the drugs discussed in this chapter do not fit into other categories or are not important enough for a separate chapter. They are grouped together here because they have certain features in common: they inhibit protein synthesis in bacteria (with macrolides, lincosamides, and chloramphenicol acting at a similar site), are relatively broad-spectrum, and have a large volume of distribution (i.e., they achieve effective concentrations in most tissues).

Some of these drugs are not as common or as available as in previous years. Some older drugs have given way to newer derivatives. For example, newer macrolides such as azithromycin have replaced erythromycin for some uses in small-animal medicine, and florfenicol has replaced chloramphenicol for use in cattle. Earlier editions of this text should be consulted for more in-depth discussion of these older agents.

CHLORAMPHENICOL

CHEMICAL FEATURES. Chloramphenicol chemically is d-(-)-threo-1-*p*-nitrolphenyl-2-dichloroacetamido 1,3-propanediol (Fig. 37.1), has a pK_a of 5.5, and was first isolated from the soil organism *Streptomyces venezuelae* in 1947. The chloramphenicol used today is manufactured synthetically. Chloramphenicol is slightly soluble in water and freely soluble in propylene glycol and organic solvents. Chloramphenicol is a broad-spectrum antibiotic, affecting gram-positive and gram-negative organisms, aerobic and anaerobic bacteria, and many intracellular organisms. Chloramphenicol has three functional groups that largely determine its biological activity: the *p*-nitrophenol group, the dichloroacetyl group, and the alcoholic group at the third carbon of the propanediol chain (Yunis 1988). Replacement of the *p*-NO_2 group by a methylsulfonyl (HC_3-SO_2) moiety produces thiamphenicol and a substantial change in biological activity, while modification of the propanediol group by the addition of a fluorine atom results in the synthesis of florfenicol. Both thiamphenicol and florfenicol will be discussed in more detail later in this chapter. Loss of the dichloroacetyl group altogether results in loss of biological activity (Yunis 1988; Hird and Knifton 1986).

DRUG FORMULATIONS. Three formulations of chloramphenicol have been administered for systemic therapy in animals. Chloramphenicol base is the unconjugated form of chloramphenicol and is available only in an oral formulation. Chloramphenicol base has a bitter taste, so to increase the palatability, the ester chloramphenicol palmitate was manufactured as an alternative oral formulation. Chloramphenicol palmitate is insoluble in water but soluble in acetone and ether. Before systemic absorption, chloramphenicol palmitate is hydrolyzed in the small intestine by esterases, which release the free base form of chloramphenicol to systemic circulation. Similarly, chloramphenicol succinate is a formulation for parenteral use that requires hydrolysis reactions in the plasma to produce the active drug (Ambrose 1984). The succinate form of the drug is freely soluble in water and can be administered intravenously (IV) or intramuscularly (IM). Topical formulations of chloramphenicol have been used for otic and ophthalmic use. Because of the decreased use of chloramphenicol in human medicine, some of the formulations mentioned above are not as readily available today, if at all.

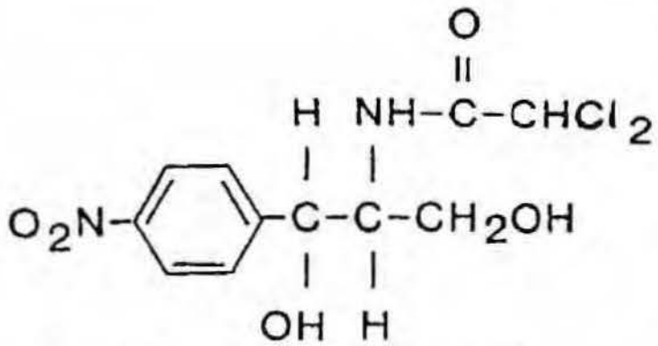

FIG. 37.1 The chemical structure of chloramphenicol.

MECHANISM OF ACTION. Chloramphenicol inhibits protein synthesis. Its biologic activity is due to interference with peptidyltransferase activity at the 50S ribosomal subunit, which is near the site of action of macrolide antibiotics and for which there can be competition (Yunis 1988). Because of the interaction with peptidyltransferase, binding with the amino acid substrate cannot occur, and peptide bond formation is inhibited. Chloramphenicol affects mammalian protein synthesis to some degree, especially mitochondrial protein synthesis. Mammalian mitochondrial ribosomes have a strong resemblance to bacterial ribosomes (both are 70S), with the mitochondria of the bone marrow especially susceptible. Prolonged administration to animals has been associated with a dose-related bone marrow suppression, especially in cats (Watson 1980).

SPECTRUM OF ACTIVITY. Chloramphenicol has a broad spectrum of activity. It is active against *Staphylococcus pseudintermedius* (*Staphylococcus intermedius* has been renamed *Staph. pseudintermedius* by most laboratories), *S. aureus*, streptococci, and some gram-negative bacteria, such as *Pasteurella multocida*, *Mannheimia haemolyticia* (previously called *Pasteurella haemolytica*), and *Histophilus somni* (previously named *Haemophilus somnus*) *Escherichia coli*, *Proteus vulgaris*, and *Salmonella* spp. may be susceptible, but resistance can occur with many gram-negative bacteria, especially the Enterobacteraceae. Resistance by staphylococci may occur with increased use. Anaerobic bacteria, *Mycoplasma* spp., and many rickettsiae also are

susceptible. The Clinical Laboratory Standards Institute (CLSI, 2007; formerly called NCCLS) approved break point for susceptibility is ≤4 μg/ml for streptococci and ≤8 μg/ml for other organisms (Watts et al. 1999).

BACTERIAL RESISTANCE. Four mechanisms of resistance to chloramphenicol have been described (Yunis 1988). The most important is plasmid mediated due to the presence of the chloramphenicol acetyltransferase enzyme, which catalyzes a reaction that modifies the hydroxyl groups. Chloramphenicol acetyltransferase was reviewed by Shaw and Leslie (1991). Other mechanisms of resistance include decreased bacterial cell wall permeability, altered binding capabilities at the 50S ribosomal subunit, and inactivation by nitroreductases.

PHARMACOKINETICS

Absorption and Distribution. The pharmacokinetic parameters of chloramphenicol have been studied in several animal species and are summarized in Table 37.1. Chloramphenicol in animals is well absorbed via both oral and parenteral routes, with a few notable species exceptions. Plasma half-lives vary, ranging from 0.9 hours in ponies to 5.1 hours in the cat (Davis et al. 1972). Watson (1992) reports that fasted cats showed differences in absorption between the chloramphenicol tablets and the chloramphenicol palmitate suspension. The liquid formulation showed a lower systemic drug availability, indicating that hydrolysis of the palmitate form is necessary and that there is a higher risk of drug failure when the palmitate suspension is used to treat sick cats that are also not eating. In ruminants, microflora present in the ruminant forestomach tend to metabolize chloramphenicol faster than it can be absorbed, making chloramphenicol administered orally of little systemic therapeutic use in ruminant animals. This point is rather moot since administration of chloramphenicol to food animals in the United States is currently illegal (discussed in more detail in Chapter 54). In most animals, 30–46% of chloramphenicol is bound to plasma proteins, leaving much of the drug in the free and active form. Chloramphenicol is widely distributed to many tissues of the body due to its nonionized state and high lipophilicity, enabling it to cross lipid bilayers quite easily. The volume of distribution (Vd) is typically greater than 1.0 l/kg and has been measured at 1–2.5 l/kg (Table 37.1). Chloramphenicol reaches sufficient concentrations in most tissues of the body, including the eye, central nervous system (CNS), heart, lung, prostate, saliva, liver, and spleen, among others (Ambrose 1984; Hird and Knifton 1986). Chloramphenicol concentrations in cerebrospinal fluid (CSF) are approximately 50% of corresponding plasma concentrations. Chloramphenicol can also cross the placental barrier in pregnant animals and can diffuse into the milk of nursing animals.

Metabolism and Excretion. Chloramphenicol is metabolized by the liver after absorption into the systemic circulation. One of the largest drawbacks to chloramphenicol administration is the rapid metabolic clearance, producing short half-lives in many species and necessity for frequent administration. In dogs, it should be administered three times daily. In horses, because of rapid elimination rates, tissue fluid concentrations persisted for only 3 hours after IV administration of chloramphenicol sodium succinate (Brown et al. 1984). Phase II glucuronidation is the principal pathway for the hepatic biotransformation of chloramphenicol, with the principal metabolite being chloramphenicol glucuronide. A few hydrolysis products have also been identified. Cats excrete chloramphenicol more slowly than other animals, perhaps owing to the cat's deficiency in some glucuronidase enzymes. One report notes that 25% of the total dose of chloramphenicol is excreted in the urine in the active form in cats compared to 6% in normal dogs (Hird and Knifton 1986). Most of the absorbed chloramphenicol (approximately 80%) is excreted into the urine as inactive metabolites via tubular secretion.

When chloramphenicol is administered to young animals, there may initially be reduced excretion. Calves showed decreased hepatic glucuronidation of chloramphenicol soon after birth, but this metabolic pathway matured quickly. Calves also showed higher oral availability than older animals because of immaturity of the rumen, with a marked decrease in oral absorption as the calves age (Burrows et al. 1984). Brumbaugh et al. (1983) found that in neonatal horses, elimination and Vd did not differ from adults. Bioavailability in foals was 83%, with an oral half-life of 2.54 hours. A dose of 50 mg/kg orally every 6 hours should be adequate for treating most susceptible bacteria in foals.

ADVERSE EFFECTS AND PRECAUTIONS. Bone marrow suppression has been the most important adverse

TABLE 37.1 Selected serum pharmacokinetic parameters of chloramphenicol in animals

effect associated with chloramphenicol administration to people. Bone marrow injury from chloramphenicol takes two forms (Yunis 1988). The first type is the most common and involves a dose-related suppression of the bone marrow precursor erythroid series. This toxicosis is reversible. The evidence suggests that this bone marrow suppression is the result of mitochondrial injury and the suppression of mitochondrial protein synthesis in bone marrow cells. Studies in animal species have described the pathology of bone marrow cell toxicity as a decreased entry into S phase in dividing bone marrow cells, vacuolation of the myeloid and erythroid series precursor cells, and inhibition of erythroid and granulocytic colony forming units (IARC 1976, 1990). In both the dog and the cat, dose-related bone marrow suppression is possible. However, signs of toxicity reverse when chloramphenicol therapy is discontinued.

The second type of bone marrow toxicity, aplastic anemia, has been described in people but not in animals. In people, it is rare and independent of dose and treatment duration, and it causes bone marrow aplasia, chiefly characterized by a profound and persistent pancytopenia. This aplastic anemia occurs in approximately 1:10,000 to 1:45,000 humans who receive chloramphenicol. There may be a genetic predisposition to this form of toxicity. It appears that the para-nitro group of the chloramphenicol molecule is responsible for this more serious form of bone marrow toxicity. The para-nitro group undergoes nitroreduction, leading to the production of nitrosochloramphenicol and other toxic intermediates, which trigger the stem cell damage in humans (IARC 1976, 1990; Yunis 1988). Modification of the molecule to eliminate the para-nitro group to produce either thiamfenicol or florfenicol reduces the risk of chloramphenicol-associated aplastic anemia.

Chloramphenicol-induced aplastic anemia in humans is important from a food-animal residue standpoint. If chloramphenicol is used to treat infections in food animals, it is possible that low concentrations of chloramphenicol in milk, meat, and other edible tissues from the animals will be consumed by people and cause aplastic anemia in susceptible individuals. Chloramphenicol residues have been known to persist for prolonged periods in food animals (Korsrud et al. 1987). Even though the amount consumed may be small, the reaction is not concentration-dependent. Thus, there is a public health risk for individuals consuming these products. For this and other reasons, the use of chloramphenicol in food-producing animals has been banned in the United States. The hazards of using chloramphenicol in food animals have also been reviewed (Settepani 1984; Lacey 1984).

Other adverse effects caused by chloramphenicol in animals are uncommon. However, young animals and cats are the most sensitive to intoxication due to impaired glucuronidation pathways. Cats given 60 and 120 mg/kg/day PO every 8 hours for 21 and 14 days (respectively) showed clinical signs of depression, dehydration, reduced fluid intake, weight loss, emesis, and diarrhea. Bone marrow hypoplasia was also documented in addition to pancytopenia (Watson 1980). Other investigators (Penny et al. 1967, 1970) administered to cats 50 mg/kg/day IM, with the cats showing marked depression and inappetence by day 7 of administration, severe bone marrow changes by day 14, and becoming extremely ill by day 21. Dogs showed milder signs of toxicity, mainly gastrointestinal (GI), but doses required to produce these effects were higher than what was administered to cats (225 mg/kg for 2 weeks).

DRUG INTERACTIONS. Chloramphenicol is an inhibitor of the cytochrome P450 drug-metabolizing enzymes. It is not known which specific family of enzymes is inhibited in animals. However, chloramphenicol administration to dogs has been shown to inhibit drug metabolism, and in dogs and cats, it prolongs pentobarbital anesthesia (Adams and Dixit 1970). Sleeping times may be prolonged by 120% in dogs and 260% in cats due to impaired metabolism of pentobarbital. Chloramphenicol also may inhibit the metabolism of digoxin, phenobarbital, propofol, primidone, and perhaps other drugs metabolized by the same enzymes. Erythromycin and chloramphenicol compete for the same site of action on bacteria, and both drugs used together may produce antibacterial antagonism.

CLINICAL USE. Chloramphenicol has been used for treatment of a wide range of susceptible microbial infections, including those caused by salmonellae, intracellular and extracellular bacteria, rickettsiae, and mycoplasmata; infections of the eyes and CNS; and infections due to anaerobic organisms (IARC 1976, 1990). One of the reasons for its popularity has been the high lipophilicity. Chloramphenicol readily penetrates cells, making it active against intracellular bacteria, and it penetrates tissues that otherwise are difficult to treat, such as the CNS. Chlor-

amphenicol was shown in one study to be equally effective for treatment of Rocky Mountain spotted fever in dogs as enrofloxacin and tetracyclines (Breitschwerdt et al. 1990). Although less popular than it once was, chloramphenicol has been used to treat infections caused by *Staphylococcus* spp., streptococci, *Brucella* spp., *Pasteurella* spp., *E. coli, Proteus* spp., *Salmonella* spp., *Bacillus anthracis, Arcanobacterium pyogenes, Erysipelothrix rhusiopathiae,* and *Klebsiella pneumoniae.* It is consistently active against anaerobic bacteria.

Chloramphenicol has been popular for treatment of infections of the CNS (encephalitis, meningitis) because it is able to cross the inflamed or uninflamed blood-brain barrier and attain therapeutic concentrations in the CSF and the brain. Despite the popularity for this use, some experts have suggested that since chloramphenicol is merely bacteriostatic against gram-negative pathogens, and there is a lack of phagocytes or immunoglobulins in CSF, chloramphenicol is not well suited to treat serious infections of the CNS (Rahal and Simberkoff 1979).

Chloramphenicol attains high concentrations in the eye when given systemically or after topical application on the cornea and is useful in treating susceptible bacterial conjunctivitis, panophthalmitis, endophthalmitis, and bacterial diseases of the cornea (Conner and Gupta 1973). Topical formulations are not as readily available owing to the risk of aplastic anemia (discussed previously), which can be caused by topical exposure. Florfenicol has been administered systemically for treating eye infections in cattle (see below.)

Chloramphenicol has been used to treat bacterial infections of the respiratory tract because it may have better penetration across the blood-bronchus barrier into respiratory secretions and respiratory lining fluid than more polar or less lipophilic antibiotics. Respiratory infections are among the infections in horses treated with oral chloramphenicol.

Chloramphenicol is one of the few drugs that can be administered orally to horses with safety. It achieves moderate systemic absorption of 21–40% (Gronwall et al. 1986) and has no serious adverse effects on the equine digestive system. However, oral administration resulted in intestinal mucosal damage and diarrhea in calves and reduced glucose absorption (Rollin et al. 1986). For treatment in horses, tablets or capsules are mixed with substances like molasses or corn syrup to facilitate oral administration. Chloramphenicol has been administered to horses for respiratory infections, pleuritis, CNS infections, and joint infections. Despite this widespread use, because of rapid elimination and poor-to-moderate absorption, one author has discouraged its use (Gronwall et al. 1986), but for foals oral doses of 50 mg/kg every 4–12 hours (frequency of administration was dependent on the minimum inhibitory concentration (MIC) of the pathogen) have been recommended (Brumbaugh et al. 1983).

Chloramphenicol has been administered to exotic animals, especially reptiles and amphibians, to treat a variety of infections (Clark et al. 1985). Chloramphenicol administration in 15 species of birds was examined, and the investigators concluded that after IM injections of 50 mg/kg, chloramphenicol would produce adequate concentrations to treat susceptible bacteria for 8–12 hours, except in pigeons, macaws, and conures because effective concentrations could not be achieved in these birds (Clark et al. 1982). However, oral absorption was poor, and this route of administration was discouraged for all birds.

CHLORAMPHENICOL DERIVATIVES

The ban on the use chloramphenicol in food-producing animals in the mid-1980s left a gap in the veterinarian's armamentarium of effective antimicrobial drugs. Because the idiosyncratic aplastic anemia is associated with the presence of the para-nitro group on the chloramphenicol molecule, attempts were made to modify the chloramphenicol structure to simultaneously retain chloramphenicol's broad spectrum of antimicrobial activity and eliminate the induction of aplastic anemia in people. Compounds synthesized in attempts to accomplish this goal are thiamphenicol and florfenicol. Thiamfenicol is not approved in the United States and will be discussed here only briefly. However, florfenicol has been approved for use in pigs, cattle and fish (in some countries) and has been effective for treatment of various infections, especially bovine respiratory disease in cattle and swine respiratory disease in pigs intended for human consumption.

THIAMPHENICOL. Thiamphenicol is a semisynthetic structural analog of chloramphenicol (Fig. 37.2). The major structural difference between chloramphenicol and thiamphenicol is that the para-nitrophenol group has been replaced by the methyl sulfonyl moiety. Thiamphenicol inhibits bacterial protein synthesis at the 50S ribosomal

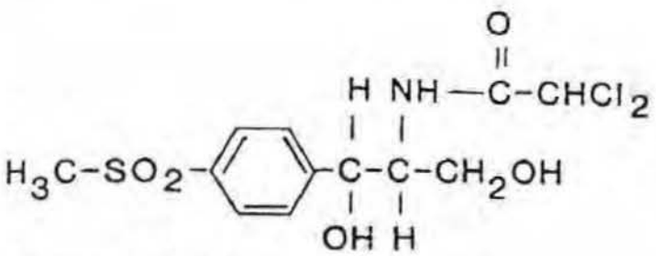

FIG. 37.2 The chemical structure of thiamphenicol.

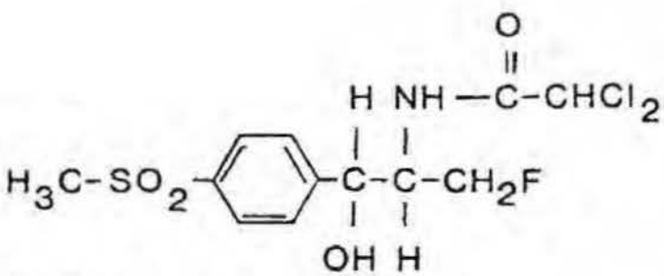

FIG. 37.3 The chemical structure of florfenicol.

subunit at the same location as does chloramphenicol. Thiamphenicol has an antimicrobial spectrum similar to that of chloramphenicol. However, its structural differences result in different pharmacokinetic properties and decreased potency. Thiamphenicol is more water soluble and less lipid soluble and therefore diffuses more slowly through lipid membranes. It is not metabolized to a significant extent in the liver (Ferrari and Bella 1974) and most of the dose is excreted in the urine as the unchanged active compound (Yunis 1988; Lavy et al. 1991a; Gamez et al. 1992). Resistance to thiamphenicol is also similar to that of chloramphenicol, with bacterial acetylation of the thiamphenicol molecule, but at a rate approximately 50% less than that of chloramphenicol.

Few pharmacokinetic studies have been performed on food-producing animals, but thiamphenicol pharmacokinetics has been studied in veal calves (Gamez et al. 1992) and lactating goats (Lavy et al. 1991a). Both studies found thiamphenicol to have a large Vd and to be rapidly eliminated in the urine. In dogs, thiamfenicol had a half-life of 1.7 hours and a Vd of 0.66 l/kg (Castells et al. 1998). In dogs the injection of thiamfenicol was well absorbed, with availability of 97%, but the terminal half-life was longer (5.6 hr), suggesting slow release from the injection site.

Thiamphenicol is considered to be less toxic than chloramphenicol, yet a reversible bone marrow suppression has been reported in humans. However, millions of people have been treated with thiamphenicol in countries in which it is approved, with no reports linking its use to aplastic anemia (Adams et al. 1987). In a thiamphenicol toxicity study in rabbits (Kaltwasser et al. 1974), no changes attributed to thiamphenicol in erythrocyte, reticulocyte, or plasma iron parameters were noted after long-term treatments of up to 90 mg/kg/day. Despite some of the advantages cited here, thiamfenicol is not presently available in North America.

FLORFENICOL. Florfenicol is structurally related to thiamphenicol; however, florfenicol contains fluorine at the 3' carbon position (Fig. 37.3). The fluorine molecule substitution at this position also reduces the number of sites available for bacterial acetylation reactions to occur, possibly making the antibiotic more resistant to bacterial inactivation. Florfenicol is as potent or more potent than either chloramphenicol or thiamphenicol against many organisms in vitro. The list of susceptible bacteria for florfenicol is the same as listed previously for chloramphenicol, except that some bacteria resistant to chloramphenicol due to acetylation may be sensitive to florfenicol. The CLSI (formerly called NCCLS) (CLSI 2007) quality control ranges of MIC for florfenicol are 2–8 μg/ml (Marshall et al. 1996). However, *Mannheimia haemolytica*, *Pasteurella multocida*, and *Histophilus somni* (previously named *Haemophilus somnus*) are several-fold more sensitive in vitro than bacteria of the Enterobacteriaceae, with MIC_{90} for *Pasteurella* and *Histophilus somni* in the range of 0.5–1.0 μg/ml. Against these bacteria, florfenicol may actually be bactericidal.

The advantage of florfenicol for administration to food animals is that it lacks the para-nitro group (Figures 37.1 and 37.3) that could contribute to the induction of aplastic anemia associated with chloramphenicol use in humans. Therefore, if residues were to occur in animals treated with florfenicol, no dangerous public health risk would ensue. However, it is possible that florfenicol can still produce a dose-related form of reversible bone marrow suppression with prolonged use or high doses, although such reactions have not been reported from routine use of florfenicol in animals. However, in one clinical account in a zoo animal, high doses induced bone marrow suppression (Tuttle et al. 2006).

Pharmacokinetics. The pharmacokinetics of florfenicol are summarized in Table 37.2.

TABLE 37.2 Selected pharmacokinetic parameters of florfenicol in animals

Species	Dose mg/kg	Half-life (hr)	Absorption (%)	V_d (L/kg)	C_{MAX} (μg/mL)	Reference

Veal calves	11 (IV)	3.71	ND	0.91	26.35	Adams et al. 1987
Veal calves	11 (oral)	3.7	89	ND	5.7	Adams et al. 1987

Note: Route of administration used is listed in parentheses. V_d is volume of distribution, C_{MAX} is the maximal concentration after administration with route listed in parentheses. ND = not determined.

Absorption. Studies in calves (Varma et al. 1986; Adams et al. 1987; Lobell et al. 1994) showed high bioavailability after oral and parenteral administrations, but there was decreased oral absorption when florfenicol was administered with milk. After IM injection in cattle, the absorption is almost complete, with systemic availability of 78%, but absorption is slow, which is demonstrated in cattle by an IV half-life of 2.65 hours but an average of 18 hours after IM injection (Lobell et al. 1994). This suggests that it is more slowly released from an IM injection site, thus prolonging the duration of effective levels. This slow elimination after IM injection in cattle prolongs the effective plasma concentration (above 1 μg/ml for respiratory pathogens) for 23 hours in calves. In horses, florfenicol is absorbed well after oral and IM administration (81% IM and 83% oral) (McKellar and Varma 1996). Oral absorption in Atlantic salmon was 96%.

Distribution. Like chloramphenicol, florfenicol has a wide distribution in most tissues of the body (Adams et al. 1987), including high concentrations in the kidney, urine, bile, and small intestine, but less penetration in the CSF, brain, and aqueous humor of the eye than that attained with chloramphenicol. Concentrations in brain and CSF are 1/4 to 1/2, respectively, the corresponding concentrations in plasma. Although in one study the distribution into CSF was only 46% relative to plasma, these levels were high enough to produce concentrations in CSF of cattle to inhibit *Histophilus somni* for over 20 hours (DeCraene et al. 1997). Florfenicol also penetrated well into the milk of lactating goats after IV and IM administration, making it of possible use in the treatment of microbial infections in the udder of lactating animals (Lavy et al. 1991b). The Vd is 0.7–0.9 l/kg in most studies in cattle. Protein binding is low in cattle (13–19%) (Bretzlaff et al. 1987; Lobell et al. 1994) but has not been reported for other species.

Elimination. The elimination half-life is 2–4 hours in cattle (Table 37.2). The half-life of less than 2 hours in horses is shorter than that in cattle. The half-life is dependent on the route of administration, which can be seen in Table 37.2 for studies in calves and dogs. The injection IM or SC can prolong the terminal half-life because of slow absorption ("flip-flop" effect).

Metabolism. Most of the dose administered to cattle is excreted as the parent drug (64%) in the urine. The rest of the drug is excreted as urinary metabolites. This possibly indicates its use in the treatment of organisms infecting the genitourinary tract of animals. Florfenicol amine is the metabolite that persists longest in tissues of cattle

and is used as the marker residue for withdrawal determination.

Pharmacokinetic Studies in Other Species. In small animals, florfenicol has limited application, but disposition was studied after oral, IM, and subcutaneous (SC) administration (Papich 1999). After IV administration in dogs, the half-life was less than 1 hour for three out of four dogs and clearance was rapid. After oral administration, inhibitory concentrations were maintained for only 4 hours. In dogs after IM injection, florfenicol mean peak plasma concentrations were 1.64 µg/ml and mean elimination half-life was 9.2 hours. Concentrations were above a MIC of 1.0 µg/ml for only 2 hours. After SC administration, florfenicol was absorbed poorly and inconsistently, with peak concentrations less than 1.0 µg/ml. By contrast, florfenicol solution in cats was absorbed well from both routes, with peak concentrations of 20 µg/ml and 27 µg/ml after IM and oral dose, respectively. Absorption was high from both routes (greater than 100% from IM and oral). IV elimination half-life was 4 hours, and Vd was 0.6 l/kg. The half-life was 5.6 hours and 7.8 hours for IM and oral dose, respectively. In cats, florfenicol produced inhibitory concentrations for 12 hours.

Florfenicol has been administered orally for treatment of infections in captive fish and is approved in some countries for this use (Aqua-Flor®). In rainbow trout at a water temperature of 10°C and given an oral dose of 10 mg/kg, florfenicol has a mean residence time of 21 hours and a peak (C_{max}) of 3.23 µg/ml and is well distributed to tissues (Pinault 1997). In salmon, florfenicol has a half-life of 12.2 hours at 10.8°C (Martinsen et al. 1993) and is also well distributed (Horsberg et al. 1994), with a Vd of 1.12 l/kg (Martinsen et al. 1993). In salmon the systemic availability of an oral dose is 96.5%. In red pacu, after a florfenicol dose of 10 mg/kg IM, the half-life was 4.25 hours, and the maximum concentration was only 1 µg/ml (Lewbart et al. 2005). To maintain concentrations effective for fish pathogens, a dose of 20–30 mg/kg every 24 hours was recommended by the authors. In sharks at a dose of 40 mg/kg IM, florfenicol produced effective levels for 120 hours (Zimmerman et al. 2006). Dosing every 3–5 days will produce concentrations in a therapeutic range.

Pharmacokinetic studies in horses show that florfenicol has longer half-life than chloramphenicol, good distribution, and good absorption. However, in experimental horses there were consistent loose stools and elevated bilirubin (McKellar and Varma 1996). Until additional studies establish safe doses, florfenicol cannot be recommended for horses.

In snakes (Boas), the half-life was 28 hours from IM injection. It was estimated that 50 mg/kg once daily for Boas is the best dose to produce therapeutic plasma concentrations, even though efficacy studies are not available. In sea turtles the clearance was rapid (60–100 ml/kg/hr) and the half-life was short (Stamper et al. 2003). It was concluded that florfenicol was not a practical drug for treatment of infections in sea turtles.

Clinical Use. Florfenicol is available in a 300 mg/ml solution for injection (Nuflor), a solution to be added to drinking water for swine and powder to be added to feed for swine. For fish there is a 500 gram per kilogram premix for fish (Aqua-Flor).

Cattle and Pigs. Several studies in cattle have been conducted to support the use of florfenicol for treating bovine respiratory disease caused by *Mannheimia haemolytica*, *Pasteurella multocida*, and *Histophilus somni* (previously named *Haemophilus somnus*). Florfenicol has been effective for treating undifferentiated bovine respiratory disease in cattle with doses of 20 mg/kg IM, given every 48 hours and injected in the neck (Hoar et al. 1998; Jim et al. 1999). It is also approved as a single dose for cattle at 40 mg/kg SC in the neck (withdrawal times listed below). Florfenicol is also approved for treatment of bovine interdigital phlegmon (foot rot, acute interdigital necrobacillosis, infectious pododermatitis) associated with *Fusobacterium necrophorum* and *Bacteroides melaninogenicus*.

Florfenicol has been effective in calves for treating experimentally induced infections and naturally occurring infectious bovine keratoconjunctivitis (Dueger et al. 1999; Angelos et al. 2000). In the naturally occurring case, florfenicol was administered one dose SC at 40 mg/kg or IM two doses 48 hours apart at 20 mg/kg. Concentrations persist in CSF for a long enough period after administration of 20 mg/kg in cattle that concentrations are above MIC of susceptible pathogens for at least 20 hours. When florfenicol was administered by intramammary infusion (750 mg/cow) to cattle (Wilson et al. 1996) with subclinical mastitis, there was poor efficacy, which could, perhaps, be attributed to an interval between treatments that was too long or to a duration of treatment that was too short.

For pigs, florfenicol is added to the feed (182 g per ton of feed), or drinking water (400 mg per gallon) for 5 days for the control of swine respiratory disease (SRD) associated with *Actinobacillus pleuropneumoniae, Pasteurella multocida, Streptococcus suis,* and *Bordetella bronchiseptica.*

Small Animals. Although some pharmacokinetic studies have been conducted in small animals and exotic animals, there are no reports of efficacy. Pharmacokinetic studies in reptiles and dogs suggest that frequent dosing with high doses would be necessary to maintain plasma concentrations above the MIC for susceptible organisms throughout the dosing interval. In cats, the pharmacokinetic evidence (discussed earlier) indicates that a dose of 22 mg/kg administered every 12 hours orally or parenterally would be adequate to produce sustained plasma concentrations for treatment of susceptible bacteria.

Use in Fish. Florfenicol has been demonstrated to be efficacious against bacteria of fish, especially trout and salmon (Fukui et al. 1987). Florfenicol premix is approved in some countries for treatment of furunculosis in salmon caused by *Aeromonas salmonicida.* Florfenicol has been administered orally for treatment of furunculosis caused by susceptible strains of *Aeromonas salmonicida* in captive fish and is approved in other countries. The premix (Aqua-Flor®) is approved for use in catfish and salmonids at a dose of 10 mg/kg for 10 days to treat susceptible fish pathogens.

Adverse Effects. Effect of florfenicol on bovine pregnancy, reproduction, and lactation have not been determined. Mild diarrhea and elevated bilirubin have been reported from administration to horses (McKellar and Varma 1996). Reversible, dose-related bone marrow suppression is possible but not reported, except for a reaction reported in a zoo animal that was mentioned previously (Tuttle et al. 2006). In cattle, diarrhea and decreased feed consumption have been observed, which are transient. A local tissue reaction from IM or SC injection is possible. When toxic overdoses were administered to calves (200 mg/kg) there was marked anorexia, decrease in body weight, ketosis, and elevated liver enzymes. In dogs administered high doses for prolonged periods there was CNS vacuolation, hematopoietic toxicity, and renal tubule dilation.

Regulatory Information. The tolerance for florfenicol is 3.7 ppm for florfenicol amine (the marker residue) in liver and 0.3 ppm in muscle. Withdrawal time for use in salmon is 12 days. Withdrawal time for oral administration to pigs in feed is 13 days and for administration in water 16 days. After injection to cattle, the withdrawal time for slaughter is 28 days if injected at a dose of 20 mg/kg IM (36 days in Canada). If injected at a dose of 40 mg/kg SC, the withdrawal time for slaughter is 38 days. A formulation with different excipients (Nuflor Gold) has a withdrawal time of 44 days in cattle when injected at 40 mg/kg SC, once. Do not inject more than 10 ml in one site. Give injections in the neck only (both SC and IM). Do not administer to dairy cows older than 20 months, to calves under 1 month of age, or to calves on an all-milk diet.

MACROLIDE ANTIBIOTICS

SOURCE AND CHEMISTRY. The macrolide antibiotics are a group of structurally similar compounds, most of which are derived from various species of *Streptomyces* soilborne bacteria. Chemically, all the drugs in this group are classified as macrocyclic lactones, with members containing 12–20 atoms of carbon in the lactone ring structure. Attached to this lactone ring are various combinations of deoxy sugars held to the lactone ring by glycosidic linkages. Since erythromycin's discovery in the early 1950s from the soil organism *Streptomyces erythreus,* numerous other macrolides have been isolated or synthesized from the parent molecule erythromycin, including tylosin, roxithromycin, erythromycylamine, tilmicosin, dirithromycin, azithromycin, tulathromycin, clarithromycin, spiramycin, and flurithromycin (Kirst and Sides 1989).

Erythromycin, tylosin (see Fig. 37.4), and tilmicosin have found the most clinical applications of the macrolide class in veterinary medicine. The newest introduced drug in this group is tulathromycin (Draxxin), approved for use in cattle for treatment of respiratory disease. New human-label derivatives such as azithromycin are increasing in popularity. Other macrolides such as oleandomycin and carbomycin have been used as feed additives for growth promotion in food animals.

Erythromycin is a large molecule consisting of a 14-atom polyhydroxylactone erythronolide ring and the two sugars clandinose and desosamine. Similarly, tylosin is composed of a 16-atom lactone ring (a tylonolide) to

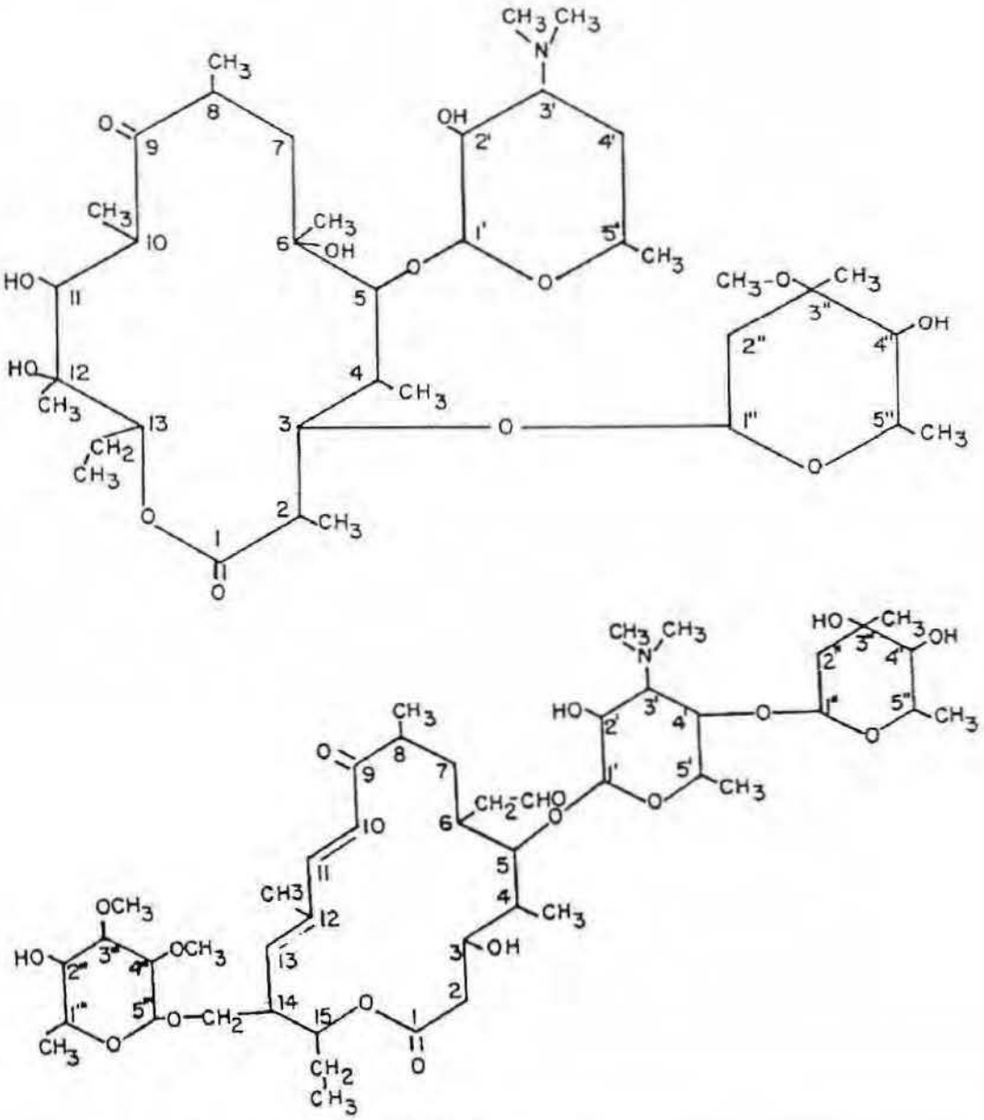

FIG. 37.4 The chemical structures of erythromycin (top) and tylosin.

which three sugars—mycinose, mycaminose, and mycarose—are attached (Wilson 1984; Kirst et al. 1982). Other macrolides with 16-member rings include josamycin and spiramycin. Azithromycin is the first drug in the group of azalides, which are semisynthetic derivatives of erythromycin (Lode et al. 1996). Azithromycin has a 15-member ring structure. Tulathromycin, the newest drug for cattle, is also a 15-member ring structure derived from the azalides. Tulathromycin has three basic nitrogen groups (tribasic) that produce a higher positive charge and increased affinity for intracellular sites compared to other drugs.

DRUG FORMULATIONS. All macrolides are weak bases, with pK_a ranges from 6 to 9; erythromycin has a pK_a of 8.7–8.8 and tylosin has a pK_a of 7.1. Erythromycin base is poorly absorbed, and oral formulations are modified to increase absorption and improve oral tolerability. Oral formulations are estolate or ethylsuccinate esters of

erythromycin. The esters are absorbed systemically, then hydrolyzed to the erythromycin base by enzymes in the body before they are active. Alternatively, other oral forms of erythromycin are formulated as a salt of stearate or phosphate. After oral administration of the salt, erythromycin dissociates from the salt in the intestine and is absorbed as free drug. There are also oral formulations intended to be added to the feed or drinking water to treat infections for poultry. Examples of these preparations are erythromycin thiocynate premix and erythromycin phosphate powder (Ery-Mycin). In addition, there are formulations of other macrolides to be added to the feed or water of cattle, pigs, or poultry for control of respiratory and other infections. Examples of these formulations are tilmicosin premix (Pulmotil) to be added to feed for pigs, tylosin phosphate premix to be added to feed for cattle, pigs, or poultry, and tylosin tartrate (Tylan soluble) for the drinking water of poultry. Veterinary forms of erythromycin injectable (e.g., Erythro-100 and Gallimycin-100) are 100 mg/ml formulations intended for IM injection only; they should not be administered SC or IV. The injectable formulation of tulathromycin (Draxxin) is 100 mg/ml for use as a single SC injection at 2.5 mg/kg, and tilmicosin (Micotil) 300 mg/ml for SC injection (10 mg/kg) to cattle and sheep.

MECHANISM OF ACTION. The antibacterial action of macrolides is produced by an inhibition of protein synthesis by binding to the 50S ribosomal subunit of prokaryote organisms. The binding site on the ribosome is near but not identical to that of chloramphenicol, and antagonism of effect is possible if macrolides are administered with chloramphenicol. Macrolides inhibit translocation of tRNA from the amino acid acceptor site, which disrupts addition of new peptide bonds and thus prevents synthesis of new proteins within the microbial cell. Macrolides can bind to mitochondrial ribosomes but are unable to cross the mitochondrial membrane (in contrast to chloramphenicol) and therefore do not produce bone marrow suppression in mammals. Macrolides in general do not bind to mammalian ribosomes, making them a relatively safe group of drugs for veterinary use.

Although most authors have listed macrolides as bacteriostatic at therapeutic concentrations (Wilson 1984), they can be slowly bactericidal, especially against streptococci. Their bactericidal action is time dependent (Carbon 1998). The antimicrobial action of erythromycin is enhanced by a high pH (Sabath et al. 1968), with the optimum antibacterial effect at a pH of 8. Therefore, in an acidic environment, such as in an abscess, necrotic tissue, or urine, the antibacterial activity is suppressed.

Resistance Mechanisms. Resistance to macrolides is usually plasmid-mediated, but modification of ribosomes may occur through chromosomal mutation. Resistance can occur from 1) decreased entry into bacteria (most common with the gram-negative organisms), 2) synthesis of bacterial enzymes that hydrolyze the drug, and 3) modification of target (the ribosome in this instance). The ribosomal attenuation involves methylation of the 50S drug receptor site. This resistance may also lead to cross-resistance with other antibiotics that preferentially bind to these sites, such as other macrolides and lincosamides (Wilson 1984). Resistance to erythromycin in animals in several microorganisms has been discussed in more detail elsewhere (Maguire et al. 1989; Dutta and Devriese 1981, 1982a,b; Leclercq and Courvalin 1991; Devriese and Dutta 1984). In small animals with staphylococcal infections, resistance was more likely if antibiotics had previously been prescribed, especially in cases of recurrent pyoderma (Lloyd et al. 1996; Medleau et al. 1986; Noble and Kent 1992). As summarized by Noli and Boothe (1999), an increasing trend toward resistance to macrolides by staphylocci has been demonstrated when treating pyoderma (increasing from 7 to 22%), whereas in some countries, the incidence of resistance has remained relatively stable at around 22–24%.

SPECTRUM OF ACTIVITY. Erythromycin is mainly effective against gram-positive organisms such as streptococci, staphylococci, including staphylococci that may be resistant to β-lactams because of β-lactamase synthesis or modification of the penicillin-binding protein target. Other organisms that show in vitro susceptibility include *Mycoplasma, Arcanobacterium, Erysipelothrix, Bordetella,* and *Bartonella.* Although the spectrum favors the gram-positive group, a few gram-negatives are susceptible, especially *Pasteurella* spp. Activity against anaerobic bacteria is only moderate. Gram-negative anaerobic bacteria often are resistant. Most other gram-negative bacteria, such as those of the Enterobacteriaceae or *Pseudomonas* spp., are resistant. The activity of tilmicosin is similar to that of erythromycin, but most of the in vitro data concern its activity against *Pasteurella, Mannheimia*

haemolytica, and *Histophilus somni*, for which it maintains good activity. Other gram-negative bacteria are resistant to tilmicosin. Tulathromycin also has activity against these organisms, as well as *Mycoplasma bovis*, with lower MIC_{90} values compared to tilmicosin.

The CLSI (CLSI 2007) guidelines for susceptibility (Watts et al. 1999) list the erythromycin breakpoint for sensitivity as ≤0.25 μg/ml for streptococci and ≤0.5 μg/ml for organisms other than streptococci.

PHARMACOKINETICS

Absorption and Distribution. Erythromycin pharmacokinetics has been studied in most animals and in humans; some of these parameters are shown in Table 37.3. Oral erythromycin is absorbed well, but inactivation of erythromycin due to gastric acidity is common for the base form of erythromycin, which is the reason that other formulations, such as erythromycin estolate or stearate forms or enteric-coated formulations, are used. They have better bioavailability owing to decreased destruction of erythromycin in the acidic environment of the stomach. The presence of food in the stomach also tends to decrease absorption of erythromycin in most species, including the dog (Wilson 1984; Eriksson et al. 1990). Erythromycin salts (erythromycin-stearate and erythromycin-phosphate) dissociate in the intestine and are absorbed as the active drug. Erythromycin esters (erythromycin-ethylsuccinate and erythromycin-estolate) are absorbed as the esters and hydrolyzed in the body to release active drug. There is no proven difference among these formulations as to which is the most favorable in most animals. However, in horses,

it was shown that the salt forms (erythromycin-phosphate or erythromycin-stearate) are preferred for oral administration (Ewing et al. 1994) because they provided the most favorable blood concentrations. A series of studies by Lakritz et al (1999, 2000a, 2000b, 2002) examined the absorption of various oral formulations in foals. The ethylsuccinate form was poorly absorbed, but the phosphate, estolate, and microencapsulated forms were better absorbed (16%, 14.7%, and 26%, respectively). Absorption is better in foals when food was withheld. Crushed tablets of enteric-coated preparations are substantially degraded in the stomach or are metabolized in the intestine wall and are not recommended for oral administration to animals.

SC or IM injections of erythromycin can be painful and irritating; therefore, the PO route is preferred whenever possible. The only formulations that can be given IV are the glucoptate and lactobionate forms, because these are the only forms soluble in aqueous solution.

Macrolides tend to concentrate in some cells because the basic drug is trapped in cells that are more acidic than plasma. Tissue concentrations for erythromycin, tylosin, and tilmicosin are higher than serum concentrations, especially in the lungs, which is relevant because these drugs are often used to treat respiratory infections. The lung concentrations are so high for tilmicosin that they persist for at least 72 hours after a single dose. Tulathromycin levels in lung tissue persist much longer than in plasma (184 hr half-life in lungs versus 58–99 hrs for plasma). In addition to the lungs, erythromycin concentrations are equal to or higher than plasma concentrations in several body fluids such as bile and prostatic, seminal, pleural, and peritoneal fluids, as well as in many tissues, such as the liver, spleen, heart, and kidneys, among others. Erythromycin does not penetrate the blood-brain barrier in high enough concentrations to be therapeutic; however, it can cross the placenta and attain therapeutic concentrations in the fetus. High concentrations are also obtained in the feces of animals due to biliary excretion (Wilson 1984). These high tissue concentrations are reflected in a relatively large Vd of 3–6 l/kg (Riviere et al. 1991). The tylosin Vd is 1–2.5 l/kg for most species of animals. The new macrolide azithromycin is discussed in more detail later in this section. Its distribution to tissues is higher than other macrolides discussed so far, and its Vd has been measured at over 20 l/kg in animals. For tulathromycin, the Vd is over 11 l/kg. Protein binding for macrolides is low, with values of 18–30% for most species. Protein binding in some species may be predominantly to the alpha-1-acid glycoprotein, rather than albumin (Kinoshita et al. 1995).

Tylosin has good absorption from the GI tract, and no enteric coating is required to maintain the stability of the compound in the stomach. It is widely distributed to basically the same tissues as described for erythromycin, metabolized by the liver, and excreted via the bile and feces.

Tilmicosin has slow absorption, 22% bioavailability, a half-life in plasma of 4 hours, and extensive penetration in milk (Ziv et al. 1995). However, because of the high and persistent distribution to tissues, especially lungs, the plasma pharmacokinetics seem to have little correlation to the observed clinical effects (Gourlay et al. 1989).

Metabolism and Excretion. Metabolism of erythromycin is via hepatic microsomal enzymes, which cause a demethylation of one of the methyl groups on the desosamine sugar moiety of the erythromycin molecule. Little of the antimicrobial action is retained after demethylation by these enzymes. These metabolic enzymes can be induced with phenobarbital (and possibly other enzyme inducers); therefore, patients given phenobarbital and erythromycin simultaneously may experience more antimicrobial treatment failures due to increased metabolism. Most (90%) of the drug in the bile is in the metabolized form. Some active erythromycin (2–5%) is found excreted into the urine, with higher levels found in the urine after IV dosing. Renal dysfunction seemingly does not have an appreciable effect on its elimination half-life in the body (Wilson 1984). Although macrolides are not a popular choice for treating urinary tract infections because of their limited spectrum of activity, high urine pH tends to favor antimicrobial activity in the urine environment (Sabath et al. 1968).

Half-lives for erythromycin are listed in Table 37.3 and range from less than 1.0 hour in rodents and rabbits to 3–4 hours in cattle. Tylosin follows a similar pattern, with half-lives of 1–2 hours in most animals.

ADVERSE EFFECTS AND PRECAUTIONS. Side effects are reported more frequently in humans than in animals. Humans dosed with macrolides (in particular, erythromycin) have experienced nausea and vomiting (oral forms), fever, skin eruptions, cholestatic hepatitis, elevated serum aspartate aminotransferase, epigastric distress, and transient auditory impairment, among many other side

effects. Cholestatic hepatitis, most commonly associated with the estolate ester, is the most common of these adverse reactions, with the symptoms starting 10–20 days after beginning therapy and ending a few days after the cessation of therapy. Cholestasis associated with erythromycin use in humans is considered to be a hypersensitivity reaction (Sande and Mandell 1990a). In animals, however, few of these side effects are observed, and hepatitis has not been a reported association. However, regurgitation and/or vomiting has been commonly reported in small animals, especially dogs after oral administration of erythromycin. In one report, erythromycin was the drug that most frequently caused side effects after oral dosing in dogs (Kunkle et al. 1995). Stimulation of GI motility may play a role in small-animal vomiting (discussed below under clinical uses). In horses, erythromycin may induce diarrhea, which stops after therapy is discontinued and is generally not fatal. The effect of erythromycin on producing diarrhea in horses was discussed more extensively in a review (Papich 2003). Although these reactions in the horse may limit its use by some clinicians, erythromycin is still commonly used in horses to treat a variety of infections, especially in the foal. Hyperthermia (febrile syndrome) has also been observed in foals associated with erythromycin treatment (Stratton-Phelps et al. 2000), which was accompanied in some foals by diarrhea and respiratory distress.

DRUG INTERACTIONS. Erythromycin is a well-known hepatic microsomal enzyme inhibitor. Erythromycin is both a substrate and an inhibitor for the cytochrome P450 enzyme, which is the enzyme system that is most often involved in drug metabolism. As an inhibitor of the cytochrome P450 enzyme, it may inhibit metabolism of drugs such as theophylline, cyclosporine, digoxin, and warfarin. Concentrations of these drugs may increase when animals receive erythromycin, resulting in a potentiation of the pharmacologic effect or toxicity.

CLINICAL USE OF ERYTHROMYCIN. Doses of erythromycin are listed in Table 37.3. Erythromycin is primarily used for treating infections caused by gram-positive organisms. Because of the high distribution into tissues and long persistence in some cells, macrolides are particularly useful for treating some infections caused by bacteria that more polar or less lipid-soluble drugs may have difficulty reaching. Erythromycin and other macrolide antibiotics are sometimes used as a penicillin alternative when penicillins have either failed or when there is allergy to penicillins. Infections treated by erythromycin include those caused by *Staphylococcus* spp., *Streptococcus* spp., *Arcanobacterium* spp., *Clostridium* spp., *Listeria* spp., *Bacillus* spp., *Erysipelothrix* spp., *Histophilus*, *Brucella* spp., *Fusobacterium* spp., *Pasteurella* spp., *Borrelia* spp., and *Mycoplasma* spp. (Wilson 1984).

In small animals, erythromycin is used to treat pyoderma caused by staphylococci (Noli and Boothe 1999), respiratory infections caused by *Mycoplasma*, and diarrhea caused by *Campylobacter* organisms. When treating *Campylobacter*, erythromycin stopped the shedding but did not eliminate the organism. Respiratory infections are sometimes treated with erythromycin, even when a causative organism has not been identified because erythromycin crosses the blood-bronchus barrier and achieves favorable concentrations in respiratory tract secretions. Erythromycin has also been used as a treatment for undifferentiated bovine respiratory disease and for pig infections caused by *Erysipelothrix* and for pig respiratory infections caused by *Streptococcus* and *Pasteurella*. In poultry, erythromycin is used for treatment of respiratory infections caused by *Mycoplasma*. In foals, erythromycin is used, in combination with rifampin, for treatment of pneumonia caused by *Rhodococcus equi*. However, there is some evidence that erythromycin administered alone may be equally efficacious.

Clinical Use of Erythromycin to Modify Gastrointestinal Motility. Erythromycin is a common cause of vomiting and regurgitation in small animals. In one study erythromycin oral administration produced the most common adverse effects in comparison to other drugs (Kunkle et al. 1995). Although some nausea from the oral preparations is possible, most of this effect is believed to be related to a drug-induced increase in GI motility. This mechanism appears to be related to an increase in activation of motilin receptors, via release of endogenous motilin, or via cholinergic mechanisms in the upper GI tract (Hall and Washabau 1997; Lester et al. 1998). At small doses (1 mg/kg) erythromycin has been considered for use as a motility-stimulating drug in animals. In calves, administration of erythromycin, tylosin, or tilmicosin increased the rate of abomasal emptying, with erythromycin (8.8 mg/kg IM) producing the most significant effect (Nouri and Constable 2007; Nouri et al. 2008; Wittek and Constable 2005). These properties of erythro-

mycin are discussed in more detail in Chapter 47. In calves, these drugs increase the abomasal emptying rate and erythromycin (10 mg/kg IM) has been used to improve postoperative abomasal rate in dairy cows undergoing surgical correction of left abomasal displacement (Wittek et al. 2008). The clinical benefits for treating GI motility disorders has also been explored. Although 14-membered macrolides appear to have the most profound effect on the gastrointestinal tract, there is also an effect from 16-membered macrolides such as tylosin and tilmicosin (Nouri and Constable 2007).

Regulatory Considerations. Erythromycin has a 6-day withdrawal time when used according to label in cattle in the United States. Erythromycin added to feed or water for poultry has a withdrawal time of 1–2 days; the specific product label should be consulted for the exact withdrawal time. In the United States erythromycin should not be administered to lactating dairy cattle because macrolides concentrate in the milk for a long time after treatment. However, Canadian labeling lists a milk withholding time of 72 hours after a dose of 2.2–4.4 mg/kg.

TYLOSIN. Pharmacokinetic data for tylosin are listed in Table 37.4. Tylosin has been used therapeutically to treat "pinkeye" (*Moraxella bovis*) in cattle; respiratory tract infections; swine dysentery; pleuropneumonia due to *Haemophilus parahemolyticus;* and other infections in cats, chickens (Ose and Tonkinson 1985), quail (Jones et al. 1976), and turkeys (Wilson 1984). Tylosin has been used more extensively as a feed additive to promote growth in food-producing animals, such as swine, cattle, and chickens, among others (Wilson 1984). Residues from tylosin have been discussed in other papers (Knothe 1977a,b; Anderson et al. 1966). After administration to cattle there is a 21- and 14-day withdrawal time for slaughter for cattle and pigs, respectively. Tylosin concentrates in milk for a long time after administration and should not be administered to lactating dairy cattle. Specific product information should be consulted for withholding times when tylosin is administered in feed or water to pigs or poultry because withdrawal times can vary from 0 to 5 days, depending on the use.

Tylosin has also been used to treat diarrhea in dogs, which is discussed in Chapter 47 in more detail. This type of diarrhea has been characterized as "Tylosin-Responsive Chronic Diarrhea in Dogs" (Westermarck et al. 2005). In these animals, tylosin has been effective at improving clinical signs that occur with or without organisms being identified.

TILMICOSIN. Tilmicosin is 20-deoxo-20-(3,5-dimethylpiperidin-1-yl)desmycosin, a newer macrolide antibiotic that is closely related to erythromycin. Tilmicosin phosphate (Micotil 300) has been effective for treating bovine respiratory disease (Musser et al. 1996; Hoar et al. 1998;

TABLE 37.4 Selected serum pharmacokinetic parameters of tylosin in animals

Jim et al. 1999). One study (Ose and Tonkinson 1988) reports that 90% of the *Mannheimia haemolytica* and *Pasteurella multocida* isolates tested were sensitive to tilmicosin at concentrations of ≤6.25 μg/ml, and the drug was also active against *Mycoplasma*, including those from bovine isolates. Other organisms with in vitro susceptibility to tilmicosin include staphylococci and streptococci. Most gram-negative organisms other than those causing bovine respiratory disease are frequently resistant.

Tilmicosin administered to calves with pneumonia were found to respond better when treated with 10 mg/kg SC tilmicosin than with a 20 mg/kg IM dose of oxytetracycline (Laven and Andrews 1991). In a study by Gourlay et al. (1989) using calves treated with 20 mg/kg SC tilmicosin, the high success rate in treating bovine pneumonia was believed to be due in part to the prolonged presence of therapeutic concentrations of tilmicosin in the lung tissues. Due to high affinity for certain tissues, tilmicosin concentrations remain above the MIC of susceptible organisms for at least 72 hours. Resistance among cattle respiratory pathogens has been recognized (Musser et al. 1996). However, because tilmicosin has such a high concentration in some tissues (e.g., the lung), in vitro measurements of resistance may have little relationship to whether or not the drug produces a cure in cattle with respiratory disease (Musser et al. 1996).

Tilmicosin also has been used as a prophylactic antibiotic (metaphylaxis) for administration to calves entering a feedlot situation. Tilmicosin reduced the incidence of pneumonia in susceptible calves when administered prophylactically as a single 10 mg/kg SC injection (Morck et al. 1993; Schumann et al. 1990). Tilmicosin used as a metaphylactic treatment in newly arrived feedlot calves reduced prevalence of bovine respiratory disease and improved growth of calves (Vogel et al. 1998).

The CLSI break point for tilmicosin susceptibility is ≤8 μg/ml for cattle respiratory pathogens (*Mannheimia haemolytica*) and ≤16 μg/ml for swine respiratory disease pathogens (CLSI 2007). The currently approved dose is 10 mg/kg SC as a single treatment. After treatment with tilmicosin phosphate in cattle, there is a 28-day withdrawal time. Tilmicosin should not be administered to lactating dairy cattle because residues may persist in milk for more than 30 days.

Tilmicosin phosphate is approved for treatment of swine respiratory disease caused by *Actinobacillus pleuropneumoniae* and *Pasteurella multocida*. This form (Pulmotil) is administered as a feed additive and has been shown to be effective for controlling pneumonia in swine (Moore et al. 1996). There is a 7-day withdrawal time for slaughter when administered to swine.

Tilmicosin has also been used for treatment of pasteurellosis in rabbits (McKay et al. 1996). Single doses of 25 mg/kg SC were an effective treatment for pasteurellosis in rabbits.

Adverse Reactions to Tilmicosin. Injections of tilmicosin to horses, goats, swine, or nonhuman primates can be fatal. The heart is the target of toxicity in animals, perhaps mediated via depletion of cardiac intracellular calcium, resulting in a negative inotropic effect (Main et al. 1996). Epinephrine worsens the cardiac toxicity in pigs, but dobutamine has alleviated the cardiac depression in dogs (Main et al. 1996). The effects of toxicity are increased heart rate, arrhythmia, and depressed contractility. Injected doses of 20 and 30 mg/kg to pigs caused death, but oral tilmicosin in pigs produces no toxic effects. In cattle, injected SC doses of 50 mg/kg caused myocardial toxicity; 150 mg/kg was lethal. Doses as low as 10 mg/kg IV have caused cardiac toxicity as well (Ziv et al. 1995). The risk of toxicity is particularly important for humans.

There are warnings on the tilmicosin label that accidental injection into humans has caused death. Published reports (Veenhuizen et al. 2006) indicate that more than 12 people have died as a result of tilmicosin administration—some have been accidental. The deaths are caused by cardiovascular toxicity.

TULATHROMYCIN. Tulathromycin (Draxxin) is the most recent addition to this group of drugs. Tulathromycin is an azalide derivative of erythromycin, with three charged nitrogen groups; therefore it has been called a *triamilide* (Evans 2005). These charged groups may be important to increase the intracellular concentrations compared to older macrolides with fewer charges. It is registered for use in cattle and pigs; it has not been used in other species. In cattle and pigs it is registered for treating respiratory infections (Bovine Respiratory Disease—BRD, and Swine Respiratory Disease—SRD), for which the pathogens have been discussed earlier in this chapter. In addition to these pathogens the label includes *Mycoplasma bovis* in this drug's indications. It also is used to prevent BRD when administered to cattle (metaphylaxis)

that are at risk for developing respiratory disease (Booker et al. 2007).

Tulathromycin has improved gram-negative activity compared to other drugs in this group, which translates to lower MIC values for cattle and swine respiratory pathogens (e.g., *Pasteurella, Mannheimia, Histophilus*, etc.) and bactericidal activity for many pathogens. Another important feature is the long half-life in tissues. The serum half-life was 90 hours, but the half-life in lung tissues was 184 hours and 142 hours in cattle and swine, respectively (Evans 2005). Because of this long half-life, it can be administered only once (e.g., 2.5 mg/kg SC in cattle and IM in swine) and produces high drug concentrations for several days. Withdrawal times are 18 days for cattle, and 5 days for swine.

There is some limited evidence that tulathromycin may be useful for treating pulmonary infections in foals (Venner et al. 2007). At 2.5 mg/kg IM once per week, it resolved pulmonary lesions and, except for diarrhea in some foals, was well tolerated.

The susceptible break point for tulathromycin for cattle respiratory disease pathogens is ≤16 μg/ml (CLSI 2007).

CLARITHROMYCIN. Clarithromycin (Biaxin®) is one of the newer macrolides that is semisynthetically derived from erythromycin. It is primarily used in people because it is tolerated better than erythromycin, has a broader spectrum, and concentrates in leukocytes. Clarithromycin in combination with ranitidine and bismuth (Tritec®) is currently used to treat *Helicobacter pylori* infections in people. In dogs, clarithromycin does not have pharmacokinetic features that are as favorable as those of azithromycin (the half-life is not as long), and except for pharmacokinetic studies, its use in veterinary medicine has not been reported (Vilmànyi et al. 1996).

Most veterinary experience has been in foals, where clarithromycin has been investigated as a potential treatment for respiratory infections. It has more activity against *Rhodococcus equii* isolated from foals (Jacks et al. 2003). In foals, clarithromycin is absorbed orally and has a half-life of 4.8 and 5.4 hours, depending on the study (Jacks et al. 2002), but it does not persist in tissues for as long as azithromycin (Suarez-Mier et al. 2007). Oral absorption was 57% (Womble et al. 2006), compared to 70–75% in dogs. In foals, oral clarithromycin at a dose of 7.5 mg/kg every 12 hours produces concentrations sufficient for treatment of *Rhodococcus equi* infections (Jacks et al. 2002). It has been more successful at this dose than azithromycin (Giguère et al. 2004).

AZITHROMYCIN. Azithromycin (Zithromax®) is the first drug in the class of azalides approved for people, and it is used frequently in small animals, exotic species, and horses off-label. Azalides are derived from erythromycin and their mechanisms of action are similar. (Erythromycin has a 14-member ring structure, and azithromycin has a 15-member ring structure.) Azithromycin has better oral absorption, is better tolerated, has a much longer half-life (especially in tissues), and has a broader spectrum of activity than erythromycin.

Azithromycin is active against gram-positive aerobic bacteria (staphylococci and streptococci) and anaerobes. However, the activity against staphylococci is not as good as erythromycin. It has some activity against gram-negative bacteria such as *Haemophilus* but not against enteric gram-negative bacteria or *Pseudomonas*. It has activity against many intracellular organisms, including *Chlamydophilia* (formerly called *Chlamydia*) and *Toxoplasma*. It is also active against mycobacteria and *Mycoplasma* (Lode et al. 1996)

The primary pharmacokinetic difference between azithromycin and erythromycin is the long half-life and high concentration in tissues. Azithromycin has an extraordinary ability to concentrate in tissues, particularly leukocytes, macrophages, and fibroblasts. The tissue concentration can be as much as 100 times serum concentrations. Concentrations in leukocytes can be at least 200–300 times the concentrations in serum (Panteix et al. 1993). In cats, the serum half-life is 35 hours, tissue half-lives vary from 13 to 72 hours, and the Vd is 23 l/kg (Hunter et al. 1995). In dogs, it also exhibits rapid uptake and persistent concentrations in tissues; the Vd is 12 l/kg, and plasma and tissue half-lives are 29 and 90 hours, respectively (Shepard and Falkner 1990). Oral absorption is high, with bioavailability values of 58% in cats (Hunter et al. 1995) and 97% in dogs (Shepard and Falkner 1990). In people, azithromycin is absorbed much better on an empty stomach (Lode et al. 1996).

In horses, azithromycin also demonstrates favorable pharmacokinetic and pharmacodynamic properties (Davis et al. 2002; Jacks et al. 2002, 2003; Suarez-Mier et al. 2007). For example, Davis et al. (2002) showed that oral absorption was 39% and had a plasma half-life of 18 hours in foals. More importantly, the drug persisted in leuko-

cytes and alveolar macrophages for at least 120 hours after a single dose at concentrations greater than 5.0 µg/ml, with a half-life in leukocytes of over 49 hours. Concentrations in PMNs were over 200 times the plasma concentrations. These results were similar to those reported by Suarez-Mier et al. (2007). It had a volume of distribution of 12 l/kg, which probably accounts for the long persistence in inflammatory cells.

Of particular interest is the fact that the intracellular reservoir of azithromycin can apparently produce effective drug concentrations in the interstitial fluids, even after the plasma concentrations have declined below detectable levels (Girard et al. 1990). In fact, plasma pharmacokinetic parameters have little correlation to the in vivo efficacy of azithromycin. Intracellular stores of azithromycin in leukocytes also can serve as a mode of delivery of azithromycin to infected tissues, especially early abscesses, since the leukocytes are attracted to these sites via chemotaxis (Girard et al. 1993). The slow release of azithromycin from leukocytes distinguishes azithromycin from other macrolides and fluoroquinolones, which, despite achieving high concentrations in leukocytes, are released rapidly from cells in a drug-free environment (Panteix et al. 1993).

Clinical Use of Azithromycin. The therapeutic uses for azithromycin are similar to those of other macrolides such as erythromycin (Lode et al. 1996). The MIC for susceptible organisms is 2 µg/ml. It has become popular for treating infections in dogs, cats, exotic animals, and birds. Results of treatment of intracellular infections caused by *Toxoplasma* spp. and *Mycobacterium* spp. have been conflicting in people and are not yet reported for animals. Because of the long half-life and persistence of drug in tissues, the regimen employed in people is to administer a dose once daily for 3–5 days. Thereafter, effective drug concentrations are expected in tissues for up to 10 days. In dogs, doses of 5–10 mg/kg once daily orally for 1–5 days have been suggested. In cats, doses of 5 mg/kg once daily or every other day or one dose two to three times a week orally have been used.

There are several reports of azithromycin clinical use in foals with pulmonary infections, such as those caused by *Rhodococcus equii*. Because of favorable pharmacokinetics, cited above, plasma, leukocyte, and alveolar macrophage concentrations persist long enough to allow for every-other-day administration. Based on this work the dose for foals is 10 mg/kg every 24 hours initially, followed by treatment every 48 hours orally.

Safety of Azithromycin. Azithromycin is generally well tolerated. In people, gastrointestinal disturbances are the most common side effects (nausea, vomiting, diarrhea, abdominal pain). In dogs, high doses may cause vomiting. From the clinical reports, it appears to have been well tolerated in foals. Some transient diarrhea is possible. Adult horses may be more prone to developing diarrhea and more caution is urged with clinical use in these animals.

Erythromycin is well known to decrease the activity of drug-metabolizing enzymes in the liver. This can increase the toxicity of some drugs administered concurrently. Although azithromycin is reported to have less effect on the hepatic enzymes, some caution is needed when combining azithromycin with other drugs.

LINCOSAMIDES

Lincosamides are a group of monoglycoside antibiotics containing an amino-acidlike side chain. There are two antibiotics within this group: lincomycin and clindamycin. Lincomycin and clindamycin are structurally similar. Lincomycin has a hydroxyl moiety at the 7 position of the molecule, and clindamycin contains a chlorine at this position, making clindamycin a more active molecule against bacteria than its parent molecule, lincomycin, and better absorbed orally. The lincosamides, like the macrolides, are used primarily to treat gram-positive infections in cases where there is resistance or intolerance to penicillins. Clindamycin also is a common drug for treatment of anaerobic infections. Common infections treated with lincosamides include infections involving *Staphylococcus* spp. and *Streptococcus* spp. (Burrows 1980).

LINCOMYCIN

Source and Chemistry. Lincomycin is the antibiotic produced by *Streptococcus lincolnensis* var. *lincolnensis*, discovered in the 1950s; its name comes from cultures of soil that originated in Lincoln, Nebraska (Fig. 37.5). Lincomycin was first marketed for human clinical use in 1964 and for veterinary use in dogs and cats in 1967. Lincomycin was added to feed premixes for chickens in 1970 and to swine premixes in 1976 for growth promotion. An injectable form was ready for clinical use in swine in 1979 (Ford and Aronson 1985; Kleckner 1984). Lincomycin is a weak base with a pK_a of 7.6 (Riviere et al. 1991).

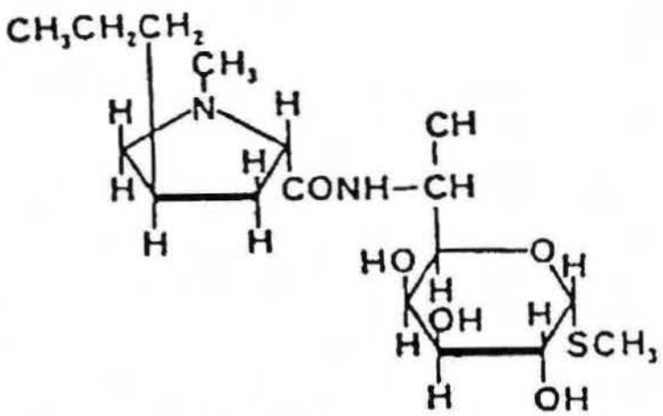

FIG. 37.5 The chemical structure of lincomycin.

Formulations. Lincomycin is available as an oral premix for pigs and chickens (Lincomix) and a soluble powder for drinking water (Lincomix). Lincomycin hydrochloride oral syrup and tablets have been used for dogs and cats (Lincocin), as well as lincomycin hydrochloride injection, but use in small animals is not as common as it once was. Ruminants and horses should not be exposed to lincomycin-supplemented feed. The toxicity is described in more detail below.

Mechanism of Action. Lincomycin inhibits protein synthesis in the microbial cell by binding to the 50S ribosomal subunit in much the same way described for macrolides. Other antibiotics, such as erythromycin and clindamycin, function similarly by binding at different sites to the same ribosomal subunit. Concurrent use of these antibiotics typically results in a decrease in the overall efficacy against the microbe due to one bound antibiotic physically overlapping the binding site of another (Burrows 1980).

Spectrum of Activity. Lincomycin is active against essentially the same bacteria as listed for macrolides.

Absorption and Distribution. Lincomycin is rapidly but incompletely absorbed when administered orally to animals, with one report stating that lincomycin oral absorption in swine given 10 mg/kg is in the range 20–50% (Hornish et al. 1987). Peak serum levels in most animals are reached within 60 minutes after an oral dose and within 2–4 hours after IM injection. Lincomycin is well distributed in the body, with highest tissue concentrations in the liver and kidneys, while very low levels are obtained in the CSF (Burrows 1980; Ford and Aronson 1985; Kleckner 1984). The Vd in animals ranges from 1 to 1.3 l/kg.

Metabolism and Excretion. The half-life after oral, IM, or IV administration is approximately 2–4 hours. Most of the oral dose, measured as ^{14}C-labeled lincomycin, was recovered in the feces and 14% in the urine after a single oral administration to the dog (Kleckner 1984); thus, biliary secretion of lincomycin appears to be an important route of elimination. After a single IM injection, 38% of the dose was found in the feces and 49% in the urine of the dog. Urine excretion of the radiolabeled drug was complete in 24 hours and fecal excretion was complete within 48 hours for both dosing routes. It is not known whether this radioactivity was associated with an unchanged/unmetabolized lincomycin or with the metabolites of this compound. An unpublished report cited by Hornish et al. (1987) stated the parent drug was the primary form present in the urine of dogs and humans.

Because of the potential for residues in meat, from a food-animal residue viewpoint, the metabolism and excretion of lincomycin have been studied more extensively in swine and chickens (Hornish et al. 1987). When administered to animals, lincomycin concentrations are highest in the liver and kidney, with low, albeit detectable, levels in muscle and skin. Lincomycin can pass unchanged from the body via the bile and feces or urine or can be metabolized to the glucuronide, *N*-demethyl lincomycin, or lincomycin sulfoxide forms by the liver. Swine given oral doses of lincomycin showed that 11–21% was excreted into the urine: 50% unchanged lincomycin, trace amounts of *N*-demethyl lincomycin, no lincomycin sulfoxide or glucuronide forms, and the rest labeled "unidentified substances." The feces contained the remainder of the excreted lincomycin: 17% unchanged lincomycin, possible trace amounts of lincomycin sulfoxide, and 83% uncharacterized metabolites (Hornish et al. 1987). Similarly conducted studies in chickens treated orally for 7 days with lincomycin showed that the excreta contained ≈80% lincomycin, ≤10% lincomycin sulfoxide, ≤5% *N*-demethyl lincomycin.

Adverse Effects and Precautions. Dogs and cats have few adverse reactions to lincomycin. Loose stools in the dog and vomiting in the cat have been the major side

effects reported (Kleckner 1984). Pigs may occasionally develop diarrhea and/or swelling of the anus within the first 2 days of treatment and will self-correct within a week after withdrawal from the antibiotic.

The most serious adverse effect from lincomycin reported in people is that of pseudomembranous colitis. This is a serious disease in people caused by an overgrowth and production of toxin from *Clostridium difficile*, which may be fatal. In animals with fermenting GI tracts (horses, ruminants, rabbits, hamsters, chinchillas, and guinea pigs) there also is a high risk of GI bacterial overgrowth with *Clostridium* from lincomycin treatment. Severe enteritis, enterocolitis, may lead to diarrhea and death. Other bacteria also have been implicated in this reaction, such as *Salmonella* spp. or *E. coli* (Burrows 1980; Plenderleith 1988). Rehg and Pakes (1982) have implicated *Clostridium difficile* and *Clostridium perfringens* toxins in lincomycin toxicity in rabbits. Lincomycin-induced enterocolitis has been reported for rabbits (Maiers and Mason 1984; Thilsted et al. 1981), horses (Raisbeck et al. 1981; Plenderleith 1988), sheep (Bulgin 1988), and large ruminants (Plenderleith 1988). Lincomycin has been reported to produce ketosis in dairy cows (Rice and McMurray 1983).

Clinical Use. Lincomycin is used to treat gram-positive aerobic and anaerobic infections in patients for many of the same indications for which one would use erythromycin or other macrolide. In dogs and cats, lincomycin has been used to treat penicillin-resistant or suspected penicillin-resistant strains of *Staphylococcus* spp. and *Streptococcus* spp. bacteria found in bone, the upper respiratory tract, and the skin. Although it has been used for skin infections, it is not as popular as it once was (Noli and Boothe 1999). Doses in dogs and cats generally are 22 mg/kg every 12 hours orally. The use of lincomycin to treat bacterial infections in dogs and cats has been largely replaced by clindamycin therapy.

Lincomycin has been utilized to treat bacterial arthritis in swine caused by *Staphylococcus* spp., *Streptococcus* spp., *Erysipelothrix* spp., and *Mycoplasma* spp. and pneumonia caused by *Mycoplasma* spp. Doses in pigs are 11 mg/kg every 24 hours IM. It has also been used as a feed additive (Rainier et al. 1980), drinking-water supplement (Hamdy 1978), and parenteral product (Hamdy and Kratzer 1981) to control or treat swine dysentery.

In broiler chickens, lincomycin has been used as a feed additive to increase the rate of weight gain and improve feed efficiency, in addition to treating necrotic enteritis in this species. The addition of 2 g/ton of lincomycin to the feed of broilers resulted in a significant decrease in the incidence of necrotic enteritis (Maxey and Page 1977). Lincomycin has also been used with success in psittacines (Mandel 1977). Lincomycin use in the eyes of rabbits has also been reported (Kleinberg et al. 1979). Topical corneal administration of 1% lincomycin in water to rabbits showed local therapeutic levels could be maintained from 30–45 minutes to 2 hours postdose in the cornea, aqueous humor, and iris-ciliary body and that de-epithelialization of the corneal epithelium served to enhance the ocular topical absorption of this antibiotic.

Sheep, goats, and calves have been treated with parenteral lincomycin-spectinomycin antibiotic combinations for gram-positive and gram-negative respiratory tract infections. The lincomycin-spectinomycin combination (50 mg lincomycin with 100 mg spectinomycin [Linco-Spectam] per ml) at a dose of 1 ml/10 kg body weight IM has been used to treat foot rot in sheep caused by *Bacteroides nodosus* with better success than systemic penicillin-streptomycin therapy (Venning et al. 1990).

Regulatory Considerations. When added to feed for poultry and pigs, the slaughter withdrawal time ranges from 0 to 6 days, depending on the preparation and dose. Consult the package insert for specific recommendations. When injected in pigs, the withdrawal time for slaughter is 2 days.

CLINDAMYCIN

Source and Chemistry. Clindamycin chemically is 7-chlorolincomycin, a derivative of lincomycin and an antibiotic produced by *Streptococcus lincolnensis* var. *lincolnensis*. The replacement of the hydroxyl group at the C7 position of the lincomycin molecule by a chloride results in a more active antibacterial effect when compared to lincomycin. The chemical structure of clindamycin is shown in Figure 37.6. It is a weak base with a pK_a of 7.6. Both clindamycin hydrochloride (HCl) and clindamycin palmitate are for oral administration. Clindamycin HCl is directly active when administered, whereas the palmitate form must be converted to clindamycin in the small intestine. Clindamycin palmitate is more palatable than clindamycin HCl. Clindamycin phosphate is the parenteral form of clindamycin and must undergo hydrolysis in the plasma for it to become active.

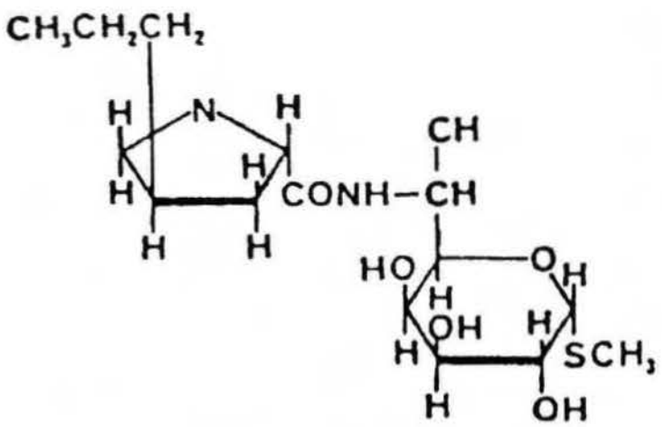

FIG. 37.6 The chemical structure of clindamycin.

Mechanism of Action. Clindamycin exerts its antibiotic activity by inhibiting protein synthesis at the 50S ribosomal subunit (Hedstrom 1984) in a manner identical to that described for lincomycin. Plasmid-mediated resistance to clindamycin has been reported in *Bacteroides fragilis* (Tally et al. 1979) and cross-resistance to lincomycin can occur (Harari and Lincoln 1989).

Spectrum of Activity. Clindamycin is distinguished from the macrolide antibiotics and lincomycin by its high activity against anaerobic bacteria, including gram-negative anaerobes such as *Bacteroides* spp. In small animals, anaerobic infections are one of the major uses of clindamycin. However, one report (Jang et al. 1997) indicated that only 83% of *Bacteroides* from small animals were sensitive to clindamycin and only 80% of the *Clostridium.* Other than anaerobes, clindamycin is active against the same bacteria previously listed for macrolides and lincomycin. An additional organism for which there is activity is *Toxoplasma,* but the clinical use of clindamycin for treating toxoplasmosis in cats is controversial (described in more detail below).

Absorption and Distribution. Clindamycin is better absorbed from the GI tract in humans and animals than lincomycin, yielding higher serum concentrations, and is more active than lincomycin due to the chlorine substitution (Nichols and Keys 1984). Brown and co-workers (1989, 1990) have described the pharmacokinetics of oral clindamycin HCl disposition in the cat. Groups of cats were given oral doses of either 5.5, 11.0, or 22.0 mg/kg once daily of clindamycin (Antirobe), with physical, histologic, and hematologic changes recorded during therapy. Mean residence time ranged from 4.5 to 6.5 hours. It was also found that the 5.5 and 11.0 mg/kg oral doses maintained a serum MIC above that necessary for most *Staphylococcus aureus* infections and that the 11.0 and 22.0 mg/kg doses gave serum concentrations above the MIC for many susceptible anaerobes. Clindamycin is distributed well to tissues and attains high intracellular concentrations as exhibited by the high Vd. The apparent Vd in cats ranged from 1.6 to 3.1 L/kg. The highest concentrations of clindamycin were found in the lung, followed by liver, spleen, jejunum, and colon. Although the CSF had very low but detectable levels of clindamycin, the brain had higher than anticipated concentrations. This was most likely due to clindamycin's lipophilic nature, having a greater affinity for the lipid matrix of the brain than for the aqueous CSF. Bone marrow also had appreciable levels of clindamycin accumulation, due to sequestration of clindamycin in the fat, the concentration of clindamycin in the white blood cell precursors, or a combination of both factors.

In the dog (Budsberg et al. 1992; Lavy et al. 1999), clindamycin phosphate was administered IV, IM, and SC at 10 and 11 mg/kg. The elimination half-life was 2–3.2 hours IV but longer (5–7 hr) from IM and SC injection. The Vd was 0.9–1.4 l/kg. The bioavailability of clindamycin in one study after IM injection was 87% (Budsberg et al. 1992), but in another study bioavailability was greater than 100% from an IM dose and over 300% from the SC dose (Lavy et al. 1999). It appears that the prolonged elimination half-life from the SC administration ("flip-flop" effect) resulted in a falsely high estimate of the true availability following IM and SC administration in these studies. In one study, it was reported that clindamycin is too painful for IM administration (Budsberg et al. 1992), but in another study, IM administration of a buffered, more concentrated 20% solution was better tolerated. However, the SC dose was much better tolerated (Lavy et al. 1999) and produced more prolonged concentrations. When clindamycin was administered to dogs at a dose of 11 mg/kg oral and IV, the half-life was identical from each route (4.37 hr), and the volume of distribution was 2.48 L/kg (Batzias et al. 2005). Oral absorption was 73%.

In sea turtles (unpublished data from the author), clindamycin had extremely rapid clearance and a short half-life. There was very little oral absorption. These results

in sea turtles suggest that it would be impractical to use in these animals.

Unlike lincomycin, the presence of food does not appear to affect oral absorption of clindamycin. There is good penetration into respiratory secretions, pleural fluid, the prostate, bones, and joints, but with low concentrations appearing in the CSF. The concentrations of clindamycin in phagocytes are ten- to twentyfold (and as high as 40) times the plasma concentrations (Harari and Lincoln 1989). Despite the high intracellular concentrations of clindamycin in phagocytes, intracellular killing is poor (Yancy et al. 1991), perhaps because the drug is sequestered in subcellular sites. Macrophages take up clindamycin by an active transport mechanism and concentrate clindamycin up to 50 times the extracellular concentration (Dhawan and Thadepalli 1982). Because phagocytes are the cells most likely to enter infected tissues, such as abscesses, it is possible for clindamycin to be transported to an abscess and eradicate the bacteria (Yancy et al. 1991). Clindamycin also crosses the placental barrier, but its safety during pregnancy has not been determined.

Metabolism and Excretion. Clindamycin HCl requires no metabolism to be active once administered orally. Clindamycin phosphate requires hydrolysis to occur in the plasma to be active; similarly, clindamycin palmitate requires the removal of the palmitate moiety in the small intestine to be active. The commercial form for small animals (Antirobe) is clindamycin HCl.

Clindamycin metabolites are much like those described for lincomycin. In dogs, 36% of the administered dose of clindamycin is excreted unchanged by the bile and urine. The balance of the dose appears to be active or inactive metabolites, 28% excreted by the liver in the glucuronide form (no antimicrobial activity), 28% as clindamycin sulfoxide (25% of the antimicrobial activity of the parent antibiotic), and 9% as *N*-demethyl clindamycin, which has 4–8 times the antimicrobial activity of the parent compound (Dhawan and Thadepalli 1982). The bile is the major excretion route. The colonic contents of humans administered clindamycin were found to suppress microbial activity for as long as 2 weeks after the discontinuation of therapy.

Adverse Effects and Precautions. Like lincomycin, the most serious adverse effect in humans is pseudomembranous colitis, from overgrowth of *Clostridium difficile*. This has not been a reported problem in animals. In dogs and cats, vomiting and diarrhea are possible but they are transient and not serious. However, GI problems such as those discussed above for lincomycin in ruminants, horses, rabbits, and rodents are possible, and the same precautions apply that were discussed for lincomycin. Greene et al. (1992) orally administered to cats 25 and 50 mg/kg clindamycin HCl divided in 2 doses and found that diarrhea and vomiting are two clinical signs most often associated with oral therapy. The highest frequency for both of these clinical signs occurred in the 50 mg/kg treatment group and was thought to be related to either a direct irritant effect on the GI tract or some effect on intestinal water absorption. Cats are also reluctant to accept the oral liquid form of clindamycin because of poor palatability. As reported for other oral drugs in cats (eg, doxycycline hyclate) oral administration of clincamycin hydrochloride has been associated with esophageal injury (Beatty et al. 2006).

A study was performed in cats to ascertain the effect of prolonged clindamycin therapy on vitamin K–dependent blood clotting times (Jacobs et al. 1989). The study showed that factor VII levels did not significantly change in cats treated with a total daily dose of 25 mg/kg orally once daily for 6 weeks compared to controls.

Clinical Use. Clindamycin possesses an antimicrobial spectrum similar to that of lincomycin, but it is much more extensively used clinically than lincomycin because of higher activity against anaerobes, increased potency, and more complete oral absorption. Clindamycin has been reported to be as much as 20 times more potent than lincomycin in the treatment of *Staphylococcus* and *Streptococcus* infections in humans (Harvey 1985). Clindamycin is active against aerobic species of organisms, including *Staphylococcus, Streptococcus, Actinomyces, Nocardia, Mycoplasma,* and *Toxoplasma*. The anaerobic bacterial spectrum of activity includes *Bacteroides fragilis, Fusobacterium* spp., *Peptostreptococcus* spp., and *Clostridium perfringens* (Harari and Lincoln 1989). Clindamycin has been used to treat wounds, abscesses, osteomyelitis, and periodontal diseases caused by these organisms. Clindamycin is found in high concentrations in the prostate, making it an acceptable choice for treating bacterial prostatitis when caused by gram-positive organisms.

The use of clindamycin for treating toxoplasmosis is controversial. Lappin et al. (1989) performed a retrospective study of cats diagnosed with *Toxoplasma gondii* infections and found that those cats treated with clindamycin resolved all clinical signs of the disease except those lesions

involving the eyes. Clindamycin alone or in combination with a corticosteroid helped to resolve the active retinochoroiditis and the anterior uveitis associated with this disease. Even though clindamycin may help clinical signs associated with toxoplasmosis, it may not help to clear organisms from the CNS or the eye. In experimentally infected cats, there was a paradoxical effect in that cats with toxoplasmosis treated with clindamycin had a worsening of clinical signs. As discussed in more detail by Davidson et al. (1996), this paradoxical effect may be due to an inhibition of intracellular killing of organisms by clindamycin.

Clindamycin can be used to treat *Staphylococcus* spp. infections in dogs with experimentally induced posttraumatic osteomyelitis (Braden et al. 1987, 1988). An oral dose of 11 mg/kg twice daily for 28 days was found to be efficacious in treatment of these infected dogs, resulting in a 94% recovery rate in the clindamycin-treated dogs. Clindamycin also has been shown to be effective for treatment of superficial and deep pyoderma in dogs and is a common choice as an alternative to β-lactam antibiotics (Harvey et al. 1993; Noli and Boothe 1999; Scott et al. 1998). Although 11 mg/kg every 24 hours has been used to treat staphylococcal infections (pyoderma) in dogs, for most infections dosing 11 mg/kg every 12 hours is used by many veterinarians for treating most *Staphylococcus* spp. infections.

MISCELLANEOUS ANTIBIOTICS

BACITRACIN. Bacitracin is a complex labile polypeptide consisting of 5–10 separate chemical components first isolated from a *Bacillus subtillus*–contaminated wound in 1943 (Teske 1984). Bacitracin A ($C_{66}H_{103}N_{17}O_{16}S$) is the major component of this mixture and accounts for most of the antibiotic activities. Bacitracin inhibits peptidoglycan synthesis in bacteria by nonspecifically blocking phosphorylase reactions, some of which occur during cell wall synthesis (Lancini and Parenti 1982). Development of resistance to bacitracin is rare.

Bacitracin is active against gram-positive organisms. Bacitracin is not absorbed from the GI tract when given orally. Systemic administration has resulted in a high incidence of nephrotoxicity (albuminuria, cylindruria, azotemia), in addition to pain, induration, and petechiae at the site of injection. In contrast, bacitracin is nonirritating and rarely induces allergic reactions when used topically. Bacitracin (bacitracin, bacitracin methylenedisalicylate, bacitracin manganese, zinc bacitracin) has been used as a feed additive to promote growth in many species of animals, but its most common use today is in topical applications to treat susceptible skin, ear, and eye infections. Bacitracin inhibits many organisms found on skin, such as hemolytic and nonhemolytic *Streptococcus* spp., coagulase-positive *Staphylococcus* spp., and some *Clostridium* spp., and it is often combined with other antibiotics that have a gram-negative spectrum of activity (polymyxin B, neomycin). Zinc bacitracin administered topically may increase the activity of bacitracin due to zinc's astringent properties, which decrease inflammation (Harvey 1985).

NOVOBIOCIN. Novobiocin is a dibasic acid ($pK_a = 4.3$ and 9.1) derived from coumarin and is utilized clinically as a mono- (Na^+) or dibasic- (Ca^{++}) salt form. Novobiocin possesses activity against both gram-positive and gram-negative bacteria but is more active against the gram–positive bacteria, in particular *Staphylococcus* species. Other susceptible organisms include *Neisseria* spp., *Haemophilus* spp., *Brucella* spp., and some strains of *Proteus* spp. It may be used as an alternative to penicillins in cases involving penicillin-resistant *Staphylococcus* spp., although other penicillin substitutes (cephalosporins, macrolides, clindamycin) are better clinical choices.

Novobiocin has several toxic effects on bacteria, but its exact mechanism and site of action are unknown. Novobiocin has been shown to cause nonspecific inhibition of cell wall synthesis by inhibiting formation of alternating *N*-acetylmuramic acid pentapeptide and *N*-acetylglucosamine residues; it also inhibits teichuronic acid in some species of bacteria. The concentrations needed to inhibit these cell wall components are greater than the minimal concentration needed to inhibit growth, suggesting these effects on bacteria are secondary effects. DNA and RNA synthesis, protein synthesis (β-galactosidase), respiration, and oxidative phosphorylation are also inhibited in some species of bacteria and in rat liver homogenates (Morris and Russell 1971), with none seemingly being the primary antibiotic effect. Novobiocin is also known to induce an intracellular magnesium deficiency, but there is no direct convincing evidence that this is the mechanism responsible for novobiocin's antimicrobial activity.

Novobiocin is initially highly effective against *Staphylococcus* spp. infections, but resistance to this antibiotic develops quickly (Morris and Russell 1971; Harvey 1985).

Synergism occurs when novobiocin is combined with tetracycline. Novobiocin has been combined with tetracycline to broaden the spectrum of activity and to decrease the resistance to novobiocin, but these older combinations are used infrequently today. Novobiocin and tetracycline have been reported to be efficacious in cases of canine upper respiratory diseases such as "kennel cough" and tonsillitis (Maxey 1980), but the use for this problem in dogs has declined substantially. Toxic side effects in animals and humans given novobiocin systemically have been reported and include skin rashes, leucopenia, pancytopenia, anemia, agranulocytosis, thrombocytopenia, nausea, vomiting, and diarrhea. Few side effects have been reported for this antibiotic used in its topical form in domestic animals.

THIOSTREPTON. Thiostrepton is a polypeptide antibiotic produced by *Streptomyces aureus* and has a predominately gram-positive spectrum, although some gram-negative organisms are also affected. Thiostrepton is not absorbed from the GI tract and is used primarily for topical local therapy, usually combined with other antibiotics and/or glucocorticosteroids for dermatologic therapy (Huber 1982).

RIFAMPIN. Rifampin is a complex macrocyclic high-molecular-weight semisynthetic antibiotic derived from rifamycin B, produced by *Nocardia mediterrea*. Rifamycin B is chemically modified to produce rifampin (U.S. and Canadian name), also known as *rifampicin* in Europe. The chemical structure of rifampin is shown in Figure 37.7. Rifampin has a high activity against gram-positive bacteria

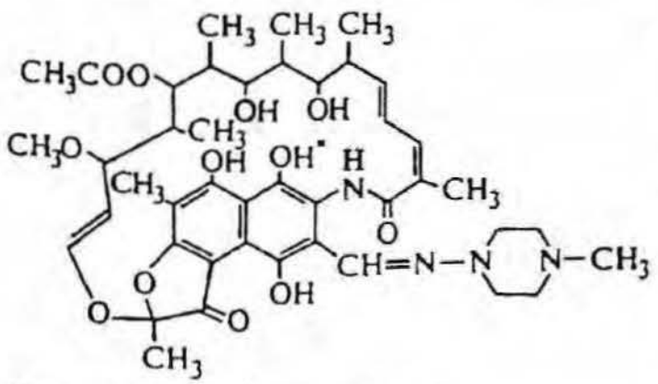

FIG. 37.7 The chemical structure of rifampin.

(*Staphylococcus* spp.), *Mycobacterium* spp., *Haemophilus* spp., *Neisseria* spp., and *Chlamydia* spp., but more limited activity against the gram-negative bacteria.

Rifampin is highly lipid soluble, is stable in acidic environments, and can concentrate in neutrophils and macrophages, which is therapeutically advantageous in diseases involving intracellular organisms (*Brucella, Mycobacterium, Rhodococcus, Chlamydophilia,* etc.) and chronic granulomatous diseases. Rifampin enters the microbial cell and forms stable complexes with the β subunit of DNA-dependent RNA polymerases of microorganisms. This binding results in inactive enzymes and inhibition of RNA synthesis by preventing chain initiation. This inhibition can also occur in mammalian cells, but much higher concentrations are needed. MICs for gram-positive organisms generally occur at 0.1 μg/ml, while gram negative bacteria have MIC values ranging from 8 to 32 μg/ml. This large disparity in MIC values is attributed to rifampin's ability to more easily permeate the gram-positive organism cell wall than the gram-negative organism cell wall rather than differences in bacterial RNA polymerases.

Pharmacokinetics. Rifampin is rapidly absorbed from the GI tract after oral administration in humans, dogs, calves, horses, and foals. Rifampin absorption is highest in an acidic environment. Rifampin is approximately 80% bound to plasma proteins, with the remainder being widely distributed to all tissues of the body, with particularly high concentrations of the drug found in the lungs, liver, bile, and urine. After oral absorption or parenteral administration, rifampin is primarily metabolized to the bioactive metabolite 25-desacetylrifampin, with some minor glucuronidation products formed in the liver. Both parent and metabolite compounds are excreted in the bile. Both forms are passively filtered through the kidneys, with renal clearance being approximately 12% of total glomerular filtration rate.

Multiple dosing of rifampin often results in decreased, rather than increased, peak serum concentrations. This phenomenon is due to autoinduction of liver enzymes and is known to occur in humans, swine, dogs, calves, and rodents (Frank 1990). Hepatic enzyme induction by rifampin will also alter the disposition of other drugs. Plasma ketoconazole levels decrease and the metabolism of progestin, digitalis, warfarin, ciprofloxacin, glucocorticosteroids, and several other drugs increases when they are concurrently administered with rifampin (Kenny and Strates 1981; Frank 1990; Barriere et al. 1989). In addi-

tion to being a potent inducer of hepatic cytochrome P450 enzymes, rifampin also can induce the MRD membrane efflux pump (P-glycoprotein), which may have the consequence of decreasing oral absorption of other drugs.

The pharmacokinetics of rifampin has been studied in humans (Acocella 1983; Kenny and Strates 1981), in the adult horse (Burrows et al. 1985), and in the foal (Castro et al. 1986). Adult horses given 10 mg/kg of rifampin IV, IM, or PO showed a rapid absorption of rifampin by the oral route versus the IM route, but the IM route provided longer detectable plasma concentrations in 50% of the horses than did the oral route. Adult horses given 10 mg/kg IV showed a serum half-life of 6.05 hours and an apparent Vd of 0.7 l/kg. Doses of 10 mg/kg administered IM and PO had half-lives of 7.32 and 5.84 hours, respectively. Oral doses of 25 mg/kg in adult horses had a serum half-life of 4.78 hours. It was determined that the 10 mg/kg PO dose was adequate for susceptible gram-positive infections in the adult horse, whereas the 10 mg/kg IV or the 25 mg/kg PO dose was necessary to treat susceptible gram-negative infections. The rate of excretion in the foal is lower than in the adult horse, mainly due to biliary excretion mechanisms being less developed in the foal. Foals given 10 mg/kg of rifampin orally had a mean serum half-life of 17.5 hours, significantly longer than that found in the adult horse. The authors of that study indicated that 5 mg/kg orally was sufficient in the foal to combat susceptible gram-positive infections and that higher or more-frequent doses were needed to treat susceptible gram-negative infections.

The pharmacokinetics of rifampin has also been studied in sheep (Jernigan et al. 1986), with the recommended dose from that study being 20 mg/kg orally once a day. In sheep administered a 50 mg/kg dose of rifampin IV, the serum half-life was 4.56 hours and the apparent Vd was 0.5 l/kg.

Clinical Use. Rifampin has been used to treat a wide variety of microbial infections. Susceptible organisms of interest to veterinarians include *Staphylococcus* species (including methicillin-resistant strains), *Streptococcus* spp., *Rhodococcus equi*, *Corynebacterium pseudotuberculosis*, and most strains of *Bacteroides* spp., *Clostridium* spp., *Neisseria* spp., and *Listeria* spp. Organisms known to be resistant to rifampin are *Pseudomonas aeruginosa, E. coli, Enterobacter* spp., *Klebsiella pneumoniae, Proteus* spp., *and Salmonella* spp. Wilson et al. (1988) obtained samples from clinically ill horses and tested the isolated bacteria for susceptibility to rifampin. It was found that all strains of coagulase-positive *Staphylococcus* spp., *Streptococcus zooepidemicus, Streptococcus equi, Streptococcus equisimilus, Rhodococcus equi*, and *Corynebacterium pseudotuberculosis* were highly susceptible to rifampin at MICs of 0.25 μg/ml. Gram-negative organisms isolated in that study were *Actinobacillus suis, Actinobacillus equuli,* and *Bordetella bronchiseptica,* and MIC values ranged from <0.008 to >16 μg/ml. Other isolates, such as *Pseudomonas aeruginosa, Enterobacter cloacae, Klebsiella pneumoniae, Proteus* spp., and *Salmonella* spp., were found to be resistant, having MICs greater than 4 μg/ml.

Most of rifampin use has been in horses. Rifampin is used to treat equine diseases of a gram-positive bacterial origin (e.g., *Rhodococcus equi, Streptococcus equi*). However, resistance to rifampin is quickly acquired when administered alone to combat these infections. Resistance is readily accomplished by a single mutation of the amino acid sequence of the β subunit of the DNA-dependent RNA polymerase enzyme. Mutations result in rifampin having less affinity for the RNA polymerase enzyme. Higher concentrations of rifampin are necessary to overcome this resistance in vitro. Resistance can be minimized if other antibiotics are used concurrently with rifampin that will kill the mutant strains of bacteria produced in response to rifampin. Antibiotics that can be so used are erythromycin, most of the β-lactam antibiotics, vancomycin, and gentamicin, depending on the bacterial sensitivity to these drugs (Frank 1990).

Synergism may occur between amphotericin B and rifampin against some fungi, particularly *Saccharomyces cerevisiae, Histoplasma capsulatum,* several species of *Aspergillus,* and *Blastomyces dermatitidis* (Medoff 1983). Increased permeability of rifampin across the fungal cell wall (and hence increased inhibition of RNA polymerases) due to amphotericin B–induced cell wall damage is probably the mechanism responsible for this synergism.

Adverse Effects. Rifampin is teratogenic in laboratory animals, so its use in pregnant animals should be restricted. Rifampin will color the urine, saliva, and tears of treated animals an orange-red. This effect should be explained to animal owners when prescribing so that this reaction does not cause alarm. Dogs given the human dose of 10 mg/kg orally developed increases in hepatic enzyme activity, some of which eventually progressed to clinical cases of hepatitis. Hepatitis is the most common reason to discontinue

rifampin treatment in dogs. However, lowering the total daily dose of rifampin will decrease the chances of inducing toxic side effects, especially in dogs. Although rare, rifampin can induce thrombocytopenia, hemolytic anemia, anorexia, vomiting, and diarrhea. Preexisting renal disease does not normally require a dose modification of rifampin.

NITROFURANS. Nitrofurans comprise several synthetic compounds derived from 5-nitrofuran and possess antimicrobial activity, the 5-nitro group being required for this activity. Over 3,500 nitrofurans have been synthesized to date, with only a handful being useful in animal chemotherapy. Nitrofurans and furazolidone are banned from use in food-producing animals.

Nitrofurans as a group are bacteriostatic and function by blocking oxidative decarboxylation of pyruvate to acetyl coenzyme A, depriving susceptible organisms of vital energy production pathways. Their spectrum of activity includes gram-positive and gram-negative bacteria and some protozoans, but they are most effective against the gram-negative bacteria. Nitrofurans can be administered orally or topically. Oral absorption is enhanced when administered with feed; it is widely distributed throughout the body but in low concentrations. Approximately 50% of the total dose of nitrofurans are excreted in the active form. Acidification of the urine promotes tubular reabsorption, which also decreases the overall urine concentration of the drug. An acid environment is required for the nitrofurans to diffuse across the cell membranes. Nitrofurantoin has a broad gram-positive and gram-negative spectrum and also high concentrations in the urine, making it useful as a urinary antiseptic in small animals. Nitrofuran use today is mainly in topical preparations for the eye, ear, mucous membranes, and skin; it finds limited use in treating bacterial GI tract and urinary tract disorders (Ali 1989; Ford and Aronson 1985).

The major disadvantage of nitrofurans to treat systemic infections is that the concentrations needed to reach the MIC also induce systemic toxicity. There are many reports in the veterinary literature on the toxicities induced when the nitrofurans are used systemically (Ali 1983). The toxicology of furazolidone (*N*-5-nitro-2-furfurylidene amino-2-oxazolidinone) has been investigated extensively in laboratory, food, and companion animals as well as in humans and has been reviewed by Ali (1989). The effects of feeding furazolidone to poultry have been reported (Ali 1989; Mustafa et al. 1975; Czarnecki et al. 1974a; Jankus et al. 1972; Czarnecki et al. 1974b).

Furazolidone has also been demonstrated to be carcinogenic when used at a 0.15% w/w concentration in feed for 1 year, inducing mammary tumors in a dose-related manner. Mice fed a 0.03% w/w concentration in feed for life developed bronchial adenocarcinomas in both sexes (Ali 1983). DNA is the principal target of furazolidone in some cells in vivo, causing cuts and mutations in DNA and binding to DNA, hence blocking the replication and transcription processes. Mutagenesis by nitrofurans in general also occurs and has been extensively reviewed by McCalla (1983), who notes several possible metabolic pathways by which nitrofurans can cause mutagenesis in mammalian cells. This potential for mutagenesis and carcinogenesis has caused the ban from use in food-producing animals.

VIRGINIAMYCIN. Virginiamycin is a combination of two chemicals produced by *Streptomyces virginiae,* isolated from soil samples in Belgium in the early 1960s. Virginiamycin is classified as a peptolide antibiotic composed of the predominate M fraction ($C_{28}H_{35}N_3O_7$) and the lesser S fraction ($C_{43}H_{49}NO_{10}$) (Crawford 1984). The optimum ratio of M:S is 4:1 (Gottschall et al. 1988). Administered separately, both M- and S- fractions have a reversible bacteriostatic action on susceptible bacterial populations; used together, their activity is synergistic, bactericidal, and approximately 100 times that found when used separately. Virginiamycin is not known to be synergistic with other classes of antibiotics. Virginiamycin is primarily active against gram-positive organisms, *Haemophilus* spp., and *Neisseria* spp. and has mild activity against the protozoan *Toxoplasma* spp. It works by inhibiting protein synthesis at the 23S ribosomal subunit, blocking translation but not transcription in susceptible bacteria. Virginiamycin is rapidly absorbed when administered orally, is excreted by the bile with no enterohepatic circulation, and has an affinity for dermal tissues (Crawford 1984). Gottschall et al. (1988) reported that ^{14}C-virginiamycin, specifically the M fraction, was extensively metabolized in the rumen. The S fraction underwent no detectable metabolism in the rumen, and the M fraction metabolites had considerably less antimicrobial activity than the parent compound.

All virginiamycin-like antibiotics fall into one of two groups. Group A consists of polyunsaturated cyclic pep-

tolides that have a molecular weight of approximately 500 and that contain substituted aminodecanoic acid and an oxanzole system. Group B consists of cyclic hexadepsipeptides with an approximate molecular weight of 800, and most members contain one molecule of pipecolic acid or its derivative. Both groups have low solubilities in aqueous solvents and are more soluble in organic solvents. All strongly absorb ultraviolet radiation and are therefore degraded in its presence. Virginiamycin-like antibiotics tend to affect gram-positive bacteria more than the gram-negative, with *Mycobacteria* spp. being relatively resistant and *Haemophilus* spp. and *Neisseria* spp. being very sensitive. Differences in bacterial sensitivity to different virginiamycin-like antibiotics are caused by each antibiotic's particular ability to permeate that bacteria's cell wall to gain access to the ribosomes (Cocito 1979).

Virginiamycin and virginiamycin-like antibiotics are not commonly used to treat clinical bacterial disease in domestic animals, despite their rather broad spectrum of activity. They have been used to treat swine dysentery (*Treponema hyodysenteriae*) (Olsen and Rodabaugh 1977), but other antibiotics have proven to be more efficacious. Its main use has been as a feed additive for growth promotion in food animals such as swine (Ravindran and Kornegay 1984; Moser et al. 1985), being approved for this use since 1975. Virginiamycin has also been studied in turkeys (Salmon and Stevens 1990), broilers (Miles et al. 1984), and laying hens (Miles et al. 1985) as a growth promotant, all of which experienced either increased weight gain or increased egg production.

CARBADOX. Carbadox (methyl 3-(2-quinoxalinylmethylene) carbazate N_1,N_4 dioxide) is a synthetic antibacterial agent primarily active against the gram-positive bacteria, although some gram-negative bacteria are affected as well. Available in 1973, carbadox was marketed as a growth promotant in swine and also for the control of swine dysentery (*Treponema hyodysenteriae*), bacterial enteritis (in particular, *Salmonella cholerasuis*), and nasal infections of *Bordetella bronchiseptica* in swine (Farrington and Shively 1979; Huber 1982). Carbadox was shown to be better than lincomycin for the treatment of swine dysentery (Anonymous 1980; Rainier et al. 1980). Resistance to carbadox has been reported in *E. coli* via R-plasmids (Ohmae et al. 1981).

The daily feeding of carbadox in feed concentrations of more than 100 ppm for growth promotion in pigs has resulted in toxicities in some weaned pigs, which include growth retardation, dry feces, wasting, dehydration, urine drinking, and a strong interest in salt-containing products (van der Molen et al. 1989a). It is now known that carbadox suppresses aldosterone production, leading to hypoaldosteronism, which then leads to decreased plasma sodium and increased plasma potassium concentrations. These ion alterations are due to stimulation of the renin-angiotensin system with subsequent morphological changes in the zona glomerulosa of the adrenal cortex (van der Molen et al. 1989a,b,c).

VANCOMYCIN. Of the glycopeptides, vancomycin is the only one used in veterinary medicine. Teicoplanin has been used in Europe but is not available in the United States. Vancomycin was discovered in the 1950s. In the 1960s and 1970s it was not used much because the penicillins and cephalosporins were active against most gram-positive bacteria. But in the last 10–15 years resistant enterococcal and staphylococcal infections have generated more reliance on vancomycin in human medicine. Vancomycin is a tricyclic glycopeptide having an approximate molecular weight of 1500. It is produced by the soilborne actinomycete *Streptomyces orientalis*. It is freely soluble in water, odorless, and slightly bitter to the taste. Vancomycin is highly active against gram-positive cocci (in particular, *Staphylococcus* spp. and streptococci), enterococci (*Enterococcus faecium* and *E. faecalis*), as well as *Neisseria* spp. Because it has activity against methicillin-resistant *Staphylococcus* species, including *S. aureus* (MRSA) and *Staphylococcus pseudintermedius* and β-lactam resistant *Enterococcus* species, it has become extremely valuable for the treatment of these infections. It also is active against gram-positive anaerobic cocci (but not anaerobic gram-negative bacteria) and has been administered to people for diarrhea caused by *Clostridium* spp.

Vancomycin functions as a bactericidal antibiotic by inhibiting the synthesis of the linear peptidoglycan in the bacterial cell wall during replication, resulting in the bacterium's rapid death. Its action is time-dependent, but the pharmacokinetic-pharmacodynamic (PK-PD) that best predicts clinical results is the area-under-the-curve (AUC) to MIC ratio (AUC:MIC). Over 80 *n*-alkyl vancomycins have been synthesized by reductive alkylation of vancomycin, with some forms being five times more active than vancomycin and with some having longer elimination half-lives (Nagarajan et al. 1989).

Adverse Effects. The most common adverse effect is kidney injury. Early formulations of vancomycin were associated with a high incidence of adverse effects. Most of these effects were associated with rapid IV administration, which induced flushing of the skin, pruritus, tachycardia, and other signs attributed to histamine release. Ototoxicity also was reported. The incidence of nephrotoxicity and ototoxicity may be partially caused by the common practice of simultaneously administering vancomycin with aminoglycosides. Newer formulations are safer, but histamine release still is possible from IV administration. Toxicity studies on vancomycin have been performed in many species of laboratory animals (Wold and Turnipseed 1981). The LD_{50} for the canine was 292 mg/kg, but death did not occur until several days after dosing. Dogs that died typically had blood urea nitrogen (BUN) values between 250 and 300 mg/dl, death presumably being due to acute nephrotoxic renal failure.

Clinical Use and Administration Guidelines. Clinical use of vancomycin has been limited in veterinary medicine and most of our clinical recommendations for use are derived from pharmacokinetic studies performed in dogs and horses and recommendations of effective blood concentrations for people. Vancomycin must be administered via IV infusion, although in rare instances intraperitoneal administration has been used. Vancomycin is poorly absorbed orally and this route is not used except to treat intestinal infections. IM administration is painful and irritating.

In dogs the half-life is somewhat shorter and the Vd smaller than in humans (Zaghlol and Brown 1988). In order to keep the plasma concentration within a suggested window of 10–30 μg/ml, the dose rate of 15 mg/kg q6-8h IV is recommended. (This dose actually produces peaks and troughs of approximately 40 and 5 μg/ml, respectively, but it is the most convenient dose that can be used because of the short half-life in dogs.) This dose should be infused slowly over 30–60 minutes, or at a rate of approximately 10 mg/min. The total dose to be administered can be diluted in 0.9% saline or 5% dextrose solution, but not alkalinizing solutions. Vancomycin is available in vials of 500 mg to 5 g (Vancocin, other brands, and generic). If vancomycin is used to treat enterococcal infections, it is strongly recommended to coadminister an aminoglycoside (e.g., amikacin or gentamicin) because when used alone, vancomycin is not bactericidal.

Vancomycin is used much less frequently in horses, but has been necessary occasionally for treatment of methicillin-resistant *Staphylococcus* infections and drug-resistant infections caused by *Enterococcus*. The guidelines for treatment were developed by Orsini et al. (2005) from their pharmacokinetic studies. A dose of 7.5 mg/kg is infused over at least 30 minutes every 8 hours in horses. Adverse reactions with this protocol have been minimal. To treat distal limb infections in horses regional limb perfusion or interosseous regional infusions have been used according to a protocol developed by Rubio-Martinez et al. (2005, 2006), in which 300 mg total dose is diluted in 60 ml saline solution and infused in the distal limb.

If vancomycin is administered according to the recommended dosing rates, adverse reactions described earlier are rare. A slow infusion is recommended to minimize histamine release. To avoid other toxic reactions, dose recommendations are designed to avoid high plasma concentrations. In people, therapeutic drug monitoring is often performed to ensure that peak concentrations are below 50 μg/ml and the trough concentrations are above 5 μg/ml. If animals have renal disease or unique physiologic changes (e.g., pregnant or a neonatal animal), drug disposition may change, and peak and trough plasma concentrations should be monitored to adjust the dose appropriately.

Regulatory Considerations. In August 20, 1997, the US FDA prohibited the extralabel use of glycopeptides in food-producing animals for fear of glycopeptide-resistant bacteria being transmitted to humans from treated animals (Bates et al. 1994). Feeding glycopeptides to animals is not legal in the United States.

METHENAMINE. Methenamine (hexamethylenetetramine) is a urinary antiseptic most commonly used to treat urinary tract infections in small animals. It may be used in conjunction with an antibiotic or occasionally by itself in some cases of bacterial urinary tract infections that have become refractory to conventional antibiotic therapies. Methenamine is activated by a hydrolysis reaction to form formaldehyde and ammonia in acidic urine. It has been proven to be effective against a wide variety of gram-positive and gram-negative organisms but will not affect the growth of *Candida albicans*. It can be either bacteriostatic or bactericidal depending on the pH of the urine (Huber 1982; Harvey 1985).

Methenamine is quickly absorbed when given orally, but absorption is not complete because some is hydrolyzed in the stomach. It is excreted via the urine, and is associated with a low systemic toxicity. For this drug to be efficacious, the urine must be at an acidic pH in order to liberate free formaldehyde. Methenamine has been administered with a urinary acidifier to lower the urine pH. Acid urine also exerts some independent weak antibacterial activity. Concurrent use of other urinary acidifiers, such as ascorbic acid, arginine HCl, methionine, cranberry juice (hippurate), and ammonium chloride, will enhance the antibacterial action of methenamine. Methenamine is most effective when the urine pH is 6 or below. One of the forms of methenamine used is methenamine hippurate, which is available in human tablet form and is administered to dogs. Sulfonamides should not be administered with methenamine due to the formation of insoluble formaldehyde-sulfonamide precipitates. Since methenamine is largely eliminated via the kidney, its use should be restricted or closely monitored in cases of renal insufficiency (Huber 1982; Harvey 1985). Methenamine is less effective for treating infections caused by urea-splitting organisms which increase the urine pH (e.g., *Proteus mirabilis*).

Methenamine mandelate has been used experimentally in the treatment of burn wounds in rats. Topical doses of 5% and 10% were highly efficacious against experimentally induced burns infected with a virulent strain of *Pseudomonas* spp. (Taylor et al. 1970).

POLYMYXINS. Polymyxins are a group of *N*-monoacetylated decapeptides discovered in 1947 and are produced by *Bacillus polymyxa*. They contain seven amino acids in a cyclic configuration and have a molecular weight of approximately 1000. Several polymyxins have been isolated and have been named A, B, C, D, E, and M. Of these six antibiotics, B and E in their sulfate salt forms are the only ones used clinically. The largest use of polymyxin has been in topical ointment preparations. Polymyxin B sulfate is a mixture of polymyxin B1 ($C_{56}H_{98}N_{16}O_3$) and polymyxin B2 ($C_{55}H_{96}N_{16}O_{13}$); polymyxin E is more commonly known as colistin (Harvey 1985). Polymyxin B1 has a pK_a ranging from 8 to 9.

Polymyxins are basic surface-active cationic detergents that interact with the phospholipid within the cell membrane, penetrate that membrane, and then disrupt its structure. This action subsequently induces permeability changes within the cell that result in cell death, giving polymyxins bactericidal properties.

Polymyxins are not absorbed to any extent from the GI tract when administered orally but are rapidly absorbed when given parenterally, with 70–90% plasma protein binding. Polymyxin B is rapidly distributed to the heart, lungs, liver, kidney, and skeletal muscle, with excretion mainly via the urine (Sande and Mandell 1990a). The pharmacokinetics of some of the polymyxins in calves, ewes, rabbits, and dogs is reviewed in greater detail elsewhere (Ziv and Sulman 1973a; Ziv et al. 1982; Craig and Kunin 1973; al-Khayyat and Aronson 1973a,b). Ziv and Sulman (1973a) reported that an IV administration of 5 mg/kg polymyxin B in ewes resulted in a serum half-life of 2.7–4.3 hours and a Vd of 1.29 l/kg.

Polymyxins have a gram-negative antibacterial spectrum, which includes *Aerobacter, Escherichia, Histophilus, Klebsiella, Pasteurella, Pseudomonas, Salmonella,* and *Shigella. Proteus* spp. and most strains of *Serratia* spp. are not affected by polymyxins, and all gram-positive bacteria are resistant. If bacteria are sensitive to the polymyxins, they rarely acquire resistance. The ability of each antibiotic in this group to kill these bacteria varies (Harvey 1985). The antimicrobial actions of polymyxin B are inhibited by divalent cations, unsaturated fatty acids, debris, purulent exudate, and quaternary ammonium compounds.

Since the polymyxins are not absorbed into the body when given orally, polymyxin B has been used for "bowel sterilization" prior to abdominal surgeries and in irrigation solutions to flush the peritoneal cavities during those procedures. Polymyxins used to be the major drugs for treatment of *Pseudomonas* infections in humans, but since the advent of better penicillins, aminoglycosides, and cephalosporins, their use has declined over time. Nephrotoxicity occurs due to glomerulus and tubular epithelium damage. In addition, respiratory paralysis (usually due to a rapid IV injection, too much peritoneal lavage, or a preexisting renal condition); and CNS dysfunction, including depression, pyrexia, and anorexia, also occurs. Polymyxins are mainly used in topical skin, mucous membrane, eye, and ear preparations. No adverse systemic effects have been reported when they are applied to intact or denuded skin surfaces. Polymyxin antibacterial activity is markedly decreased in the presence of pus, in tissues containing acidic phospholipids, and in the presence of anionic detergents or other chemicals that antagonize cationic detergents (Harvey 1985).

In addition to its narrow-spectrum antimicrobial properties, polymyxin B has demonstrated a protective effect against the adverse effects of endotoxin produced by gram-negative bacteria. This property has been studied more in horses than in other species and has been part of an anti-endotoxin protocol in equine medicine (Morresey and Mackay 2006). Infusions ranging from 1,000 to 10,000 units per kg (a common dose is 6,000 units/kg, equivalent to 1 mg/kg) administered every 8 hours have been shown to be safe and effective for treating endotoxemia in horses. Mechanistically, the cationic portion of polymyxin B binds to the anionic lipid A portion of this endotoxin. This effectively renders the endotoxin inactive, thereby preventing most of the adverse effects that gram-negative endotoxin has on the mammalian body.

SPECTINOMYCIN. Spectinomycin (Spectam) resembles aminoglycosides in some properties. It is highly water soluble and is easily mixed in aqueous solutions. Compared to aminoglycosides, it does not contain amino sugars or glycosidic bonds, but it has an aminocyclitol nucleus like the aminoglycosides. An important difference between spectinomycin and the aminoglycosides is in the adverse effects and spectrum of activity. Spectinomycin lacks the toxic effects of aminoglycoside antibiotics and can be used without the concern about renal injury.

Antimicrobial Activity. Spectinomycin, like aminoglycosides inhibits protein synthesis via a 30S ribosomal target. It is a broad-spectrum drug with activity against gram-positive and some gram-negative bacteria, but little anaerobic activity. It also has good activity against *Mycoplasma*. It is used in cattle because it has activity against *Mannheimia (Pasteurella) haemolytica, Pasteurella multocida,* and *Histophilus somni* (formerly *Haemophilus somnus).*

Pharmacokinetics. Like the aminoglycosides, spectinomycin has a small volume of distribution. It is poorly absorbed after oral administration (10% or less), but some systemic levels are achieved after oral administration in monogastric animals. Most of an oral dose is eliminated in the feces, but after an injection the primary route of elimination is the kidneys. Oral administration has been used for a local effect for treatment of diarrhea.

The half-life of spectinomycin is approximately 2 hours in cattle at a dose of 10 mg/kg IM or IV, and 1.2 hours after a dose of 20 mg/kg IV. After oral dosing in dogs of 100 or 500 mg/kg, the plasma concentrations (peak) were 22 and 80 μg/ml, respectively. The half-life in dogs is 2.72 hours at the 100 mg/kg dose. After IM injection in dogs, the half-life was 1.1 hours. In pigs, the half-life was 1 hour after IM administration.

Clinical Use. Older formulations have been used that contain both lincomycin and spectinomycin (lincospectin). Formulations containing only spectinomycin (Spectam) include spectinomycin oral solution, spectinomycin powder for drinking water, and spectinomycin hydrochloride injection for poultry. Spectinomycin sulfate is used for injection in cattle (Adspec®), which is more highly absorbed than the hydrochloride salt. Spectinomycin tablets for dogs are an old formulation that is not currently used. (The sponsor of Adspec® [Pfizer Animal Health] has announced discontinuation of the manufacture of this drug.)

Clinical use is primarily confined to food animals. There are no small animal formulations currently available. Administration to horses has not been reported. In pigs, spectinomycin has been used orally as spectinomycin hydrochloride oral solution. It has in vitro activity against some gram-negative bacteria and has been used as a feed additive for pigs because of its activity against *Mycoplasma*. It has also been administered orally to pigs for treatment of bacterial enteritis caused by *E. coli* (50–100 mg/animal oral) and as an injection for treatment of respiratory infections. In poultry, spectinomycin has been used as injection and added to drinking water for prevention and treatment of respiratory disease and other infections.

In cattle, spectinomycin has been used as an IM injection for treatment of respiratory infections (10–15 mg/kg SC in the neck, q24 h × 3–5 days). Poultry formulations were used in cattle off-label prior to approval of Adspec®, when it was a past practice to mix the water soluble powder intended for drinking water as an IV solution for administration to cattle. Studies have shown that this practice may result in severe pulmonary edema and death.

New Developments	1004

The use of the fluoroquinolone antibacterial agents in veterinary medicine has increased tremendously in the last 15 years. The fluoroquinolones are synthetic antibacterial agents introduced in veterinary medicine first as enrofloxacin. Since then, there has been a great deal of research on this class of drugs to better understand their mechanism of action, antimicrobial spectrum, pharmacokinetics in a wide variety of animal species, and clinical use. In addition, pharmaceutical companies have developed new compounds to increase the number of these drugs available to veterinarians. The advantages of the fluoroquinolones are that they are rapidly bactericidal against a wide variety of clinically important bacterial organisms, are potent, are well tolerated by animals, and have been administered via a variety of routes (orally via tablets and drinking water, subcutaneously, intravenously, intramuscularly and topically).

Fluoroquinolones approved for use in veterinary medicine for small animals include enrofloxacin, difloxacin, orbifloxacin, and marbofloxacin. Danofloxacin and enrofloxacin were approved for cattle, and enrofloxacin for pigs. Enrofloxacin and sarafloxacin were once approved for poultry but have been withdrawn because of *Campylobacter* resistance concerns. Fluoroquinolones that are labeled for humans and are of potential interest for veterinary medicine include ciprofloxacin. The newest

generation of fluoroquinolones with increased activity against gram-positive cocci and anaerobic bacteria includes grepafloxacin, trovafloxacin, levofloxacin, moxifloxacin, gatifloxacin, and pradofloxacin. Grepafloxacin and trovafloxacin already have been discontinued because of adverse effects in people.

CHEMICAL FEATURES

The currently available fluoroquinolones have the same quinolone structure (Fig. 38.1); various chemical substitutions and side groups account for the different physical characteristics of each drug. These differences may account for variations in lipophilicity, volume of distribution (Vd), oral absorption, and elimination rate, but they do not change the antibacterial spectrum appreciably. For example, enrofloxacin has one fluorine substitution, difloxacin has two fluorine substitutions, and orbifloxacin has a three-fluorine substitution, but the presence of more than one fluorine does not increase antibacterial effects (Asuquo and Piddock 1993). When lipid solubility is expressed as the octanyl:water partition coefficient, enrofloxacin and difloxacin have high lipophilicity. Ciprofloxacin has a partition coefficient that is approximately 100-fold less than partition coefficients were determined in the laboratory of one of the authors and are unpublished.)

No studies are available to show that these chemical differences among the drugs can account for differences in clinical response. However, the differences may account for some variation in absorption and distribution. For example, ciprofloxacin oral absorption is approximately one-half that of enrofloxacin in dogs; ciprofloxacin absorption in horses is less than 10%, compared to 60% for enrofloxacin. The less lipid-soluble fluoroquinolones (marbofloxacin, orbifloxacin) have a lower Vd than the ones with higher lipid solubility (enrofloxacin, difloxacin) (Table 38.1). One explanation for this observation is that the more lipid-soluble drugs have higher intracellular concentrations, but higher tissue binding also could explain the differences in Vd.

Quinolones are amphoteric molecules that can be protonated at the carboxyl and the tertiary amine portion of the molecule. The pK_a varies among the drugs slightly, but generally the pK_a for the carboxyl group is 6.0–6.5 (5.5–6.3 in some references) and the pK_a for the nitrogen of the piperazine group is 7.5–8 (Nikaido and Thanassi 1993) (as high as 7.6–9.3 in some references). For two common drugs, enrofloxacin and ciprofloxacin, the pK_a for the car-

Na = Data not available or not applicable.

Nd = Not determined, NR = not recommended.

$t_{1/2}$ = Half-life of the terminal portion of the plasma concentration vs. time curve.

Vd = Apparent volume of distribution (area method).

AUC = Area under the curve of the plasma concentration vs. time curve.

C_{max} = Maximum plasma concentration after administration of oral or IM dose.

%F = Percentage of oral or IM administered dose absorbed (determined from comparison of IV dose).

[a]Half-life, Vd, and AUC are from an IV dose unless otherwise noted.

[b]Assay type = Assay using HPLC is able to distinguish between enrofloxacin and ciprofloxacin, and values shown in table represent enrofloxacin. Assays performed by bioassay represent the parent drug and active metabolites. Bioassay may include concentrations of ciprofloxacin.

[c]Registered dose with the FDA in the United States. In some European countries doses may vary or may not include the flexible range. In most cases, when treating non-*Pseudomonas* infections, the lowest dose in the range listed is used.

[d]After multiple dosing with ciprofloxacin, the C_{max} was 1.18 mg/mL and the 12 hr AUC was 9.58 mg/hr/mL.

[e]Oral absorption of ciprofloxacin estimated from a comparison of independent oral and IV studies.

[f]These parameters determined after administration of 5.8 mg/kg of enrofloxacin.

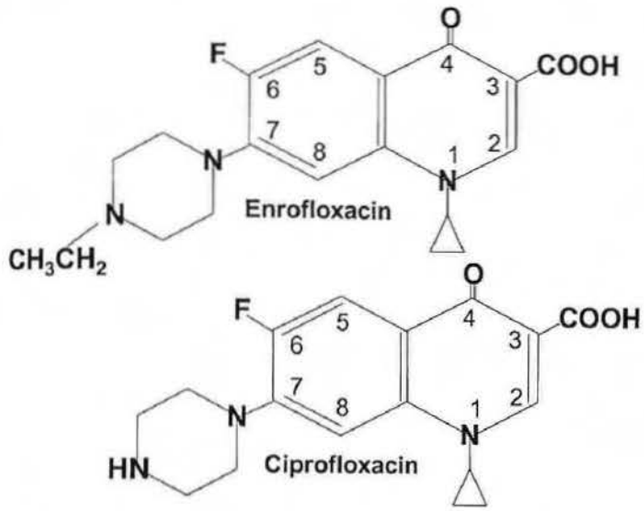

FIG. 38.2 Structure of enrofloxacin and ciprofloxacin.

pseudomonads, among other gram-negative bacteria. The change to a carbon from a nitrogen at position 8 decreased some of the adverse central nervous system effects and increased activity against staphylococci.

The newer generation of quinolones have a bicyclic substitution at position 7, instead of a piperazine. This increased the activity to include a wider range of bacteria. In addition, a substitution at the 8 position on the ring enhances the bactericidal effects and improves the spectrum of activity to include more gram-positive and anaerobic bacteria. For example, the 8-methoxy substitution produces the drug moxifloxacin, a human quinolone with improved activity against gram-positive bacteria (Behra-Miellet et al. 2002; Aktaç et al. 2002; Pestova et al. 2000). Pradofloxacin, a new veterinary quinolone with similar activity has a cyano substitution at position 8, and this drug has improved gram-positive and anaerobic activity compared to enrofloxacin and ciprofloxacin (Silley et al. 2007). This drug is discussed in more detail at the end of this chapter in the section "New Developments."

MECHANISM OF ACTION

Quinolones are bactericidal by inhibiting bacterial DNA replication and transcription. Two-stranded DNA is tightly coiled in the cell and must be separated for transcription and translation. To facilitate coiling, winding, and unwinding, the enzyme DNA gyrase allows the strands to be cut and reconnected. This allows coiling because negative supercoils can be introduced. DNA gyrase, a topoisomerase, consists of A and B subunits. The most common target site for quinolones is the A subunit of DNA gyrase coded by the gene *gyrA*. Mammals are resistant to the killing effects of quinolone antimicrobials because Topoisomerase II in mammalian cells is not inhibited until the drug concentration reaches 100–1000 μg/ml. Bacteria are inhibited by concentrations of 0.1–10 μg/ml or less. The Clinical Laboratory Standards Institute (CLSI, formerly called *NCCLS*) break point for ciprofloxacin, the prototypical fluoroquinolone, for susceptible bacteria is 1.0 μg/ml (CLSI 2007). Another target is the Topoisomerase IV enzyme composed of subunits *parC* and *parE*. This site of action is less important for gram-negative bacteria but is a target of fluoroquinolones in some gram-positive bacteria such as streptococci and staphylococci (Ferrero et al. 1995). Among the newer fluoroquinolones (e.g., moxifloxacin, gatifloxacin) the primary target for gram-positive bacteria may be the DNA-gyrase rather than Topoisomerase IV, or these drugs also may be dual inhibitors against both targets (Intorre et al. 2007). The action of quinolones on DNA gyrase and Topoisomerase IV has been reviewed in more detail in other papers (Drlica and Zhao1997; Blondeau et al. 2004).

ANTIBACTERIAL SPECTRUM

Fluoroquinolones in general exhibit good activity against most gram-negative bacteria, especially those of the Enterobacteriaceae. Representative minimum inhibitory concentration (MIC) values are shown in Table 38.2. *Escherichia coli, Klebsiella* spp., *Proteus* spp., *Salmonella* spp., and *Enterobacter* spp. are usually susceptible. *Pseudomonas aeruginosa* is variably susceptible and, when it is susceptible, usually has a higher MIC than other susceptible organisms. Against *P. aeruginosa,* ciprofloxacin is the most active (Rubin et al. 2008).

Gram-positive bacteria are variably susceptible. *Staphylococcus aureus, Staphylococcus pseudintermedius* and other *Staphylococcus* species usually are susceptible. However, the MIC values for staphylococci typically are higher than for gram-negative bacteria, and staphylococcal resistance to fluoroquinolones has been a problem in human patients. Methicillin-resistant strains of staphylococci (MRSA) are often resistant to fluoroquinolones.

The use of the newest generation of fluoroquinolones has not yet been reported in veterinary medicine, except in experimental studies. These drugs, such as moxifloxa-

TABLE 38.2 Comparative microbiological data for common pathogens

Marbofloxacin (dogs and cats)	≤1	2	≥4
Orbifloxacin (dogs and cats)	≤1	2–4	≥8
Ciprofloxacin (human)*	≤1	2	≥4

*The break point listed for ciprofloxacin is based on human use, not veterinary use.

cin, gatifloxacin, and the veterinary drug pradofloxacin have increased activity against gram-positive cocci and anaerobic bacteria and may have advantages for certain infections (Behra-Miellet et al. 2002; Aktaç et al. 2002; Pestova et al. 2000; Silley 2007). Against gram-negative bacteria, such as the Enterobacteriaceae, they have equal or similar activity. Against *Pseudomonas aeruginosa,* these drugs are not as active as ciprofloxacin. Whether these newer fluoroquinolones will replace standard treatment with β-lactam antibiotics for treatment of streptococci remains a question (Legg and Bint 1999).

Factors that may affect activity are cations at the site of infection and low pH. Cations such as Al^{+3}, Mg^{+3}, Fe^{+2}, and Ca^{+2} can bind a carboxyl group on the drug and significantly decrease activity. Low pH at the site of action also can affect the MIC (Ross and Riley 1994), especially for drugs that have a piperazine at position 7 (Fig. 38.1). For example, in urine, the MIC for fluoroquinolones may increase due to the presence of cations in the urine and low pH (Fernandes 1988). This activity in urine may increase the MIC from 4- to 64-fold. Fluoroquinolone activity in an abscess is not diminished despite the observation that in pus there is cellular material that can bind drugs, a low pH, and slow-growing bacteria (Bryant and Mazza 1989). The activity of fluoroquinolones in this milieu may explain its efficacy for treating infections associated with abscessation.

SUSCEPTIBILITY TESTING. Susceptibility testing is performed either by the agar-disk-diffusion (ADD) method or broth dilutions (MIC test). The CLSI (formerly NCCLS) (CLSI 2007) has published interpretive criteria to set break points for most fluoroquinolones (Table 38.3). For isolates in the "Intermediate" range , the organism "could be considered as susceptible if appropriate dosing modifications, explained in the package insert, are applied. The MIC quality-control ranges for wild-type organisms are also available from CLSI.

RESISTANCE

Resistance most frequently develops via the *gyrA* mutation that codes for the A subunit of the DNA gyrase enzyme. A mutation at the serine-83 residue has been one of the most common, but at least 10 additional mutations at the

gyrA gene have been identified to confer resistance (Ferrero et al. 1995). Mutations in the *parC* gene that codes for Topoisomerase IV enzyme also are important (e.g., GrlA mutation). A mutation in *parC* coding for resistant Topoisomerase IV may be more important in gram-positive bacteria than in gram-negative isolates, but may also produce high-level resistance. The *parC* mutation causes a high-level resistance when detected with mutations of *GyrA*. The multidrug resistance membrane efflux mechanisms reduce the accumulation of antibiotics in the bacteria. These efflux mechanisms are known to produce a high-level resistance to fluoroquinolones when they are present with other target site mutations (Zhanel et al. 2004). Efflux mechanisms may play an important role in *Pseudomonas aeruginosa* fluoroquinolone resistance and could explain why resistance is high among these bacteria (Zhanel et al. 2004). Because the efflux membrane pumps may affect other drugs, this may produce cross-resistance to other antimicrobials.

Resistance can occur through a multistep process (Everett et al. 1996). A single mutation can increase the MIC slightly (perhaps one dilution), and each subsequent mutation produces a progressively higher level resistance in a stepwise fashion. For example, resistant strains of *E. coli* with MIC >8 μg/ml may possess multiple mutations for the target genes and may also show enhanced drug efflux. Unlike plasmid-mediated bacterial resistance, in which resistance may disappear after selective antibiotic pressure is removed, chromosomal (mutational) resistance exhibited by fluoroquinolone-resistant bacteria can be maintained in bacteria after drug administration is discontinued. Plasmid-mediated resistance has been found in *E. coli* and *Klebsiella* organisms, but the clinical significance of plasmid-mediated resistance has not been identified (Martinez-Martinez et al. 1998). Chromosomal mutations, rather than plasmid-mediated resistance, is overwhelmingly the most important source of clinical resistance.

CLINICAL RESISTANCE PROBLEMS. Resistance to fluoroquinolones has become a problem in human medicine that some investigators have attributed to increased prescribing of these drugs. Resistance to fluoroquinolones by *E. coli, Staphylococcus aureus,* and *Streptococcus pneumoniae* has been documented (Chen et al. 1999; Murphy et al. 1997; Sanders et al. 1995; Neu 1992; Peña et al. 1995; Perea et al. 1999; Everett et al. 1996). Clinical resistance in human hospitals among staphylococci appeared relatively quickly after introduction of ciprofloxacin (Neu 1992; Sanders et al. 1995; Hedin and Hambreus 1991). Resistant bacteria also have been identified in companion animals. Resistance in small animals has been documented for *E. coli, P. aeruginosa, Enterobacter, Proteus,* and other gram-negative bacteria. Resistance among staphylococci isolated from small animals has also been documented (Lloyd et al. 1999), but the prevalence remains low (Pinchbeck et al. 2007; Petersen et al. 2002; Ganière et al. 2001; Intorre et al. 2007). Frequent use may increase this prevalence. In a study of bacteria causing chronic otitis in dogs, 14% of *Staphylococcus intermedius* from the middle ear were resistant to enrofloxacin (Cole et al. 1998). If methicillin-resistant strains of *Staphylococcus* are identified, many are multidrug resistant and often exhibit fluoroquinolone resistance in addition to resistance to other drugs (Jones et al. 2007). The newer generation of fluoroquinolones, discussed previously, such as moxifloxacin and gatifloxacin may have better activity against these resistant strains (Intorre et al. 2007).

Pseudomonas organisms have been particularly troublesome because single-step mutations are common for this bacteria, which can easily lead to high-level resistance after exposure. This is an important problem in companion animal medicine because; except for the fluoroquinolones, there are no other oral drugs with which to treat infections caused by *Pseudomonas aeruginosa.* Resistance is primarily caused by a *GyrA* mutation, but an additional mutation in *parC* could cause a high-level resistance (Jalal and Wretlind 1998). Strains with both mutations were significantly more resistant than strains with one mutation. As discussed earlier, efflux mechanisms may also contribute to resistance among *Pseudomonas* (Zhanel et al. 2004). Factors leading to resistant *P. aeruginosa* are an inadequate dosage and extended treatment at low doses. From the horizontal and middle ear of dogs with chronic otitis, 87 and 65%, respectively, of the pseudomonads cultured were resistant to enrofloxacin (Cole et al. 1998). Other studies have confirmed increased frequency of resistance among *Pseudomonas aeruginosa* isolated from chronic infections in dogs (Petersen et al. 2002; Martin Barrasa et al. 2000).

HUMAN HEALTH RISKS. Infectious disease experts have warned that frequent usage of fluoroquinolones may

lead to increased resistance in animals (WHO 1997). Transfer of fluoroquinolone resistance from animals to people has been suggested to occur for *Campylobacter* species (Endtz et al. 1991) and *Salmonella typhimurium* type DT-104 (Threlfall et al. 1995; Threlfall et al. 1997; Griggs et al. 1994). An increase in the incidence of resistant *Campylobacter jejuni* infecting people was linked to consumption of *Campylobacter*-contaminated chicken. The increased resistance occurred primarily after 1995, which coincides with the time that fluoroquinolones were approved for use in poultry as an additive to drinking water (Smith et al. 1999). Investigators have also associated resistance in salmonellae with veterinary use of fluoroquinolones in livestock (Piddock et al. 1998). However, resistant strains of *Salmonella typhimurium* may have occurred spontaneously because some of the resistant salmonellae have come from farms in which fluoroquinolones were not administered to animals (Griggs et al. 1994). Nevertheless, some scientists have warned that continued use of fluoroquinolones in livestock is a public health risk because it can potentially lead to resistant mutants of salmonellae being passed on to humans through the food chain. Because of these concerns, there have been limited approvals of fluoroquinolones for food-producing animals, and the extralabel use of fluoroquinolones is prohibited in food-producing animals in the United States. Because of the risk of *Campylobacter* resistance, all fluoroquinolone formulations for poultry have been removed from the market.

PHARMACOKINETICS

Mammals are relatively consistent in elimination half-life and Vd. Reptiles with lower renal clearance generally demonstrate longer half-lives—as long as 55 and 36 hours for enrofloxacin in alligators and Monitor lizards, respectively (Papich 1999). There may be an allometric relationship in pharmacokinetic parameters among mammals ranging in size from mice to cattle (Bregante et al. 1999; Cox et al. 2004). The allometric relationship was improved considerably when the pharmacokinetic parameters were corrected for the percentage of protein-unbound enrofloxacin in the plasma. In particular, for enrofloxacin the Vd was the most directly proportional to animal body weight, with the animals with largest body weight having the largest Vd.

Among the drugs, there are differences in the pharmacokinetic parameters, which in animals are listed in Table 38.1. Whether these differences translate to clinical differences, however, has not been shown, because there are no comparative studies. For example, it does not appear that differences in half-life can account for different clinical results for skin infection treatment in dogs because enrofloxacin, which has the shortest half-life (Table 38.1), and marbofloxacin, which has the longest half-life, have both been reported to be effective when administered once daily (Paradis et al. 1990; Carlotti et al. 1995; Carlotti 1996; Gruet et al. 1997; Koch and Peters 1996; Lloyd 1992; Kwochka 1993; Ihrke 1996, 1998; Cester et al. 1996). Likewise, even though there is a range of values for Vd among the drugs, this has not translated into a superior clinical efficacy. Marbofloxacin and orbifloxacin, which have a Vd in the range of 1–2 l/kg, achieve effective skin concentrations and appear as clinically effective as drugs such as enrofloxacin with a Vd of 2.5–5 l/kg. The data published (Walker et al. 1990, 1992) or available from manufacturer technical information show that all the fluoroquinolones, regardless of their Vd and lipophilicity, achieve concentrations in tissues, except for the central nervous system and eye, that are at least as high as plasma. Differences in Vd, however, account for a range of maximum plasma concentrations (Cmax) among the drugs (Table 38.1). Drugs with the lowest Vd are diluted less in body fluid and produce higher plasma concentrations than drugs with a higher Vd. The consequence of this difference is reflected in the dose administered (dose = Vd × Cmax).

ORAL ABSORPTION. Oral absorption of fluoroquinolones is high for most animals studied (Table 38.1). Whether fluoroquinolones are administered with or without food has little effect on oral absorption. Fluoroquinolones administered with food may exhibit a slow or a prolonged absorption, but the extent of absorption, determined by the total AUC (area under the curve of the plasma concentration versus time curve) is not affected significantly. Administration with food has prolonged the terminal half-life when enrofloxacin was administered orally to reptiles (Papich 1999), sheep, pigs (Gyrd-Hansen and Nielsen 1994), and chickens (Anadón et al. 1995).

In clinical situations involving animals difficult to dose, fluoroquinolones may be added to a patient's food in order to provide a more convenient dosing form. For example, enrofloxacin tablets were placed in whole fish, which were fed to dolphins to produce good absorption (Linnehan et al. 1999), and enrofloxacin was injected into mice and

fed to Monitor lizards also producing good absorption (Hungerford et al. 1997). Chewable tablets of enrofloxacin (Taste-Tabs) do not affect oral absorption (manufacturer's data).

In dogs, cats, and pigs, oral absorption of fluoroquinolones approaches 100% (Table 38.1), but in large animals, extent of absorption has been less. Oral absorption of fluoroquinolones is variable in horses. Ciprofloxacin showed an oral absorption of only 6.8% in ponies (Dowling et al. 1995) and only 10% (mean) in adults (Torill et al. 2009). But enrofloxacin absorption is 63% (Giguère et al. 1996) in adult horses and 42% in foals (Bermingham et al. 2000). The value reported for adult horses is probably artificially high because the study used a bioassay that overestimates the concentration of enrofloxacin in plasma. With the exception of ciprofloxacin, other studies listed in Table 38.1 indicate relatively good oral absorption of these drugs in horses. Studies in ruminants produce conflicting results on oral absorption. In sheep, oral absorption was reported to be 61% (Pozzin et al. 1997), but absorption in ruminant calves was listed as less than 10% (Vancutsem et al. 1990). In sheep, absorption from oral administration was high (Bermingham et al. 2002). In addition, this study showed that when enrofloxacin was mixed with food and administered orally to sheep, absorption was high and half-life longer than after the IV dose. The long oral half-life was the result of slow release from the feed (possible adsorption) or slow emptying from the rumen ("flip-flop" effect). Absorption is also good in nondomestic ruminants such as the hoofstock kept in zoological parks (Gandolf et al. 2003, 2006). In camels (although not a true ruminant), oral absorption was reported to be negligible (Gavrielli et al. 1995), but our laboratory found that absorption was 29% (mean) in alpacas and was capable of producing high enough concentrations to treat susceptible gram-negative pathogens at 10 mg/kg (Gandolf et al. 2005).

In birds, oral absorption of enrofloxacin has been reported to be good, with effective levels being achieved by adding the drug to the bird's drinking water. This method of administration has been employed to treat sick pet birds (Flammer 1998) and chickens (Knoll et al. 1999). However, as mentioned previously, administration to food-producing poultry is prohibited in the United States. After continuous medication in the drinking water, steady-state plasma concentrations of enrofloxacin are 0.53 μg/ml (Knoll et al. 1999). In fish enrofloxacin absorption has been estimated to be 40–50% (Lewbart 1998).

INTRAMUSCULAR AND SUBCUTANEOUS INJECTION. Absorption is virtually complete from intramuscular (IM) injection. There have not been many studies that examined subcutaneous (SC) injection, but in the studies that are available, absorption was nearly complete. Delayed absorption from injection is possibly due to a slow release from the injection site caused by tissue binding or tissue injury that disrupts blood flow.

In cattle, e.g. (Kaartinen et al. 1995), half-life was 1.68 hours from IV injection of enrofloxacin (5 mg/kg), but 5.9 and 5.55 hours from IM and SC injection, respectively, even though the extent of absorption was high. In the study by Davis et al., (2007) the half-life of enrofloxacin after a SC injection to calves at 12.5 mg/kg was 6.79 hr (mean), and 7.25 hr for the metabolite ciprofloxacin. For danofloxacin, the IV half-life in cattle was 0.9 hours and the IM half-life was 2.26 hours. In some animals there was delayed absorption from IM or SC injections, which produced longer half-lives from these routes compared to IV administration (this is known as "flip-flop" absorption kinetics).

METABOLISM. Metabolism of enrofloxacin to ciprofloxacin occurs via deethylation of the ethyl group on the piperazine ring. Other metabolites are produced from further metabolism of ciprofloxacin, but these are minor and do not contribute to the antibacterial effects. There are also minor insignificant metabolites of some of the other drugs. Examination of the extent of metabolism of enrofloxacin to ciprofloxacin in dogs and cats was reported in several studies (Küng et al. 1993a; Monlouis et al. 1997; Cester et al. 1996; Richez et al. 1997b; Kordick et al. 1997; Heinen 1999; Seguin et al. 2004) in which high-pressure liquid chromatography (HPLC) was used to determine the specific concentrations of enrofloxacin and ciprofloxacin after enrofloxacin administration. An analysis of the data shows that at Cmax 20% and 10% in dogs and cats, respectively, of the total fluoroquinolone concentration is contributed by ciprofloxacin. (That is, ciprofloxacin accounts for 20 and 10% of enrofloxacin plus ciprofloxacin concentrations.) In cats, the proportion of ciprofloxacin to total quinolone concentration was 17% and was not affected by age (Seguin et al. 2004). In cattle, the proportion of ciprofloxacin in plasma has been measured as 25% (Richez et al. 1994) and as high as 41% (Davis et al. 2007). Also, in the latter study, the proportion of ciprofloxacin in tissues of calves was higher than that of

enrofloxacin. But in pigs, foals, and some reptiles there were only small traces of ciprofloxacin metabolized from enrofloxacin (Zeng and Fung 1997; Bermingham et al. 2000; Richez et al. 1997a). Studies in fish show that after administration of enrofloxacin, about 2% of the maximal concentration is made up of ciprofloxacin (Lewbart et al. 1997). Difloxacin is metabolized to the active metabolite sarafloxacin by demethylation, but the amount of sarafloxacin from difloxacin in dogs has been small (Heinen 1999).

In chickens, the concentrations of ciprofloxacin in plasma and tissues after administration of enrofloxacin are minimal (Knoll et al. 1999; Anadón et al. 1995). However, similar to studies in cattle (Davis et al. 2007), one of these studies reported that the ratio of ciprofloxacin:enrofloxacin tissue concentrations was greater than 1.0 after administration of enrofloxacin despite the low plasma concentrations of ciprofloxacin (Anadón et al. 1995). The ciprofloxacin concentration residues were still present in tissues of chickens 12 days after dosing.

If there are active metabolites produced, such as ciprofloxacin from enrofloxacin, this can cause errors in the interpretation of drug assays when a bioassay (microbiological assay) is used because a bioassay does not distinguish parent drug from active metabolite. Pharmacokinetic studies performed using bioassay techniques and compared with HPLC methods have demonstrated that bioassay can overestimate the combined enrofloxacin and ciprofloxacin concentrations in animals by as much as 70% for the AUC and 29% for the Cmax (Cester et al. 1996). This finding agrees with another study in dogs: a microbiological assay overestimated the total enrofloxacin + ciprofloxacin AUC determined by HPLC by as much as 30–70% (Küng et al. 1993b).

EXCRETION. The fluoroquinolones are primarily excreted via the kidneys by glomerular filtration and tubular excretion (Bregante et al. 1999). The role of tubular excretion has been demonstrated by showing that probenecid can decrease the clearance for some fluoroquinolones. For most of the drugs a major portion of the parent drug or metabolites can be recovered in the urine, with a smaller amount recovered in the feces. An exception is difloxacin, for which 80% of a dose was recovered in the feces and renal clearance accounted for less than 5% of the total systemic clearance.

PROTEIN BINDING. No studies have shown that fluoroquinolones are so highly protein bound that this limits distribution to tissues or causes a protein-binding interaction if displaced by another drug. Table 38.4 shows some of the protein-binding data generated. In most instances protein binding is low, but for animals for which multiple studies are available, as shown in Table 38.4, there is a lack of consistency among studies, which is probably related to differences in technique used to measure protein binding.

TISSUE DISTRIBUTION. Distribution to most tissues is listed for each drug in the manufacturer's package insert or Freedom of Information (FOI) summary. Specific

TABLE 38.4 Plasma/serum protein binding of fluoroquinolones in animals (% bound)

Animal	Enrofloxacin	Ciprofloxacin	Marbofloxacin	Orbifloxacin
Camel	17–24			
Cattle	56, 36–45, 60, 46	31, 70, 19		
Sheep	69			
Horse	22	37		21 (at 1 μg/mL)
Pig	27	23.6, 35		
Dog	15–25, 27, 35, 72	44, 18.5	9.1, 22	13.24 (at 1 μg/mL)
Rabbit	53, 50, 35, 6.0	33, 28		
Chicken	21	30		
Mouse	42			
Rat	50

Note: When two or more values are listed, they represent results from independent studies.

studies for enrofloxacin have been conducted to show that it distributes to bone (Duval and Budsberg 1995), prostate (Dorfman et al. 1995), and skin (DeManuelle et al. 1998). In tissues in which high intracellular distribution does not occur, total tissue concentrations will generally be in equilibrium with drug concentrations in the extracellular fluid (Nix et al. 1991). For example, concentrations of enrofloxacin in canine cortical bone were approximately 30% of the corresponding plasma concentration (determined by bioassay), which approximates the concentration in the extracellular fluid space (Duval and Budsberg 1995).

Definitive studies that examined fluoroquinolone concentrations in tissue extracellular fluids (the site of action for these antibiotics) showed that the protein binding (discussed above) does not appreciably affect distribution to tissues. The protein unbound fraction in plasma (active drug) can be used to predict free drug concentrations of fluoroquinolone in tissue fluids (Bidgood and Papich 2005; Davis et al. 2007). In tissues in which the fluoroquinolones accumulate intracellularly, high tissue concentrations are reported because measurement of tissue concentrations is typically performed by homogenizing the tissue, which disrupts cells and releases intracellular concentrations. Tissue concentrations measured in this manner represent both intracellular and extracellular concentrations and can overestimate active drug concentrations. Some tissues, such as liver and kidney, may have fluoroquinolone concentrations several-fold higher than corresponding plasma concentrations.

Fluoroquinolones attain particularly high intracellular concentrations in macrophages and neutrophils: intracellular concentrations of 4–10 times plasma concentrations can be expected (Pascual et al. 1990; Tulkens 1990; Garaffo et al. 1991; Easmon and Crane 1985). In canine alveolar macrophages, the accumulation of enrofloxacin was 10 times the plasma concentration (Hawkins et al. 1998). The intracellular concentrations occur because fluoroquinolones are sufficiently lipid soluble to cross the cell membrane, or there may be active mechanisms to transport these drugs into cells. Fluoroquinolones also have a slower efflux from these cells. In humans, ciprofloxacin has an intracellular half-life of 6.7 hours in neutrophils versus 3.7 hours in serum (Easmon et al. 1986).

The high intracellular distribution in leukocytes may account for higher drug concentrations of fluoroquinolones in infected tissue compared to healthy tissue. Leukocytes, attracted via chemotaxis, may transport active drug to the site of infection. Dogs with superficial and deep pyoderma had significantly higher enrofloxacin concentrations in affected skin compared to healthy skin from control dogs (DeManuelle et al. 1998). Skin from dogs with deep pyoderma had higher enrofloxacin concentrations than skin from dogs with superficial pyoderma and there was significant correlation between dermal inflammation (dermal inflammatory cell count) and drug concentration.

Concentrations in urine may be several times higher than plasma concentrations. Concentrations of enrofloxacin, marbofloxacin, and orbifloxacin in urine of dogs are listed by the manufacturer to be 43, 40, and 84.5 μg/ml, respectively. One exception to the high urine excretion is difloxacin, of which, according to the manufacturer, less than 5% of the dose is cleared in the urine. Fluoroquinolones are among the few drugs that adequately penetrate the prostate gland in sufficient concentrations to treat infection. Enrofloxacin concentration (determined by bioassay) in the prostatic fluid and prostate tissue exceeded serum concentration at all times after administration (Dorfman et al. 1995). There were no differences in tissue concentrations when infected prostate was compared to healthy tissue. Concentrations of other fluoroquinolones in prostate tissue have been reported by the manufacturers to be 3.36, 5.6, and 1.35 μg/gram for difloxacin, marbofloxacin, and orbifloxacin, respectively.

PHARMACODYNAMICS (PK-PD)

MIC values for bacteria are listed in Table 38.2. Even though there are differences in potency among the currently available fluoroquinolones, a pattern is apparent: *Pasteurella,* such as the strains found in skin wounds, are the most susceptible; the gram-negative enteric bacilli (e.g., *E. coli* and *Klebsiella*) also have low MIC values. The gram-positive cocci such as the common skin pathogen *Staphylococcus pseudintermedius* have MIC values at a somewhat higher range, and *P. aeruginosa,* if sensitive at all, has MIC values that are among the highest for susceptible bacteria. Although not listed in Table 38.2, streptococci, enterococci, and anaerobic bacteria typically have MIC values high enough that they are usually in the resistant category.

Fluoroquinolones are bactericidal and that they act in a concentration-dependent manner rather than a time-dependent manner. The exposure to the bacteria has been measured by using the maximum peak concentration

(Cmax) in relation to the bacteria MIC and expressed as the Cmax:MIC ratio. A Cmax:MIC ratio that is at least 8–10 times (i.e., a peak concentration that is 8–10 times the MIC) is desirable. In the last 5–8 years, the favored parameter for predicting efficacy has been the area under the curve (AUC) for a 24-hour dose interval in relation to the MIC, expressed as the AUC_{24}:MIC ratio. An AUC:MIC ratio of 125–250 has been associated with the optimum antibacterial effect (Lode et al. 1998; Hyatt et al. 1995; Dudley 1991; Nicolau et al. 1995; Wright et al. (2000).

These targeted Cmax:MIC and AUC:MIC ratios were based on in vitro or in vivo studies performed with immunosuppressed laboratory animals or on clinical studies involving people with serious illness (Forrest et al. 1993; Blaser et al. 1987; Sullivan et al. 1993). A study in neutropenic mice showed that the optimum therapeutic effect was attained when the Cmax:MIC ratio was greater than 10, but at lower drug doses when the Cmax:MIC ratio was less than 10, the AUC:MIC was better linked to outcome (Drusano et al. 1993). A Cmax:MIC ratio of at least 8–10 has been associated with less resistance (Blaser et al. 1987). When lower ratios were achieved, the mutant strains that occur spontaneously were not suppressed, and resistance was allowed to emerge because these mutant strains have MIC values that are at least 4–8 times that of the parent (wild-type) strain (Drusano et al. 1993).

As reviewed by Wright et al. (2000), there is evidence that for some clinical situations, AUC:MIC ratios as low as 30–55 are necessary for a clinical cure, since the study in which 125 was cited involved critically ill human patients. AUC:MIC ratios for clinical success may be lower for gram-positive bacteria than for gram-negative bacteria. This was also shown in the paper by Ambrose and Grasela (2000), in which they presented data and reviewed the relevant publications. Because some of the studies above that cited ratios for target attainment used laboratory animals (usually immunosuppressed) or people with severe illness, the ratios needed for a cure may have been higher than needed in many veterinary patients. For example, if one compares the AUC in Table 38.1 to representative MIC values from Table 38.2, an AUC:MIC ratio of 50–60 in some patients appears adequate (Cester et al. 1996). In one model of skin infection in dogs caused by *Staphylococcus intermedius* (MIC 0.5 μg/ml), infections were prevented with Cmax:MIC ratios of only 3–5.5 μg/ml of marbofloxacin (Gruet et al. 1997). Perhaps a more competent immune system or less serious infection accounts for this discrepancy between laboratory studies and clinical observations in veterinary medicine. Other veterinary studies also reveal that the ratios necessary for clinical results may not be as high as reported from studies in laboratory rodents or people (Lees and Aliabadi 2002).

DOSE GUIDELINES

Doses listed in Tables 38.1 and 38.5 cover a wide MIC range among susceptible bacteria, from as low as 0.03 μg/ml, to as high as 1.0 μg/ml. The upper end of the dose is limited by safety (such as gastrointestinal effects); the lower dose is determined by efficacy. There is no advantage to frequent dosing (multiple times/day) as long

TABLE 38.5 Dose recommendations for enrofloxacin in exotic animals

Animal	Dose	Route	Interval	Reference
Alligator	5 mg/kg	IV, oral	Every 96 hr	Helmick et al. 1997
Savanna monitor	5 mg/kg (10 mg/kg for *Pseudomonas* spp.)	IM, oral	Every 96 hr	Hungerford et al. 1997
Burmese python	5 mg/kg (higher doses for *Pseudomonas* spp.)	IM	Every 48 hr	Young et al. 1997
Indian star tortoise	5 mg/kg	IM	Every 24 hr	Raphael et al. 1994
Red-eared slider	5 mg/kg	oral, IM	Every 72 hr (oral), every 48 hr (IM)	James et al. forthcoming
Gopher tortoise	5 mg/kg	IM	Every 24–48 hr	Prezant et al. 1994
Bottlenose dolphin	5 mg/kg	oral	Every 24 hr	Linnehan et al. 1999
Parrot and cockatoo	7.5–15 mg/kg	oral	Every 12 hr	Flammer 1998
Fish (ornamental)	5 mg/kg	IM, oral, or IP	Every 48 hr	Lewbart 1998

Note: These recommendations are based on an analysis of pharmacokinetic data and limited clinical experience. There have been no well-controlled efficacy studies or safety studies in these animals.

as a sufficiently high Cmax:MIC or the same AUC:MIC is achieved; therefore, the doses discussed for mammals and listed in Table 38.1 are intended for once-daily administration.

A range of doses allows relatively low doses of fluoroquinolones to be administered to treat the most susceptible organisms. That is, for susceptible *E. coli* or *Pasteurella* organisms, the lowest approved dose can be administered. To achieve the necessary concentration for some *Staphylococcus* or gram-positive bacteria that have higher MIC values, a higher dose may be needed, e.g., a dose in the middle of the dose range in Table 38.1. When the MIC values are high for organisms such as *P. aeruginosa,* the highest safe dose should be considered (Walker et al. 1992; Meinen et al. 1995).

CLINICAL USE

DOGS AND CATS. The administration of fluoroquinolones to dogs and cats constitutes one of the largest applications of these drugs for veterinary medicine. They have been used extensively during the past 20 years for infections of the skin, soft tissue, oral cavity, urinary tract, prostate, external and middle ear, wounds, respiratory tract, and bone (Paradis et al. 1990; Ihrke and DeManuelle 1999; Ihrke 1996; Ihrke et al. 1999; Carlotti et al. 1999; Griffin 1993; Hawkins et al. 1998; Dorfman et al. 1995; Cotard et al. 1995). The first veterinary quinolone was enrofloxacin, and veterinarians now have experience with marbofloxacin, orbifloxacin, and difloxacin. The efficacy of the fluoroquinolones is established for indications listed on the labels approved by the U.S. Food and Drug Administration (FDA). In the United States, enrofloxacin, marbofloxacin, and orbifloxacin are approved for dogs and cats; difloxacin is registered for dogs only. In Europe, ibafloxacin also is available.

The efficacy of enrofloxacin and marbofloxacin has been demonstrated specifically for canine pyoderma through published reports (Ihrke and DeManuelle 1999; Ihrke 1996; Paradis et al. 1990; Carlotti et al. 1999; Ihrke et al. 1999). One disease in particular for which enrofloxacin's efficacy has been demonstrated is German Shepherd dog pyoderma when the drug is administered orally once daily at a dose rate of 5–10 mg/kg (Ihrke and DeManuelle 1999; Koch and Peters 1996).

In addition to treatment of infections in these common sites, fluoroquinolones also have been used to treat rickettsial infections (Breitschwerdt et al. 1990, 1999) and have been examined for treating *Bartonella* infections in cats (Kordick et al. 1997). Against *Rickettsia rickettsii*, enrofloxacin is equally as effective as doxycycline or chloramphenicol (Breitschwerdt et al. 1990), but the success for eliminating *Bartonella* in cats has been equivocal (Kordick et al. 1997). Enrofloxacin has been used successfully to treat acute ehrlichiosis in dogs caused by *E. canis* and *E. platys* at a dosage of 5 mg/kg once daily for 15 days (Kontos and Athanasiou 1998). However, success in treating chronic ehrlichiosis has not been demonstrated. Fluoroquinolones also have been used to treat infections caused by *Mycoplasma* and *Mycobacteria*. Although the activity against *Mycoplasma* can be variable (Hannan et al. 1997), it has been effective for some opportunistic mycobacterial infections in cats (Studdert and Hughes 1992). Enrofloxacin and danofloxacin were consistently more active against veterinary *Mycoplasma* isolates than flumequine (Hannan et al. 1997).

SMALL MAMMALS. Enrofloxacin and other fluoroquinolone antibiotics are used frequently in small mammals such as rabbits, mice, rats, and exotic species for skin and visceral infections (Göbel 1999; Cabanes et al. 1992; Broome and Brooks 1991). One of the reasons fluoroquinolones are popular for treatment in small mammals is the potent activity against gram-negative pathogens affecting these animals and the excellent oral absorption. Another important advantage is the good safety record of the fluoroquinolones in small mammals. Oral tablets of fluoroquinolones have been administered directly or crushed to make a suspension that can be conveniently administered orally to the small mammals mixed with water, fruit, or some other palatable flavoring. Small mammals such as rodents and rabbits are prone to gastrointestinal disturbances and enteritis caused by overgrowth of bacteria, especially *Clostridium* organisms after administration of β-lactam and macrolide antibiotics. Because fluoroquinolones are not active against the anaerobic bacteria that compete with *Clostridium* organisms, bacterial overgrowth of pathogenic opportunistic bacteria has not been a problem as it has with other drugs, such as penicillins or macrolides.

Of the available drugs, enrofloxacin has been the most extensively studied. The doses listed in textbooks and review articles for mice, gerbils, hamsters, rats, and guinea pigs are 2.5–5.0 mg/kg up to 10–20 mg/kg IM, SC, or

orally administered twice daily. The pharmacokinetics has been reported (Table 38.1), and there is some experience with the drug's efficacy. In rabbits oral enrofloxacin has been effective for improving clinical signs associated with pasteurellosis. The recommended dose of enrofloxacin for rabbits is 5 mg/kg IM, SC, or oral. Although it does not completely eradicate the bacteria in pasteurellosis in rabbits, it is considered the drug of choice (Göbel 1999; Broome and Brooks 1991).

REPTILES. The use of fluoroquinolones in reptiles has become popular because of their activity, safety, and convenience of administration (Papich 1999; Jacobson 1999; Rosenthal 1999). The only fluoroquinolone studied extensively is enrofloxacin. It is active against gram-negative organisms often implicated in serious infection of reptiles, including *Salmonella* spp., *Aeromonas hydrophilia, Klebsiella* spp., and *P. aeruginosa,* and its pharmacokinetics has been summarized in a review (Papich 1999). It shows remarkable differences among the reptiles, but generally the elimination is longer than in mammals or birds, which allows long dose intervals—as long as every 96 hours in some species. The elimination rate of drugs in reptiles varies with the animal's body temperature, because body temperature affects metabolic rate. When enrofloxacin is administered, there is variable metabolism to the active metabolite ciprofloxacin among the reptiles. Elimination half-life ranged from 55 hours in alligators to 5.1 hours in tortoises (Young et al. 1997; Raphael et al. 1994; Helmick et al. 1997; Hungerford et al. 1997; Prezant et al. 1994). Monitor lizards, pythons, and turtles had half-lives of 36, 17.6, and 6.4 hours, respectively. Analysis of pharmacokinetic data and appraisal of clinical experience (Jacobson 1999; Papich 1999) suggest a range of doses (Table 38.5), but safety and efficacy studies have not been performed.

Pharmacokinetic studies have shown good absorption of enrofloxacin from IM administration, and this route may prolong the half-life, probably because of delayed absorption from the injection site. Although some authors have suggested that oral administration should be avoided in reptiles because of unreliable absorption, absorption was good after oral administration to alligators, lizards, and turtles (Helmick et al. 1997; Hungerford et al. 1997; James et al. forthcoming). Because of slow gastrointestinal transit time, oral absorption may prolong the half-life (flip-flop effect).

BIRDS. The fluoroquinolones are an important group of antibiotics for pet birds and exotics kept in zoo collections. Despite pharmacokinetic studies in poultry, these drugs are prohibited in poultry in the United States. Administration is via drinking water oral gavage, or by injection. Fluoroquinolones have the advantage of good activity against bacterial pathogens important to birds, including *E. coli, Klebsiella* spp., *Pseudomonas* spp., *Staphylococcus* spp., and for treatment of *Chlamydophila psittaci* (formerly called *Chlamydia psittaci*). Resistance is possible for *E. coli* and *Pseudomonas* spp., however, and activity against gram-positive cocci (e.g., streptococci and enterococci) is low. Although there is in vitro susceptibility of *Chlamydophila* to fluoroquinolones, experience suggests that enrofloxacin can decrease clinical signs but not eliminate the infections (Flammer 1998). Therefore, fluoroquinolones are not recommended for mass medication of pet birds, and doxycycline is still the choice for this indication.

For pet birds, the dose is higher than for mammals because the clearance is faster and metabolic rate is higher. Pharmacokinetic studies of enrofloxacin in birds (see Table 38.1) indicate a dose of 15 mg/kg IM or orally every 12 hours (Flammer 1998; Flammer et al. 1991). One advantage of enrofloxacin for treating birds is that it has been possible to add it to the drinking water of pet birds so they can be conveniently medicated. Enrofloxacin added to drinking water at a concentration of 0.3–0.5 mg/ml has been used to treat highly susceptible bacteria (Flammer et al. 1990). Enrofloxacin is well absorbed via this route, and as long as the bird is drinking, effective plasma concentrations can be attained. One concern with the IM injection is that it can produce irritation at the site of injection, which is problematic because birds have a limited muscle mass into which one can inject.

Enrofloxacin has been administered to ducks at a dose of 10 mg/kg every 24 hours IM or orally.

FISH. Fluoroquinolones have been considered for treatment of infections in ornamental fish and for use in aquaculture. These drugs are active against important gram-negative bacterial pathogens of fish, and they appear to be well tolerated. Enrofloxacin has been administered orally to Rainbow trout kept in water maintained at 10° and 15°C. Although oral absorption is less than in mammals, it was good enough to produce effective plasma concentrations (Bowser et al. 1992). MIC values for pathogens infecting fish range from 0.0064–0.032 μg/ml

for the most sensitive organisms to 0.25–0.45 μg/ml for *Streptococcus* spp. Thus the dose of 5 mg/kg should produce effective plasma concentrations for most susceptible pathogens (Bowser et al. 1992). In Atlantic salmon, enrofloxacin administered at 10 mg/kg intraperitoneally, intramuscularly, and orally was well absorbed from these routes, with no advantage of one route over another, but it produced a wide range of half-lives and Vd. Oral absorption in salmon was 46%, but the authors concluded that at 5 mg/kg this route would be suitable for therapeutic treatment (Stoffregen et al. 1997). Tissue concentrations were high, with concentrations detected at 120 hours after dosing.

Enrofloxacin has also been studied in red pacu as a model for other ornamental fish (Lewbart et al. 1997). For treatment of bacterial infections in ornamental fish, Lewbart (1998) recommends enrofloxacin at a dose of 5 mg/kg. This can be administered IM, IP, or orally with a recommended interval of every 48 hours, but the IM route produces the most predictable plasma concentrations. The oral dose can be prepared as a mixture of 0.1% in fish food (10 mg per 10 g of food). Enrofloxacin also has been added to water and used as a bath for fish in which the drug is absorbed across the surface area of the gill to produce systemic levels. In this treatment 2.5–5.0 mg enrofloxacin per liter is used as a 5-hour treatment bath repeated every 24 hours (Lewbart et al. 1997). The resulting peak plasma concentration after such a treatment was 0.17 μg/ml. Studies of the stability of enrofloxacin in water at various degrees of salinity and pH showed enrofloxacin to be stable when added to a water bath (unpublished results from the laboratory of one of the authors, MGP). However, the effect of the drug on nitrifying bacteria in the water should be considered. Studies in cuttlefish showed that clearance was surprisingly rapid, and doses of 5 mg/kg every 12 hours would be necessary to maintain effective concentrations (Gore et al. 2005). However, the same study indicated that systemic absorption from immersion of cuttlefish in an enrofloxacin medicated bath was possible.

LARGE ANIMALS. In horses, there is no fluoroquinolone approved for use, but increasing interest in use in these animals. Although none is registered for use in horses in the U.S., several pharmacokinetic studies have generated data for these drugs. These data, as well as clinical experience, have shown that this class of drugs can be valuable for treating infections in horses. Their valuable properties include the following: 1) ability to administer by oral, IV, and IM routes, although only enrofloxacin is available in an injectable formulation in the United States; 2) spectrum of activity that includes staphylococci and gram-negative bacilli such as *Klebsiella pneumoniae, Escherichia coli,* and *Proteus* spp.; 3) spectrum of activity that does *not* include anaerobic bacteria, therefore posing little risk of disrupting bacteria in the GI tract; and 4) good safety profile in adult horses.

The oral absorption of enrofloxacin in horses has generally been in the range of 50–70% (Table 38.1). Most bacteria that infect horses are susceptible, but resistance is expected for streptococci and anaerobes. Strains of *P. aeruginosa* may be resistant or only moderately susceptible. *Rhodococcus equi* can be resistant, and success in treating *Rhodococcus* infections in horses with enrofloxacin has not been encouraging. Based on the studies cited in this section, as well as clinical experience to date, an injectable dose of enrofloxacin at 2.5 to 5 mg/kg once daily or an oral dose of 7.5 to 10 mg/kg once daily is recommended (Giguère et al. 1996). The higher oral dose is used to accommodate the decreased systemic availability from an oral dose. For orbifloxacin (Orbax), an oral dose of 5 mg/kg once daily is recommended (Davis et al. 2006). These doses meet PK-PD criteria for susceptible bacteria discussed earlier in this chapter. For marbofloxacin (Zeniquin), IV doses of 2 mg/kg q24h may be adequate for treatment of most gram-negative infections caused by Enterobacteriaceae (Bousquet-Mélou et al. 2002; Peyrou et al. 2004; Carretero et al. 2002). However, this dose would not be adequate for many gram-positive bacteria, such as *Staphylococcus* spp., with MIC values of 0.25 μg/ml or higher. The injectable formulation is not available in the United States; therefore, oral tablets of marbofloxacin would be required for administration. Marbofloxacin has systemic availability of approximately 62% in horses. (Bousquet-Mélou et al. 2002). Oral dosing at 2 mg/kg may be adequate for susceptible Enterobacteriaceae with MIC values less than 0.2 μg/ml, but not for other bacteria. Doses higher than 2 mg/kg have not been studied in horses. As mentioned earlier, ciprofloxacin is not recommended because the oral absorption was poor in ponies and adult horses. Enteritis may occur in horses owing to the poor absorption and disruption of intestinal bacteria.

The method of administration for horses has been to 1) crush up tablets used in small animals, 2) administer the injectable solution (2.27% or 10%) IM (neck muscle) or

IV, or 3) administer the concentrated 10% solution orally (Baytril-100 cattle formulation). All these methods appear to produce adequate plasma concentrations, except for the administration of the concentrated 10% solution (Baytril-100) orally. This solution has produced inconsistent and incomplete absorption in horses, possibly because of its insolubility in solutions of low pH (Haines et al. 2000). In other studies, absorption of this solution was better when horses were fed (Boeckh et al. 2001). This solution also has been associated with oral mucosal lesions in horses. Some clinicians have produced more consistent oral absorption and reduced mucosal irritation when the 100 mg/ml solution was compounded into a gel (Epstein et al. 2004).

Moxifloxacin (Avelox) is a human drug of this group and has been used on a limited basis for treatment of infections in dogs and cats caused by bacteria that have been refractory to other drugs. When administered to horses, moxifloxacin had favorable pharmacokinetics that could make it suitable for oral use in horses (Gardner et al. 2004). However, oral administration also produced diarrhea in the experimental horses studied, and one of these horses tested positive for *Clostridium difficile* toxins A and B. The spectrum of activity of this drug may be broad enough to disrupt the normal flora.

In cattle and sheep, the pharmacokinetics of enrofloxacin and danofloxacin has been reported (Table 38.1) and doses have been derived from these studies or clinical trials. Enrofloxacin and danofloxacin are approved for use in cattle in the United States and some European countries. These fluoroquinolones have been highly active against important pathogens causing Bovine Respiratory Disease (BRD) in cattle. The MIC_{90} values listed for *Histophilus somni, Mannheimia haemolytica,* and *P. multocida* are 0.03, 0.06, and 0.03 μg/ml, respectively. Extralabel use is not allowed in food-producing animals (see Chapter 54). The dose ranges from a single SC dose of 7.5–12.5 mg/kg, or treatment for 3 days at 2.5–5.0 mg/kg, once daily, SC. The withdrawal time is 28 days. It is not approved for lactating cattle or dairy calves, but disposition into milk of lactating cows has been studied. Enrofloxacin is highly excreted in milk. (See the section on administration of fluoroquinolones to nursing animals below.)

Danofloxacin (A-180). Danofloxacin (A-180) is also approved in the U.S. for treatment of BRD in cattle. In Europe, this drug has been approved for several years, as the name Advocin®. It has a broad spectrum of activity, similar to enrofloxacin, including bovine isolates of *Pasteurella, Mannheimia haemolytica, Haemophilus somnus,* and *Mycobacterium bovis.* The manufacturer reported a half-life values of 4.35, and volume of distribution of 3.6 l/kg at the label dose of 6 mg/kg. Some earlier work at lower doses (Giles et al. 1991) reported similar results (half-life 4 hrs and Vd of 2.76 l/kg). Lung tissue concentrations were higher than the corresponding serum concentration and persist above the MIC for 12–24 hrs after injection (Giles et al. 1991; Apley and Upson 1993). In a comparison between enrofloxacin and danofloxacin (Terhune et al. 2005) danofloxacin produced plasma concentrations that were 56 times the MIC of 0.03 μg/ml, which is the MIC reported for North American BRD isolates. Although it is not legal to use fluroquinolones in the U.S. in an off-label manner, studies have also shown danofloxacin to be effective for bacterial enteritis in calves.

ADMINISTRATION TO NURSING, PREGNANT, OR YOUNG ANIMALS

Nursing Animals. Distribution also has been measured for milk in rabbits and cattle. Enrofloxacin is excreted rapidly in the milk after administration. In cattle after administration of enrofloxacin at 5 mg/kg, enrofloxacin concentrations in milk parallel the concentrations in serum, with a Cmax of 1.3–2.5 μg/ml, but concentrations of the active metabolite ciprofloxacin exceed those of enrofloxacin (Kaartinen et al. 1995; Tyczkowska et al. 1994). Danofloxacin distribution into milk of cows exceeded serum concentrations (Shem-Tov et al. 1998). In rabbits the milk-to-plasma ratios were 3.6 and 2.6 for enrofloxacin and ciprofloxacin, respectively, after administration of 7.5 mg/kg IV (Aramayona et al. 1996). The reason for the high distribution of fluoroquinolones into milk is not known, because these concentrations do not match what is predicted from simple diffusion into milk, even after considering ion trapping. Protein binding is higher in milk, and the milk proteins may act as a reservoir for enrofloxacin and ciprofloxacin (Aramayona et al. 1996). Despite these concentrations of fluoroquinolones in milk, the activity of enrofloxacin in mastitic milk is decreased, possibly owing to lower pH, chelation with cations, or other factors in milk that inhibit fluoroquinolone activity (Kaartinen et al. 1995), and it has not been shown that fluoroquinolones are effective drugs for treating clinical

mastitis. In the United States, this would be considered extralabel use and is prohibited.

When administering fluoroquinolones to nursing animals, the amount in the milk should be considered because fluoroquinolones may cause arthropathy in some species of young animals (discussed further in the section on safety below). Disposition into milk was studied in two mares after administration, and it was shown that although both ciprofloxacin and enrofloxacin were present in milk at levels that were as high or higher than the mares' plasma concentrations, the total doses administered to the foals via suckling were small, and the plasma concentrations in the foals were negligible (author's observations). Young nursing animals may have decreased oral absorption caused by interference from calcium in milk (see information below on kittens in the section on young animals).

Pregnant Animals. When administering fluoroquinolones to pregnant animals, there will be some drug transfer across the placenta because these drugs are lipophilic and have low protein binding, and drug transfer is not limited by tissue barriers. Placental transfer has been specifically examined in rabbits, in which it was shown that the more lipophilic drug, enrofloxacin, crossed the placenta to a greater degree (80%) than ciprofloxacin (5% placental transfer), which is less lipophilic (Aramayona et al. 1994). Despite the rather high transfer of enrofloxacin across the placenta, there have been no reports of adverse effects when fluoroquinolones were administered to pregnant animals. Manufacturer studies have not shown any adverse effects on pregnancy or reproduction.

Young Animals. There is a risk that fluoroquinolones may cause damage to the developing cartilage of young animals. This is discussed more thoroughly in the section on safety. There have been few pharmacokinetic comparisons of young animals versus older animals, but the studies available demonstrate that young animals were exposed to more drug than adults because of slower clearance. After administration of enrofloxacin, calves at 1 day of age had smaller Vd, longer half-life, and decreased clearance than at 1 week of age (Kaartinen et al. 1997). There also was a smaller amount of metabolism of enrofloxacin to ciprofloxacin in 1-week-old calves than in older ones. Rabbit pups exhibited lower clearance and longer half-life for enrofloxacin than adult rabbits (Aramayona et al. 1996). This pattern was also seen in horses: foals at 1–2 weeks of age showed little metabolism of enrofloxacin to ciprofloxacin after administration of IV and oral doses. Foals also exhibited slower clearance and longer half-life than adults (Bermingham et al. 2000).

In kittens, enrofloxacin was administered at 5 mg/kg via various routes (oral, IV, SC) (Seguin et al. 2004). There was no evidence of adverse effects or impaired excretion of enrofloxacin in kittens. The half-life in young cats (2, 6, and 8 weeks old) was shorter, and clearance more rapid, than in adult cats, Volume of distribution in 6–8-week-old cats was larger, and combined with the shorter half-life, produced lower plasma concentrations than in adults. Oral administration to kittens produced low plasma concentrations and it was hypothesized that interference with milk in nursing kittens may lower oral absorption (see section "Drug Interactions," below).

SAFETY

The fluoroquinolones have had a remarkably good safety record. For enrofloxacin, the LD_{50} in laboratory rats is 5000 mg/kg. When high doses were administered to animals during safety testing, one of the most common problems was gastrointestinal disturbances (nausea, vomiting, diarrhea), but these were usually produced at high doses and were not serious. Because these drugs currently registered for animals do not alter the anaerobic flora of the gastrointestinal tract, there usually is minimal disruption of the intestinal bacterial population, even when these drugs are administered orally to small rodents. There have been no reports of cutaneous drug reactions resulting from fluoroquinolone usage in the veterinary literature, but some of the FOI summaries from manufacturers report an occasional reddening of the skin of dogs when high doses were administered.

There have been no reports of adverse effects on reproduction or pregnancy from administration of fluoroquinolones. Although the use in pregnant animals has been discouraged because of toxicity to developing cartilage, there have been no clinical reports where this effect has been described in offspring of treated animals.

With very high concentrations, adverse central nervous system (CNS) effects have been observed. The mechanism responsible for the CNS effects is believed to be inhibition of the inhibitory neurotransmitter GABA. Fluoroquinolones injected rapidly IV or administered at high doses can induce CNS excitement. Fluoroquinolones can precipitate convulsions in some animals and should not be administered to animals that are prone to seizures.

BLINDNESS IN CATS. In cats high doses of fluoroquinolones have caused ocular problems from drug-induced changes in the retina (Corrado et al. 1987). This concern was precipitated by a report by Gelatt and colleagues (Gelatt et al. 2001) in which retinal degeneration was associated with enrofloxacin administration. This was followed by studies by the manufacturer in which toxicosis from enrofloxacin was described and new dose labeling was announced. The most common ophthalmologic abnormalities were mydriasis, lack of menace reflex, and poor papillary light reflexes. Acute blindness may occur and retinal lesions may be observed, which include increased tapetal reflectivity and attenuation of retinal blood vessels. In one review of safety studies (Corrado et al. 1987) nalidixic acid (one of the earlier quinolones) at 100 mg/kg/day, but not norfloxacin at 200 mg/kg/day produced both electrical and histopathologic changes in feline retinas. In another review (Schluter 1987), the author states that feline retinas are particularly sensitive to fluoroquinolones. When cats received 100 mg/kg of nalidixic acid there was suppression of electroretinographic waves and histologic changes in the cones and rods, but ciprofloxacin treatment at the same dose to cats had no effect on the electroretinographic findings or on the fundus.

In studies performed by the manufacturer, enrofloxacin was administered to cats at doses of 0, 5, 20, and 50 mg/kg for 21 days (8 cats per group). There were no adverse effects observed in cats treated with 5 mg/kg/day of enrofloxacin. However, the administration of enrofloxacin at 20 mg/kg or greater caused salivation, vomiting, and depression. At doses of 20 mg/kg or greater, there were mild to severe fundic lesions on ophthalmologic examination, including changes in the fundus and retinal degeneration. There was also abnormal electroretinograms, including blindness. Ford et al. (2007) reported on a study in 24 cats that received 3, 5, or 7 days of enrofloxacin at a high dose of 50 mg/kg (10 times the label dose). Ocular changes were observed by day 3 of the study. At this dose, both retinal degeneration and systemic toxic effects were observed. Because the blindness has been associated with high doses, the manufacturer has limited the dose to 5 mg/kg/day in cats.

Besides enrofloxacin, the other fluoroquinolones registered for use in cats are orbifloxacin (Orbax) and marbofloxacin (Zeniquin). The current approved dose of orbifloxacin for cats is 2.5–7.5 mg/kg/day. In a published abstract (Kay-Mugford et al. 2001), orbifloxacin oral liquid was administered to cats at 0, 15, 45, and 75 mg/kg for at least 30 days (8 cats/group). This represents 6, 18, and 30 times the lowest label dosage. No ocular lesions were observed in any cats treated with 15 mg/kg. At the higher doses, (18 and 30 times dose) there was tapetal hyperreflectivity in the area centralis and minimal photoreceptor degeneration. When marbofloxacin was administered to cats at 5.55, 16.7, and 28 mg/kg, representing 2, 6, and 10 times the lowest label dose, for 6 weeks there were no ocular lesions in cats (manufacturer's data). At 55.5 mg/kg (10 times the lowest label dose) for 14 days there were also no lesions from marbofloxacin.

PROBLEMS IN YOUNG ANIMALS. In young, rapidly growing animals it is well known that fluoroquinolones can produce an arthropathy (Gough et al. 1992; Burkhardt et al. 1997). Fluoroquinolones also have caused tendinitis and tendon rupture in people, but this effect has not been reported for animals. The species most susceptible to developmental arthropathy are rats and dogs. Dogs between the ages of 4 and 28 weeks are the most susceptible. Affected dogs may show signs of lameness and joint swelling, but if the drug is discontinued, the lesions may be reversible. Kittens, calves, and pigs are much more resistant to this effect. For example, feeder calves and 23-day-old calves were administered 25 mg/kg for 15 days without evidence of articular cartilage lesions. Young foals are susceptible to the joint arthropathy from enrofloxacin at 10 mg/kg orally (Bermingham et al. 2000). However, studies in adult horses treated with enrofloxacin have not demonstrated articular toxicity (Bertone et al. 2000; Giguère et al. 1999).

The risk increases with higher doses and in most instances has been more clinically obvious only when the highest maximum dose was exceeded (e.g., at 25 mg/kg of enrofloxacin); however, even enrofloxacin dosages of 10 mg/kg/day have induced cartilage damage in young dogs. Lesions have been observed in as few as 2 days after initiation of treatment (Yabe et al. 2001). The use of fluoroquinolones has been discouraged in children, but thousands of children have been treated with these drugs under a compassionate protocol with no reports of joint arthropathy.

Joint arthropathy is best described as a toxicity to the chondrocyte that causes vesicles to form on the articular surface. The mechanism for damage to cartilage apparently is via chelation of magnesium by the drug (Egerbacher

et al. 2001). Magnesium is necessary for proper development of the cartilage matrix, especially in young, growing animals. Chelation of the magnesium results in a local magnesium deficiency leading to loss of proteoglycan in the articular cartilage. Studies in which magnesium was supplemented to decrease cartilage damage had equivocal results. (Magnesium added to the diet while oral drugs are administered would cause a chelation and significantly decrease oral absorption.)

DISEASES OR CONDITIONS. There has been limited study of the disposition of fluoroquinolones in animals that have other conditions. In most of these instances, there were no changes in the drug's pharmacokinetics that would necessitate a change in dosage. Since the fluoroquinolones rely on both the kidneys and liver for clearance, insufficiency in one organ may result in compensation by the other clearance route. For example, renal failure may result in more reliance on hepatic clearance. In dogs with renal impairment, clearance of marbofloxacin was only slightly decreased and there was no significant effect on Vd or mean residence time (Lefebvre et al. 1998). In camels that were deprived of water for 14 days and lost 12.5% of their body weight, there was little effect on the distribution, clearance, or half-life of enrofloxacin. However, water deprivation resulted in a slower and less complete absorption from a SC injection compared to normal camels or camels injected IM (Gavrielli et al. 1995).

DRUG INTERACTIONS

Combinations with other antibiotics neither antagonize nor enhance the microbiologic effects of fluoroquinolones. The currently used fluoroquinolones will kill bacteria whether or not they are dividing (Lode et al. 1998). Therefore, use of a bacteriostatic agent should not interfere with the action of a fluoroquinolone. Although there is no evidence that other antibiotics produce a synergistic effect when administered with fluoroquinolones, they may produce an additive effect and broaden the spectrum of activity.

Fluoroquinolones are involved in some drug interactions, but few of these are serious. Drugs containing di- and trivalent cations (e.g., Ca^{++}, Mg^{++}, Al^{+3}, Fe^{+3}), such as antacids, sucralfate, and nutritional supplements can inhibit oral absorption (Nix et al. 1989). These cations, when mixed with fluoroquinolones in extemporaneously compounded preparations can chelate the drug and decrease oral absorption. Fluoroquinolones may inhibit metabolism of some drugs through an interaction with hepatic metabolism. One such example is the inhibition of theophylline metabolism by enrofloxacin (Intorre et al. 1995), in which enrofloxacin significantly increased the Cmax and decreased systemic clearance of theophylline in dogs.

FORMULATIONS AVAILABLE

Fluoroquinolones licensed for small-animal use are available as oral preparations as tablets or chewable tablets. There are no oral liquid preparations currently available in the United States, but veterinarians have used compounding pharmacists to create oral liquid preparations from tablets dissolved in an aqueous vehicle. There are two formulations of enrofloxacin, an IM injectable preparation for dogs (2.27% solution, 22.7 mg/ml), and an injectable for cattle (100 mg/ml). It is registered for IM administration, but veterinarians have administered this preparation IV. The IV administration has not produced serious problems, but one should avoid rapid IV injection; otherwise, CNS reactions are possible. In addition, mixing a solution with some intravenous solutions may cause chelation and precipitation in the IV line. Fluids of particular concern are those that contain calcium or magnesium. The formulation approved for SC injection in cattle in the United States is 100 mg/ml in an l-arginine base. This preparation may cause tissue irritation if injected in small animals. It is very alkaline and has also produced oral mucosal lesions when used for oral administration to horses (Boeckh et al. 2001).

There is an otic preparation available (Baytril otic) containing 5 mg/ml enrofloxacin and 10 mg/ml silver sulfadiazine. Some veterinarians have also used topical administration of enrofloxacin for otitis externa caused by pseudomonads (Griffin 1993, 1999; Rosychuk 1994). Other otic preparations have been mixed extemporaneously by veterinarians, even though these are not licensed or evaluated for efficacy. For example, veterinarians have mixed the 2.27% injectable solution of enrofloxacin with saline, water, or other topical ear solutions in a 1:1 to 4:1 ratio (e.g., 4 parts saline, 1 part enrofloxacin). Stability studies by one of the authors (M.G.P.) with HPLC analysis confirmed these solutions to be stable for 2 weeks at room temperature. When the infection is believed to extend to the middle ear, topical treatment alone is not sufficient,

and systemic treatment for pseudomonads should be administered.

Difloxacin (Dicural) is available in tablet form for administration to dogs, but safety has not been evaluated for cats. Danofloxacin mesylate (A-180) is used for administration to cattle, SC in the neck area. It has a 2-pyrrolidone and polyvinyl alcohol vehicle. Marbofloxacin (Zeniquin) is available in tablets for dogs and cats. There is an injectable formulation available in other countries for small animals and horses (Marbocyl), but not in the United States. Orbifloxacin is available in tablet form for dogs and cats.

NEW DEVELOPMENTS

Pradofloxacin (Veraflox) is one of the newest generation of fluoroquinolones (sometimes referred to as fourth-generation *quinolones*, or third-generation *fluoroquinolones*), which is related to the human drugs trovafloxacin, grepafloxacin, gatifloxacin, gemifloxacin, and moxifloxacin (discussed earlier in this chapter). Because the older, more familiar, fluroroquinolones, (e.g., enrofloxacin, marbofloxacin, orbifloxacin, difloxacin) have less activity against gram-positive cocci and anaerobic bacteria, and have been associated with development of resistance, these new drugs have been explored for use in veterinary medicine, as they have in human medicine (Blondeau et al. 2004).

Pradofloxacin has been evaluated in dogs and cats for skin, soft-tissue, oral, and urinary tract infections (deJong et al. 2004; Stephan et al. 2008; Spindel et al. 2008; Hartmann et al. 2008; Litster et al. 2007; Mueller and Stephan 2007). Pharmacokinetic studies are also available (Hartmann et al. 2008). Susceptibility data indicate that it is more active than other fluoroquinolones against bacterial isolates from dogs and cats (deJong et al. 2004; Ganière et al. 2005; Silley et al. 2007; Stephan et al. 2007). Because it is active against two targets of fluoroquinolones (Topoisomerase IV and DNA gyrase) development of resistant mutants may be less likely (Wetzstein 2005; Stephan et al. 2007).

Pradofloxacin has been safe in cats with respect to ocular lesions (Messias et al. 2008). At a dose of 3 mg/kg orally it was effective for treatment of urinary tract infections in dogs (Stephan et al. 2008) and at 5 mg/kg was effective for canine pyoderma (Mueller and Stephan 2007). At a dose of 5 mg/kg in a 2.5% oral suspension it was effective for urinary tract infections in cats (Litster et al. 2007).

At the time of this writing (July 2008) pradofloxacin was not registered for use. However, a closely related human drug, moxifloxacin (Avelox) of this group has been used on a limited basis for treatment of infections in dogs and cats caused by bacteria that have been refractory to other drugs.

ANTIFUNGAL DRUGS

The need for safe and effective antifungal drugs has become important, particularly in small-animal medicine, with the recognition of serious systemic fungal diseases as well as the need for effective drugs to treat skin infections caused by dermatophytes and yeasts. Some animals are at a greater risk of fungal infections because they are immunosuppressed, receiving cancer drugs, radiation therapy, or prolonged courses of corticosteroids. Fortunately, there have

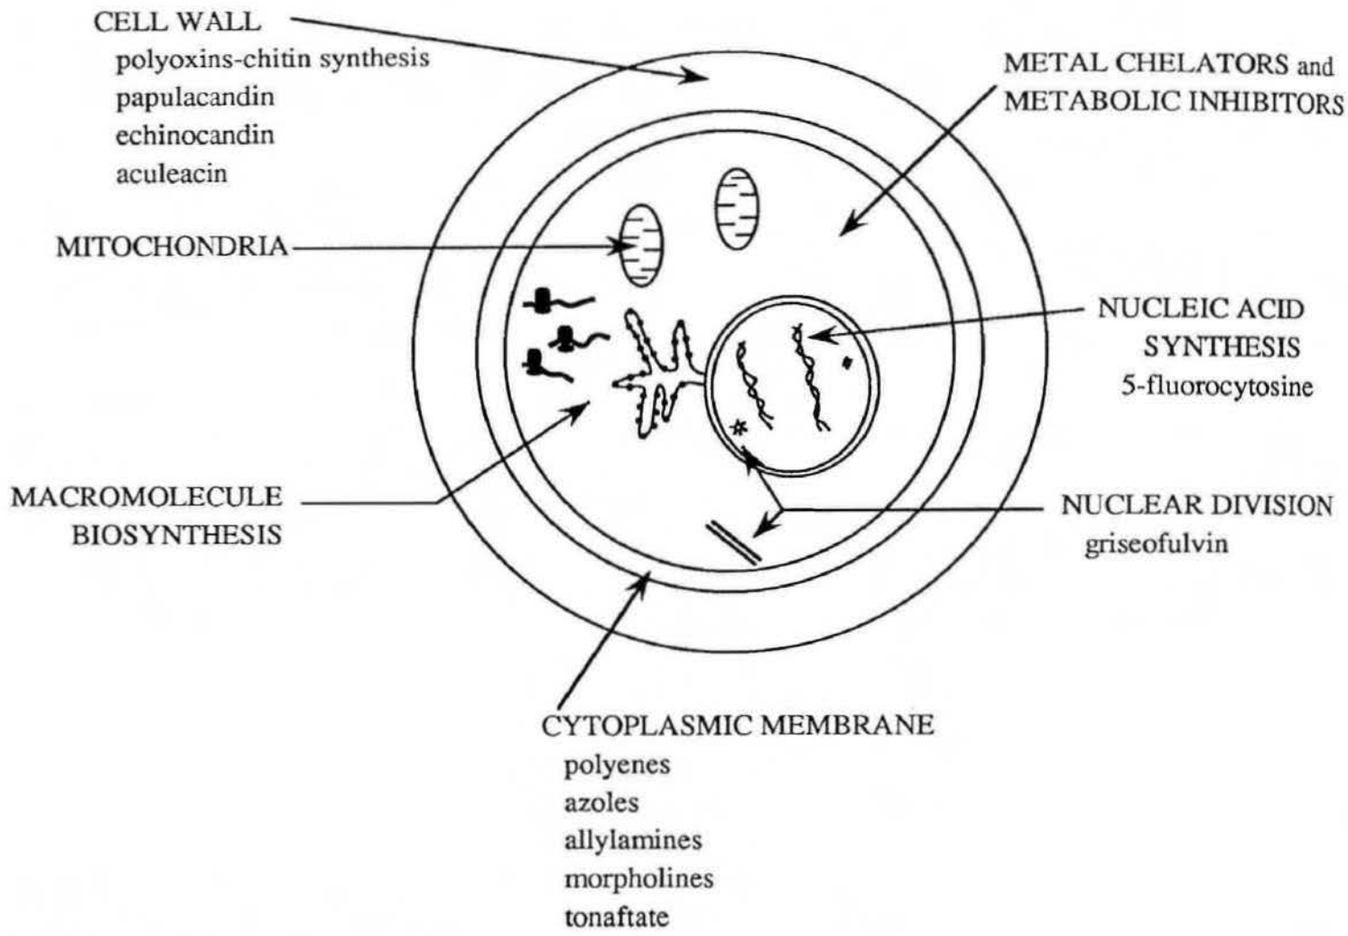

FIG. 39.1 Schematic anatomy of a fungal cell and potential sites where antifungal drugs act.

been many advances in the development of antifungal drugs in the last 10 years. Effective oral drugs are more widely used and there are newer, safer formulations of injectable agents. Figure 39.1 illustrates the sites of drug action for common antifungal drugs used in veterinary medicine.

GRISEOFULVIN

Griseofulvin (Fulvicin U/F®, Fulvicin P/G®, Grifulvin V®, Grisactin®, Grisactin ultra®), is a fungistatic antibiotic produced by *Penicillium griseofulvin dierckx*. It is colorless, slightly bitter, and virtually insoluble in water. There are two types of preparations, the microsized and the ultramicrosized. Due to increased surface area, the ultramicrosized formulations have almost 100% bioavailability, whereas oral absorption of microsized formulations is lower and more variable (25–70%). The ultramicrosized preparations are not used often in veterinary medicine due to the higher cost. If the ultramicrosized form is used, the dose must be decreased to account for differences in absorption.

MECHANISM OF ACTION. Griseofulvin's selective toxicity is based on an energy-dependent uptake into susceptible fungi that occurs preferentially in fungal cells rather than mammalian cells. Once inside the cell, griseofulvin disrupts the mitotic spindle by interacting with polymerized microtubules, thus causing mitotic arrest in metaphase. Grossly this may appear as shortened fungal hyphae that have fewer branching points. This is known

as the *curling* phenomenon. Griseofulvin may also interfere with cytoplasmic tubule formation, thereby inhibiting normal cellular trafficking.

SPECTRUM OF ACTIVITY. Griseofulvin's activity is limited to organisms causing dermatophytosis, *Microsporum* spp., *Trichophyton* spp., and *Epidermophyton*. Fungal resistance to griseofulvin, caused by decreased energy-dependent uptake into the fungal cell, has not been reported to be a clinically important problem in veterinary medicine.

PHARMACOKINETICS. Pharmacokinetic properties were reviewed by Hill et al. (1995). Within hours of oral administration, griseofulvin can be detected in the stratum corneum. Because of low water solubility, griseofulvin absorption is enhanced when given with a meal with high fat content. Griseofulvin distributes to the keratin of skin, hair, and nails. Only a small fraction of the dose is present in other body fluids or tissues. The plasma half-life in the dog is 47 minutes (Harris and Riegelman 1969); however, the half-life at the site of action—the stratum corneum—is prolonged because the drug is bound tightly to keratinocytes and remains in the skin until these cells are shed. Thus, new hair or nail growth is first to become free of disease as keratin infected by fungus is replaced by new cells.

Griseofulvin is metabolized primarily by the liver to demethylgriseofulvin and the glucuronide. It is metabolized approximately six times faster in animals than in people, which is the reason animal doses are higher than human doses (half-life in dogs is less than 1 hour, compared to 20 hours in people) (Shah et al. 1972).

CLINICAL USE

Small Animals. Griseofulvin is still used for treating dermatophytosis, but is being gradually replaced by azole drugs (see below). The recommended doses have varied, depending on the author. The label dose in dogs and cats for Fulvicin U/F® tablets is 11 to 22 mg/kg per day, but recommendations by specialists in dermatology have ranged from 44 mg/kg/day (Sousa and Ihrke 1983) to 110 to 132 mg/kg per day in divided treatments (Scott 1980). One review suggested a dose of 50 mg/kg once a day of the microsize formulation (Hill et al. 1995), and another review listed 25 mg/kg every 12 hours (deJaham et al. 2000), but the dose can be doubled for refractory cases. The most common dose is in the range of 50 mg/kg/day, which was confirmed in a report in which it was used in cats and was as effective as itraconazole for treatment of dermatophytosis (Moriello and DeBoer 1995).

Griseofulvin is available in 125 and 250 mg capsules; 125, 250, and 500 mg tablets; and 125 mg/ml oral syrup. Often, at least 4 weeks are needed for successful therapy, and some patients require 3 months (or more) of continuous therapy. As long as 4 months may be necessary to treat infections of the nail bed (onychomycosis).

Large Animals. Griseofulvin is labeled for use in horses at a dose of 2.5 gm/day orally in adult horses for a minimum of 10 days. This translates to one packet of the powder formulation or one bolus per day, administered on feed. The dose for foals is 1/2 packet or 1/2 bolus. Its use is limited to cases of dermatophytosis. There are currently no alternative registered products for use in food animals in the United States. Nevertheless, when used off-label, griseofulvin has been effective in the prevention and treatment of dermatophytes in cattle (Reuss 1978). Doses used are approximately 7.5–10 mg/kg for 7 to 35 days. A dose rate of 1 g/100 kg has been recommended for pigs for a duration of 30–40 days (Kielstein and Gottschalk 1970). Because this drug is not approved, veterinarians must determine proper food animal withdrawal times for this drug prior to administration.

ADVERSE EFFECTS. The most serious adverse effects associated with griseofulvin occur in cats and include leukopenia, anemia, increased hepatic enzyme activity, and neurotoxicosis (Helton et al. 1986). Ataxia in a kitten (Levy 1991) and bone marrow hypoplasia in an 8-year-old cat (Rottman et al. 1991) have been reported.

Prolonged treatment of eight cats with griseofulvin at the high end of the dosage range resulted in no untoward clinical, hematologic, or hepatic side effects, suggesting that griseofulvin toxicity may be idiosyncratic (Kunkle and Meyer 1987). Cats with the feline immunodeficiency virus (FIV) appear to be at increased risk for griseofulvin-associated neutropenia (Shelton et al. 1990); however, toxicity has also been reported in FIV-negative cats (Rottman et al. 1991). The mechanism of this increased

risk is unknown but may involve griseofulvin-enhanced binding of immune complexes to granulocytic cells in infected cats (Shelton et al. 1991).

Griseofulvin should never be administered to pregnant cats. Its teratogenicity has been well-documented (Scott et al. 1975; Gruffydd-Jones and Wright 1977). The teratogenic effects include cranial and skeletal malformations as well as ocular, intestinal, and cardiac problems (Scott et al. 1975). It has been given to pregnant horses with no apparent ill effect (Hiddleston 1970); however, this may be dependent on the stage of pregnancy in which the drug was given. One report documented bilateral microphthalmia, brachygnathia superior, and palatocheiloschisis of the drug when given to a mare in the second month of pregnancy (Schutte and Van den Ingh 1997).

AMPHOTERICIN B

Amphotericin B (Fungizone®, ABELCET®, Amphotec®, AmBisome®) is a polyene antibiotic with a large macrolide ring with a hydrophobic conjugated double-bond chain and a hydrophilic hydroxylated carbon chain and attached sugar (Figure 39.2) (Mechlinsk et al. 1970). It is a yellowish powder that is insoluble in water and somewhat unstable (Bennett 1990). There are several formulations of amphotericin B available, including the conventional formulation which is a micellar complex with the bile salt deoxycholate, and several new formulations which are lipid based complexes that are less toxic, but also more expensive (reviewed by Plotnick 2000).

Amphotericin B lipid complex (ABELCET) is a suspension of amphotericin B complexed with two phospholipids. Amphotericin B cholesteryl sulfate complex (Amphotec, ABCD) is a colloidal dispersion of amphotericin B. The liposomal complex of amphotericin B (AmBisome) is a unilamellar liposomal formulation which, when reconstituted, produces small vesicles of encapsulated amphotericin B. Some investigators have attempted to achieve the benefits of lipid formulations without the added cost by mixing the deoxycholate salt in a 10 or 20% lipid solution (Intralipid). This formulation is stable for up to 3 weeks after mixing (Walker and Whitaker 1998); however, the reports of the benefit of this emulsion versus the conventional formulation are inconsistent.

In comparison to the conventional formulation of amphotericin B, lipid formulations can be administered at higher doses to produce greater efficacy with less toxicity (Hiemenz and Walsh 1996). Decreased toxicity is attributed to a selective transfer of the lipid complex amphotericin B, releasing the drug directly to the fungal cell membrane and sparing the mammalian cell membranes. Reduced drug concentrations in the kidneys and diminished release of inflammatory cytokines from amphotericin lipid complex compared to the conventional formulation also may prevent adverse reactions.

MECHANISM OF ACTION. The major action of amphotericin B is to bind ergosterol in the fungal plasma cell membrane, making the membrane more permeable and resulting in leakage of cell electrolytes and cell death

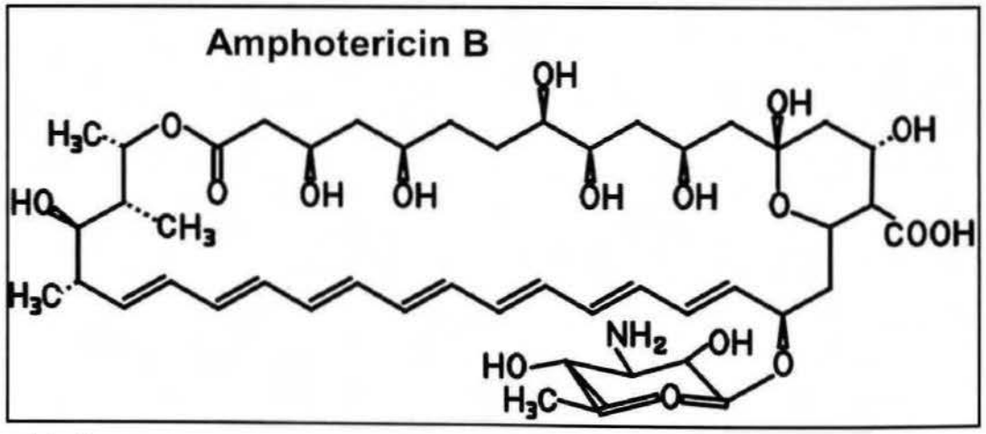

FIG. 39.2 Amphotericin B.

(Brajtburg et al. 1990). At high concentrations, amphotericin B is thought to cause oxidative damage to the fungal cell (Warnock 1991) or disruption of fungal cell enzymes. The selective toxicity of amphotericin B is based on its decreased binding to the major cell membrane sterol of mammalian cells (cholesterol) as compared to that of fungal cells (ergosterol).

Amphotericin B demonstrates concentration-dependent fungicidal activity. There is also a postfungal effect whereby a persistent antifungal effect persists after drug concentrations have declined. This property allows for intermittent therapy (e.g., every other day in dogs).

SPECTRUM OF ACTIVITY. The growth of strains of most veterinary fungal pathogens is inhibited in vitro at amphotericin B concentrations between 0.05 and 1.0 μg/ml and there is good correlation between the MIC values and clinical response (O'Day et al. 1987). Because of concentration-dependent killing, peak (C_{MAX}) concentrations should be 2–4 times above the MIC (C_{MAX}/MIC ratio of 2:4) (Goodwin and Drew 2008).

Sensitive fungi include *H. capsulatum, C. neoformans, C. immitis, B. dermatitidis, Candida* spp., and many strains of *Aspergillus*. Amphotericin B has been indicated for treatment of mucormycosis, sporotrichosis, and phycomycosis (Drouhet and Dupont 1987). Most strains of *Pseudallescheria boydii,* as well as some agents causing chromoblastomycosis and phaeohyphomycosis, are resistant to amphotericin. Clinical fungal resistance to amphotericin B, either primary or acquired, does not appear to occur commonly, although resistant strains occur in vitro. In most cases, these resistant strains contain decreased levels of membrane ergosterol (Pierce et al. 1978) and increased catalase levels may allow these fungi to be resistant to oxidative-dependent damage (Sokol-Anderson et al. 1988). The MIC concentrations were increased in some human patient populations, such as neutropenic patients (Dick et al. 1980), transplant patients (Powderly et al. 1988), and patients undergoing cytotoxic therapy.

PHARMACOKINETICS. Despite its long history of use, much is still unknown concerning the pharmacokinetics of amphotericin B, especially in the veterinary-treated animals. It is poorly absorbed from the GI tract and therefore must be given locally, intravenously, or intrathecally. Amphotericin B binds extensively (~95%) to serum proteins, mainly β-lipoprotein (Bennett 1977). Much of the drug is thought to leave the vascular space and bind to cholesterol-containing membranes. The highest concentrations are found in liver, spleen, kidney, and lungs, with little accumulation in either muscle or adipose tissue. Concentrations of amphotericin B in fluids from inflamed pleura, peritoneum, synovium, and aqueous humor are about two-thirds of those in serum. Amphotericin B readily crosses the human placenta. Penetration into normal or inflamed meninges, vitreous humor, and normal amniotic fluid is poor. This differential distribution may explain treatment failures for infections in some tissues. Although amphotericin B binds ergosterol with higher affinity than cholesterol, it was suggested that because there are more binding sites for cholesterol in the body than for ergosterol, this may sequester amphotericin B from its site of action (Bennett 1977).

CLINICAL USE. A variety of dosage protocols for amphotericin B have been described in the veterinary literature. These are summarized in Table 39.1. One such protocol for small animals was published by Rubin (1986) that is still used today. During infusion, it should be mixed with 5% dextrose solution because if it is added to an electrolyte solution the drug will precipitate, although a solution of amphotericin B with 0.45% saline and 2.5% dextrose has been used successfully subcutaneously without any visible precipitation (Malik et al. 1996). Amphotericin B is used only sporadically in equine medicine and there are no pharmacokinetic data available on amphotericin in the horse. There are no reports of use of this drug in food animals, and there are no approved formulations for use in these species.

Combination therapy using amphotericin B and flucytosine has been shown to be synergistic against cryptococcal infections (see section on flucytosine). Combinations of amphotericin B and azole antifungals have been less successful. Azole-induced depletion of fungal cell membrane ergosterol results in fewer binding sites on which polyene antifungals can exert their effect. Antagonism and synergism between these two classes of antifungal agents have been reported experimentally (Polak et al. 1982; Dupont and Drouhet 1979). Because of the slower onset of action of azole antifungals, many clinicians recommend initial therapy of serious systemic fungal infections with amphotericin B, followed by longer, follow-up treatment with an azole therapeutic protocol.

TABLE 39.1 Selected dosing protocols for amphotericin B in companion animals

Species	Formulation	Disease Treated	Dosing Protocol	Reference
Canine	Fungizone	Unspecified	Pretreatment with 0.9% sodium chloride followed by infusion of 0.5 mg/kg in 5% dextrose over 4–6 hours IV q48h; a test dose of 0.25 mg/kg is sometimes recommended.	Rubin 1986
Canine	Abelcet	Blastomycosis	1 mg/kg IV EOD to a total cumulative dose of 8–12 mg/kg.	Krawiec et al. 1996
Canine	Abelcet	Unspecified	2–3 mg/kg IV 3 times per week diluted in 5% dextrose to a concentration of 1 mg/ml for a total of 9–12 treatments (cumulative dose of 24–27 mg/kg.)	Grooters and Taboada 2003
Canine	AmBisome	Leishmaniasis	3–3.3 mg/kg IV.	Oliva et al. 1995
Canine	Fungizone 40 ml sterile water and 10 ml 10% Intralipid	Leishmaniasis	Pretreatment with 50 ml/kg of 0.9% sodium chloride followed by 10 ml/kg 20% mannitol. Drug mixture infused over 30–60 minutes at incrementally increasing dosing from 1–2.5 mg/kg IV twice a week for a minimum of 8 injections.	Lamothe 2001
Canine/Feline	Fungizone in 0.45% saline with 2.5% dextrose	Cryptococcosis	0.5–0.8 mg/kg SC in 400 ml for cats or 500 ml in dogs given twice a week for a cumulative dose of 8–26 mg/kg.	Malik et al. 1996
Feline	Abelcet	Unspecified	1 mg/kg IV 3 times per week diluted in 5% dextrose to a concentration of 1 mg/ml for a total of 12 treatments (cumulative dose of 12 mg/kg).	Grooters and Taboada 2003
Equine	Fungizone	Phycomycosis	0.38 gradually increased up to 1.47 mg/kg IV in 1 l 5% dextrose once daily.	McMullan et al. 1977
Equine	Fungizone	Pulmonary Histoplasmosis	0.3–0.6 mg/kg IV in 1 l 5% dextrose once a day or every other day.	Cornick et al. 1990
Equine	Fungizone	Systemic Candidiasis	0.1–0.5 mg/kg IV in 1 l 5% dextrose infused over 4–6 hours once daily.	Reilly and Palmer 1994
Equine	Fungizone	Candida Arthritis	0.33–0.89 mg/kg IV in 1 l 5% dextrose once a day or every other day.	Madison et al. 1995
Equine	Fungizone	Cryptococcal Pneumonia	0.5 mg/kg IV in 1 l 5% dextrose as a 1-hour infusion once a day.	Begg et al. 2004
Avian	Fungizone	Aspergillosis	1.5 mg/kg q8–12h reconstituted in sterile water and then diluted 1:50 with 5% dextrose for 3–7 days.	Tully 2000

ADVERSE EFFECTS. The most important clinical toxicosis associated with amphotericin B therapy is nephrotoxicity. It is a dose-related, predictable toxic effect that occurs in almost every animal treated with the conventional formulation. Direct tubular damage occurs because amphotericin B binds to cholesterol in the tubular cells, which results in electrolyte leakage from the cells (primarily K^+ loss) and renal tubular acidosis (Bennett 1990). Induced renal vasoconstriction and impaired acid excretion may also contribute to amphotericin B's renal toxicity (Greene 1990). Renal vasoconstriction may be caused by induced increases in the eicosanoid synthesis in renal blood vessels. The tubular damage, along with the renal vasoconstriction, leads to both an acute and a chronic cumulative renal toxicosis. Clinically, the signs of renal toxicosis are seen as increases in creatinine and blood urea nitrogen (BUN). Electrolyte loading, fluid diuresis, and slow infusion of amphotericin B have all been shown to decrease the severity and the rate of development of renal toxicity. Therefore, common protocols for administration of

amphotericin B to animals include pretreatment with sodium chloride IV solution (Rubin 1986) with or without mannitol (Legendre 1984), and a slow infusion. Slower infusion times are associated with less kidney injury (Rubin 1986). If the dose administered during a single infusion exceeds 1 mg/kg, acute renal injury is likely (Butler and 1964).

Careful clinical monitoring will help decrease the risk of permanent renal injury. Urine sediment evaluation has been suggested to detect renal toxicity earlier than serum biochemical alterations (Greene 1990); thus, urine should be evaluated for proteinuria, cylinduria, and hematuria, as well as specific gravity. In addition, BUN, creatinine, and electrolyte concentrations should be monitored. Therapy should be temporarily discontinued when active urine sediment is detected or the serum creatinine increases. After stopping therapy, patients may undergo a fluid diuresis to decrease the azotemia. If BUN and creatinine return to near-normal reference values, treatment may be resumed. If azotemia does not improve, one should consider an alternative treatment.

Other adverse effects from amphotericin that are frequently observed in animals include phlebitis, fever, nausea, and vomiting. Measures to prevent the nausea and vomiting have included administration of antiemetic drugs such as chlorpromazine, maropitant, or metoclopramide prior to infusion (see Chapter 47 on Gastrointestinal Drugs). Hypokalemia and anemia have frequently been reported in humans and therefore should be monitored.

AZOLE ANTIFUNGAL DRUGS

The azole antifungal drugs have a high safety profile, a broad spectrum of activity and are available in topical, oral, and intravenous formulations. There are two main categories of azole antifungal drugs, the imidazoles (clotrimazole, miconazole, ketoconazole) and the triazoles (fluconazole, itraconazole, voriconazole) (Fig. 39.3). Clotrimazole and miconazole are discussed in the section on topical therapy. The important physicochemical differences between azole antifungal drugs are summarized in Table 39.2.

MECHANISM OF ACTION. All azoles exert their antifungal effect on the cell membrane of fungi by inhibiting

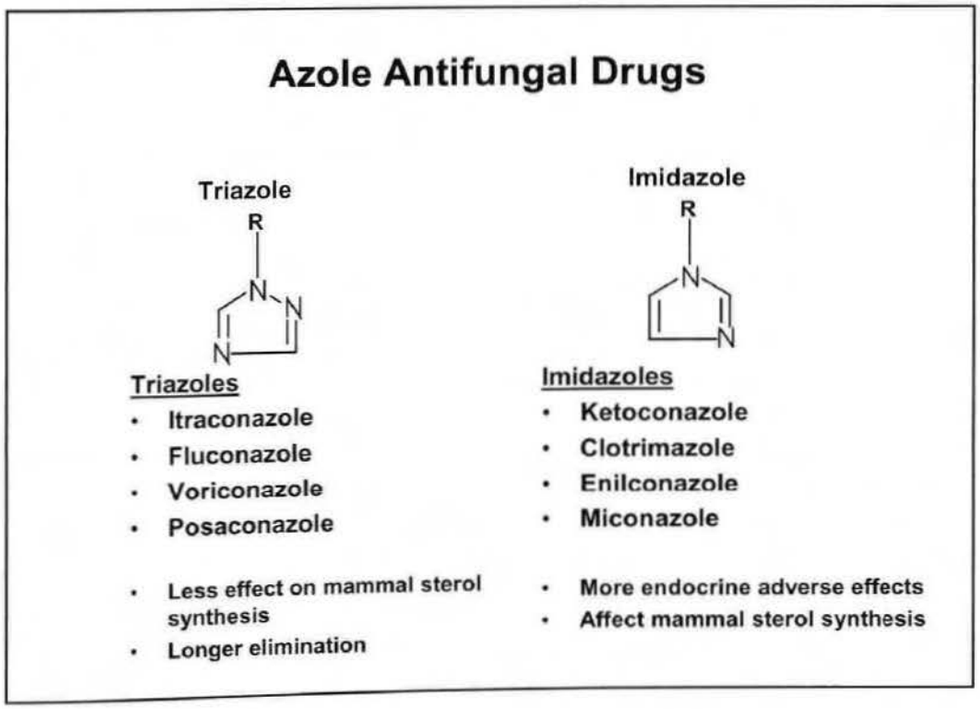

FIG. 39.3 Azole antifungal drugs.

TABLE 39.2 Comparison of the physicochemical properties and in vitro activity of commonly used azole antifungal drugs

					Activity		
Drug	Solubility	pH Dependent	LogP	Protein Binding	Yeasts	Aspergillus	Fusarium
Ketoconazole	pi	Yes	3.78	>90%	+	±	–
Fluconazole	ss	No	0.54	10–12%	+	–	–
Itraconazole	pi	Yes	5.66	>98%	+	±	–
Voriconazole	vss	No	1.81	32–58%	+	+	±

pi = practically insoluble (<0.01 mg/ml); ss = slightly soluble (1–10 mg/ml); vss = very slightly soluble (0–1 mg/ml).

synthesis of the primary sterol of the fungal cell membrane, ergosterol. Inhibition of the P450–dependent lanosterol C_{14}-demethylase enzyme results in depletion of ergosterol and accumulation of C_{14}-methyl sterols in the cytoplasmic membrane of yeasts and filamentous fungi. This enzyme is also known as CYP51A or Erg11p and is encoded by the *ERG11* gene. Inhibition of this cytochrome P450 enzyme occurs via binding of the nitrogen (N_3 of imidazoles and N_4 of triazoles) to the heme iron atom of ferric cytochrome P450. This prevents the formation of the superoxide Fe^{+3} complex ($Fe^{+3}O^{-}$) needed for hydroxylation of methyl sterols. The result is an inability to demethylate C_{14}-methyl sterols and reduced synthesis of ergosterol. Sterols with less planar configurations are then incorporated into the fungal cell wall, which changes membrane fluidity and interferes with the barrier function of the membrane and with membrane-bound enzymes.

Azole drugs are generally fungistatic at concentrations achieved clinically, although this may vary with the strain of fungus and with the drug. For azole drugs, the parameter that correlates best with clinical cure is the total exposure as measured by the area-under-the-curve in relation to the MIC (AUC/MIC ratio) (Goodwin and Drew 2008).

The potency of each azole drug is related to its affinity for binding the P450 enzyme. The selective toxicity of each compound is directly dependent upon its specificity for binding fungal P450 more readily than mammalian P450. Imidazoles are less specific than triazoles and produce side effects in animals attributed to inhibition of P450 enzymes that are responsible for the synthesis of cortisol and reproductive steroid hormones. Azoles may decrease cholesterol, cortisol, androgen, and testosterone biosynthesis and may interfere with several liver enzymes necessary for inactivation of toxic and carcinogenic agents (Polak 1990).

This inhibition of mammalian P450 enzymes is also responsible for drug-drug interactions that have been observed with the azole antifungals. When azoles are administered concurrently with other drugs that are metabolized by these enzymes, they can significantly increase the plasma concentrations of those drugs. Alternatively, when azoles are administered concurrently with drugs that induce the P450 enzymes, the concentrations of the azole drugs may be significantly decreased. The drug-drug interactions important to veterinary medicine are summarized in Table 39.3. The ability to inhibit mammalian P450 enzymes, and therefore the likelihood of drug-drug interactions, is greatest with ketoconazole, followed by itraconazole, voriconazole, and fluconazole.

Another method by which the azole antifungals can interfere with the absorption and pharmacokinetics of concurrently administered medications is through inhibition of the P-glycoprotein efflux pumps. These efflux pumps can be found in the intestine, where they limit the absorption of some substrates, as well as in the liver, kidney, eye, and CNS. Azole antifungals have the ability to inhibit P-glycoprotein pumps and therefore increase the oral absorption and tissue distribution of drugs within the body, particularly into protected sites, such as the blood-brain barrier and the blood-retinal barrier. The ability to inhibit P-glycoprotein is greatest with itraconazole, followed by ketoconazole and voriconazole (Wang et al. 2002). Fluconazole has little interaction with P-glycoprotein, which may explain why it has fewer significant drug interactions compared to the other azole antifungals (Yasuda et al. 2002; Wang et al. 2002).

KETOCONAZOLE. Ketoconazole (Nizoral®), one of the imidazoles, became available in 1979. The results of successful use in veterinary medicine was published shortly thereafter (Legendre et al. 1982; Medleau et al. 1985). Ketoconazole is available in 200 mg tablets, and generic formulations are inexpensive and readily available.

TABLE 39.3 Antifungal drug-drug interactions of significance in veterinary medicine*

	Drug/Drug Class	Result
Griseofulvin	Anticoagulants/Coumarin or inandione derivatives	Griseofulvin is a hepatic enzyme inducer, which may increase the metabolism of these drugs, resulting in decreased anticoagulant effects.
	Barbiturates	Impaired absorption and therefore possibly impaired effectiveness of griseofulvin.
Amphotericin B	Bone marrow depressants	Increased risk of anemia or other blood dyscrasia.
	Corticosteroids	Exacerbation of hypokalemia, particularly with those drugs that have significant mineralocorticoid activity.
	Digoxin	Hypokalemia caused by AmpB increases the potential for digitalis toxicity.
	Neuromuscular blocking agents	Hypokalemia caused by AmpB enhances the blockade of nondepolarizing agents.
	Diuretics	Potassium depleting diuretics will exacerbate hypokalemia.
	Flucytosine	Synergism of AmpB with flucytosine may decrease the dose of AmpB necessary, therefore reducing the nephrotoxicity, however AmpB-induced renal dysfunction may increase 5-FC concentrations, thus increasing the potential for blood dyscrasias.
Azole antifungals	Drugs that increase gastric pH	Decreases the absorption of those drugs with a pH-dependent solubility (ketoconazole and itraconazole only).
	Digoxin	Increased plasma concentrations of digoxin resulting from P450 inhibition may lead to increased digitalis toxicity.
	Benzodiazepines	Increased plasma concentrations of benzodiazepines, particularly midazolam, resulting from P450 inhibition may result in potentiation of the sedative effects of these drugs.
	Glipizide	Increased plasma concentrations of glipizide resulting from P450 inhibition may cause hypoglycemia.
	Second-generation antihistamines	Although identified in people, and not animals, there may be increased plasma concentrations of antihistamines resulting from P450 inhibition, which may result in cardiac arrhythmias, including ventricular tachycardia and torsades de pointes; not seen with fluconazole except at very high doses.
	Warfarin	Increased plasma concentrations of warfarin resulting from P450 inhibition may cause increased anticoagulant effects and bleeding.
	Cisapride	Although identified in people, and not animals, there may be increased plasma concentrations of cisapride resulting from P450 inhibition, which may result in ventricular arrhythmias, including torsades de pointes.
	Cyclosporine	Increased plasma concentrations of cyclosporine resulting from P450/P-gp inhibition may require adjustment of cyclosporine doses; has been used clinically to decrease the cost of cyclosporine treatment; not seen with fluconazole except at very high doses.
	Quinidine	Increased plasma concentrations of quinidine resulting from P450/P-gp inhibition may lead to increased quinidine toxicity.
	Nifedipine	Increased plasma concentrations of nifedipine resulting from P450/P-gp inhibition.
	Hydrochlorthiazide	Hydrochlorthiazide decreases the renal elimination of fluconazole, resulting in increases of fluconazole plasma concentrations.
	Carbemazapine	Induction of P450 enzymes by carbemazapine may decrease the plasma concentrations of antifungal drugs.
	Rifampin	Induction of P450 enzymes by rifampin may decrease the plasma concentrations of antifungal drugs.
	Phenytoin	Induction of P450 enzymes by phenytoin may decrease the plasma concentrations of antifungal drugs.
	Phenobarbital	Induction of P450 enzymes by phenobarbital may decrease the plasma concentrations of antifungal drugs.
Flucytosine	Bone marrow depressants	May exacerbate bone marrow toxicities.
	Nephrotoxic agents	May decrease flucytosine clearance, increasing the potential for bone marrow toxicity.
Terbinafine	*There are no reported drug-drug interactions with terbinafine.*	

*Not all of these interactions have been documented in veterinary medicine, but are present in human medicine and should be monitored for in veterinary patients.

Spectrum of Activity. Ketoconazole is most effective against yeast and dimorphic fungi such as *Candida, Malassezia (Pityrosporum) pachydermatis, C. immitis, H. capsulatum,* and *B. dermatitidis,* as well as most dermatophytes with MIC values less than 0.5 μg/ml. It is less effective against *C. neoformans, S. schenckii,* and *Aspergillus* spp., with MIC values varying from 6 to >100 μg/ml (Hume and Kerkering 1983).

Pharmacokinetics. Ketoconazole is relatively insoluble, except in an acid environment. It is not well absorbed orally unless there is acid secretion, such as after a meal. Ketoconazole is highly protein bound (>98%) and therefore does not penetrate into the cerebrospinal, seminal, or ocular fluid to a significant degree; although it is found in mother's milk. It distributes throughout the skin and subcutaneous tissue, making it effective for treatment of superficial and systemic fungal skin infections. The drug demonstrates nonlinear absorption and elimination kinetics, most probably due to saturation of metabolizing enzymes. It is biotransformed in the liver via O-dealkylation and aromatic hydroxylation and excreted mainly in the bile. Elimination half-life is approximately 2 hours in dogs.

Because ketoconazole is soluble only in acid aqueous environments (pH <3), gastric alkalizing agents (e.g., antacids, H_2 blockers, and parietal cell proton pump inhibitors) or diseases resulting in achlorhydria will decrease its dissolution and oral absorption. Because of lack of consistent gastric acidity, ketoconazole is absorbed poorly in horses. When ketoconazole was administered at 30 mg/kg to horses in corn syrup, the drug was not detected in serum; however, when it was administered with 0.2 N hydrochloric acid intragastrically, oral absorption increased but systemic availability was only 23% with peak serum concentrations of 3.76 μg/ml (Prades et al. 1989).

Clinical Use. In people, ketoconazole has been replaced in therapy by safer triazole antifungal drugs. But in veterinary medicine, owing to ketoconazole's efficacy, safety, cost, and ease of administration, it is still a popular antifungal agent. For dermatophytosis in cats, 10 mg/kg/day has been used (Medleau and Chalmers 1992). For candidiasis, 10 mg/kg/day for 6–8 weeks is recommended. For canine blastomycosis, histoplasmosis, cryptococcosis, and coccidioidomycosis, the dosage is 10–20 mg/kg every 12 hours. Ketoconazole was also effective in treating nasal cryptococcosis in a dog at a dose of 10 mg/kg/day (Noxon et al. 1986). For *Malassezia* dermatitis in dogs, dosages of 5–10 mg/kg/day have been recommended (Hill et al. 1995). The duration of treatment is highly variable. Four to six weeks is a minimum for most diseases; many patients with blastomycosis are treated for a minimum of 2 months and as long as 6 months. If there is CNS involvement, particularly with cryptococcosis, higher doses (40 mg/kg) may be necessary to improve penetration into the CNS. Cats have been successfully treated for cryptococcosis with a dosage of 10–15 mg/kg/day (Pentlarge and Martin 1986; Legendre et al. 1982; Medleau et al. 1985). As complete eradication of the fungal organism is difficult, relapse is common. For this reason, infections should be treated beyond the time clinical signs have resolved. Ketoconazole is not absorbed well orally in horses and it is not recommended. There are no approved formulations for use in food animals.

There are other uses of ketoconazole not related to the treatment of fungal infections. Because of its inhibitory effect on P450 and P-glycoprotein, administration of ketoconazole concurrently with cyclosporine for the treatment of immune diseases has been used to reduce the dose of cyclosporine by up to 75% and reduce the cost of cyclosporine therapy by 58% (Dahlinger et al. 1998).

Ketoconazole inhibits the synthesis of steroid hormones (via inhibition of the cytochrome P450 enzymes), most notably cortisol and testosterone. Although this may be a side effect of therapy, it has been exploited for the temporary management of hyperadrenocorticism in dogs (Bruyette and Feldman 1988; Feldman et al. 1990) and as an antiandrogen treatment. Steroid synthesis inhibition is only a temporary effect that persists only during dosing with ketoconazole (e.g., for up to 8 hours). Ketoconazole will not produce permanent hypoadrenocorticism.

Adverse Effects. Nausea, anorexia, and vomiting are the most common adverse effects, and may require cessation of therapy, particularly in cats (Medleau and Chalmers 1992). They are usually dose related and may be diminished by decreasing the dose, dividing the total dose into smaller doses, and administering each dose with food. With chronic therapy pruritus, alopecia, lightening and drying of the hair coat, and weight loss may occur (Greene 1990). Slight to moderate elevations of inducible hepatic enzymes are expected and may not be accompanied by hepatic injury. However, high elevations in hepatic enzymes, accompanied by other parameters (hyperbiliru-

binemia and clinical signs consistent with hepatic disease), may indicate hepatotoxicosis. Idiosyncratic hepatitis has been reported in animals and people (Janssen and Symoens 1983).

Ketoconazole is very potent at inhibiting fungal P450, but it also inhibits mammalian P450 at relatively low concentrations; therefore, side effects and drug interactions can occur. This includes inhibition of P450(17α) catalyzed conversion of progestins to androgens. Dose-related inhibition of testosterone has resulted in gynecomastia, sexual impotence, and azoospermia. Cats appear to be more sensitive to ketoconazole liver toxicity than are dogs but they are less sensitive to the hormonal suppressive side effects (Willard et al. 1986a,b).

Ketoconazole has been shown to be teratogenic in the rat and has resulted in mummified fetuses and stillbirths in dogs. It is therefore not recommended for use in pregnant or lactating animals. Cataracts have been reported after long-term ketoconazole therapy in dogs (de Costa et al. 1996). The average duration of therapy in affected dogs was 15 months, and dosages ranged from 6 to 31 mg/kg/day. These dogs were not diabetic. The mechanism of this reaction is not known.

FLUCONAZOLE. Fluconazole (Diflucan and generic) has replaced ketoconazole in small animals and birds for many indications. The triazole groups result in increased resistance to metabolic attack, in vivo potencies 100 times that of ketoconazole, and significantly increased aqueous solubility (8 mg/ml) (Richardson et al. 1990). Because of these properties, this compound has good efficacy in animal models and pharmacokinetics properties that are improved over other azole antifungal drugs such as ketoconazole or itraconazole. It is available in 50–200 mg tablets, powder for oral suspension, and a 2 mg/ml parenteral formulation. Compounded formulations have good oral bioavailability and can be used with a reasonable expectation of performance.

Spectrum of Activity. Fluconazole has been shown to be effective in animal models of *Blastomyces, Candida, Coccidioides, Cryptococcus,* and *Histoplasma* infections. It is not particularly active against *Aspergillus.* Resistant *Aspergillus* strains have been increasing in human medicine with MICs often >256 μg/ml. For this reason, fluconazole should not be used as a first choice for the treatment of aspergillosis unless sensitivity has been documented and can be monitored.

Efficacy of fluconazole in people has been associated with AUC/MIC ratios as being the best predictor of cures. A ratio above 25 is considered desirable for the best outcome (Goodwin and Drew 2008).

Pharmacokinetics. Fluconazole has different solubility characteristics than ketoconazole and itraconazole and is absorbed well regardless of the circumstances. Feeding or formulation (liquid versus tablet) does not affect absorption. Fluconazole demonstrates linear absorption kinetics, with bioavailability greater than 90% in most species (Brammer et al. 1990); thus, oral and IV dosages are identical. Maximum fluconazole concentrations are reached 1–4 hours after an oral dose. Unlike other azole antifungals, fluconazole is not highly protein bound. Humphrey et al. (1985) found plasma protein binding to be between 10 and 12% at concentrations of 0.1 and 1 μg/ml in mice, rats, dogs, and humans. Similar protein binding has also been documented in horses (12.3%) at a concentration of 5 μg/ml. Fluconazole's low molecular weight, water solubility, and high unbound fraction allow it to be readily distributed throughout the body, including pharmacokinetically privileged spaces. Drug concentrations in saliva, sputum, skin, nails, blister fluid, and vaginal tissue and secretions were found to be similar to plasma concentrations. The advantages of fluconazole lie in its ability to produce higher CSF concentrations than ketoconazole or itraconazole, and therefore, it may be useful for treating mycotic meningitis (Kowalsky and Dixon 1991). Fluconazole CSF/plasma or CSF/serum concentration ratios range from 0.49 in horses (Latimer et al. 2001) to 0.88 in cats (Vaden et al. 1997). The drug also penetrates well into the aqueous humor with ratios of aqueous : plasma of 0.37 in the horse and 0.79 in the cat.

Fluconazole is eliminated principally by the kidney. A unique feature of fluconazole is that this drug is the only one of the azoles that is water soluble and excreted in the urine in an active form; therefore, it may be one of the few drugs useful for treating fungal cystitis. As can be expected with a renally excreted drug, renal dysfunction affects fluconazole's elimination such that dose adjustments are necessary. When patients with normal renal function were compared with those with severe renal insufficiency, fluconazole's elimination half-life nearly tripled (from 30.1 hr to 84.5 hr) (Dudley 1990). Reduced dosages as well as extended dosing intervals have been recommended in renal insufficiency. The disparity between renal fluconazole clearance and creatinine clearance suggests

that net tubular reabsorption is responsible for the extended half-life. Half-life was measured to be approximately 14 hours in dogs, 13–25 hours in cats (Vaden et al. 1997; Craig et al. 1993), and 38 hours in horses (Latimer et al. 2001). Steady-state levels are achieved in 5–7 days; thus, the manufacturer suggests a two times loading dose during the first 12–24 hours (Dudley 1990). The lack of significant hepatic metabolism allows for linear elimination kinetics; i.e., half-life is independent of dose.

Clinical Use

Small Animals. Fluconazole is most often used for treatment of dermatophytes. Although not as active against *Aspergillus* or *Penicillium* as other azoles, it has also been used to treat canine nasal aspergillosis and penicilliosis. Ten affected dogs were treated with 2.5–5 mg/kg/day fluconazole orally for 8 weeks. Six dogs became free of disease 2–4 weeks after cessation of therapy and remained free of disease for at least 6 months. Serum alkaline phosphatase and alanine transaminase activity remained within normal ranges throughout the treatment period, and adverse side effects were not noted (Sharp 1991). Doses as high as 10–12 mg/kg/day have also been recommended in dogs. For cats with systemic cryptococcosis, clinical studies have shown a benefit from a dose of 100 mg/cat/day in one or two divided doses. Other reported doses are 2.5–5 mg/kg once a day (Hill et al. 1995). Pharmacokinetic studies support a dose of 50 mg/cat per day for nasal or dermal cryptococcosis (Vaden et al. 1997).

Exotic Animals. The doses for exotic animals are listed in Table 39.4. The half-life can be prolonged in reptiles because of the dependence on renal elimination. Subsequently the half-life is 139 hours when injected SC, which allows for treatment every 5 days (Mallo et al. 2002).

Large Animals. Oral absorption in horses is reported to be greater than 100% (Latimer et al. 2001). From this cited study a dosing regimen of a loading dose of 14 mg/kg orally, followed by 5 mg/kg q24h was derived for horses to produce sufficient concentrations in plasma and tissues. This dose has been successful in treating nasal conidiobolomycosis lesions in mares (Taintor et al. 2004) as well as disseminated candidiasis in foals (Reilly and Palmer 1994).

Adverse Effects. Fluconazole has been generally well tolerated, with mild adverse effects being reported in 5–30% of cases. The GI tract was most frequently involved, followed by the CNS and skin. Mild elevations in hepatic enzymes have been observed, and two cases of hepatic necrosis and death occurred in association with fluconazole therapy (Kowalsky and Dixon 1991). Compared to ketoconazole, there is little evidence of testosterone or other steroid biosynthesis inhibition (Shaw et al. 1987) in human or animal patients (VanCauteren et al. 1987). Hematologic abnormalities, including anemia, leukopenia, neutropenia, and thrombocytopenia, have been reported in people (AHFS Drug Information 1992). In subacute toxicity studies in dogs the highest dose tested (30 mg/kg) caused slight increases in liver weight, hepatic fat, and plasma transaminase activity. Although there is no evidence of mutagenicity or carcinogenicity, its use in pregnant patients is not recommended.

ITRACONAZOLE. Itraconazole (Sporanax®) was approved for use in the United States in 1992. Of several triazole compounds screened, itraconazole, first synthesized in 1980, was selected for further clinical development due to several criteria: 1) 5–100 times better in vitro and in vivo potency than ketoconazole, 2) good activity against *Aspergillus* spp., 3) activity against meningeal cryptococcosis in animal models, 4) few adverse side effects, and 5) favorable pharmacokinetics (Cauwenbergh et al. 1987).

Itraconazole is a weak base ($pK_a = 3.7$), is highly lipophilic (log P = 5.66), and is practically insoluble in water. There are several different formulations available. The intravenous formulation is rarely used in veterinary medicine due to expense as well as instability once reconstituted. There are three oral formulations available. The oral capsules were the first formulation marketed and they are still commonly used. They are available in 100 mg dose strength, and consist of drug coated onto small sugar spheres. The capsules require an acid environment for dissolution and therefore absorption is often highly variable. There is also an oral solution licensed for use in humans that contains 10 mg/ml of itraconazole complexed with hydroxypropyl-β-cyclodextrin, to increase the solubility. This product has been demonstrated to have higher, less variable absorption in humans, cats, and horses (Willems et al. 2001; Boothe et al. 1997; Davis et al. 2005). A third oral formulation is licensed for use in cats in some European countries (Itrafungol Vet®, Janssen-Cilag). This formulation is also an oral solution (10 mg/ml itraconazole) with propylene glycol, srobitol, and flavorings as excipients. Because of its low and highly pH-dependent solubility, compounded formulations of itraconazole are often not stable and not well absorbed; therefore, their use is not recommended.

Spectrum of Activity. Itraconazole has been tested both in vitro and in vivo against a wide variety of fungi (for review see Perfect et al. 1986; VanCutsem et al. 1987; VanCutsem 1990; Cauwenbergh and DeDonker 1987). It was found to be effective against virtually all medically important fungi, including *Microsporum, Trichophyton, Candida, Malassezia* (*Pityrosporum*), *Sporothrix, Pythium, Histoplasma, Aspergillus, Blastomyces, Coccidioides,* and *Cryptococcus.* It has little activity against *Fusarium* sp.

Like other azole antifungal drugs, the AUC/MIC is the best surrogate marker to predict efficacy. However, the most often reported drug concentrations from studies in humans have been the plasma concentrations measured at the lowest point (trough, or C_{MIN}) during multiple dosing. In these studies (Goodwin and Drew 2008) the trough concentrations greater than 0.5 to 1.0 μg/ml have been associated with clinical success.

Pharmacokinetics. Absorption is increased by an acid environment and when taken with meals (Graybill 1990) and is less variable than ketoconazole absorption. Bioavailability increases from 40% after fasting to 99.8% when given with a meal (VanCauteren et al. 1987), except in horses. Itraconazole is highly (99.8%) protein bound (95% to albumin and 5% to red blood cells) (Heykants et al. 1987); however, due to its lipophilicity and even higher affinity for tissue proteins, it is extensively distributed throughout the body. Tissue to plasma concentration ratios range from 1:1 in brain to 8:1 in keratin to 25:1 in fat stores. Highest tissue levels are seen in the liver and adrenal cortex (Heykants et al. 1987). High tissue binding also produces a very large volume of distribution (Troke et al. 1990; Heykants et al. 1990) and low plasma concentrations. Although it does not reach high concentrations in the CSF compared to fluconazole, itraconazole was found to be effective in treating meningeal cryptococcosis in both mouse and guinea pig models (Perfect et al. 1986).

Itraconazole is extensively metabolized, with less than 1% of the active drug and approximately 35% of inactive drug (as more than 10 metabolites) excreted in the urine. The major metabolite, hydroxyitraconazole, has similar antifungal activity to the parent drug, and is often found at concentrations 2–3 times higher than itraconazole in the plasma in humans (Willems et al. 2001). The metabolite to parent drug ratio is reported to be similar in dogs (Yoo et al. 2002); however, this metabolite has not been found in either cats (Itrafungol®, package insert) or horses (Davis et al. 2005). The predominant route of elimination for itraconazole is in the bile. Due to the increased metabolic stability of the triazole ring versus the imidazole ring (Richardson et al. 1990), itraconazole has a longer half-life (17–25 hr) than ketoconazole (8 hr) in humans. There is disagreement about the elimination rate since the terminal half-life in the dog has been reported to be 8–12 hours (VanCauteren et al. 1987) and 44–58 hours (Heykants et al. 1987). Differences in study methods, assay sensitivity, and pharmacokinetic analysis may account for this discrepancy. More important than plasma half-life, therapeutically active concentrations are maintained much longer in tissues than in plasma. For example, itraconazole can be detected for 4 days in vaginal epithelium and for 4 weeks in skin and nails after cessation of therapy. These long-lasting tissue concentrations account for the ability to administer this drug intermittently for some fungal infections, as will be discussed below in the dosing section. Itraconazole, like ketoconazole, exhibits nonlinear pharmacokinetics; steady-state concentrations were found to be three times higher after 14 days of therapy than those predicted by a single dose, and the half-life was seen to increase from 24 to 36 hours (Heykants et al. 1990).

Pertinent to the pharmacokinetics is the ability of itraconazole to inhibit drug metabolizing enzymes. Itraconazole and its metabolites are cytochrome P450 inhibitors (Templeton et al. 2008). Metabolizing enzymes may be saturated producing nonlinearity in elimination. In addition, repeated dosing may produce a time-dependent decrease in clearance and accumulation (Templeton et al. 2008). Therefore, with repeated dosing, the clearance may decrease and half-life increase.

Clinical Use

Small Animals. Itraconazole is considerably more potent than ketoconazole (5 to 100 times more active) and is associated with fewer side effects. It has no endocrine effects compared to ketoconazole. Itraconazole is highly bound in plasma and there is strong binding to keratin producing drug concentrations in skin that persist 2–4 weeks after cessation of drug therapy. It may be excreted into the sebum, increasing the concentrations in skin. This allows for pulse-dosing for some diseases, which is described in the dosing section.

Histoplasma, Cryptococcus, and *Blastomyces* are highly susceptible; *Candida, Aspergillus,* and *Penicillium* are less sensitive. Itraconazole also has been used to treat cutaneous Leishmaniasis because the *Leishmania* organism has ergosterol in high concentrations in its cell wall.

Cats. Itraconazole is probably better tolerated in cats than ketoconazole. Nevertheless, toxic reactions still are possible. Since most adverse effects are dose-related, one is advised to lower the dose in animals in which adverse effects are observed. One report indicated that there were dose-related GI effects of anorexia and vomiting in cats from administration of itraconazole (Mancianti et al. 1998).

The dosing regimens for cats were reviewed by Moriello (2004). Doses in cats vary from 5–10 mg/kg once a day, orally for at least 56 days, to 10 mg/kg once a day, for 28 days, followed by pulse therapy of 1 week on/1 week off. Lower doses of 1.5 to 3 mg/kg once daily for cycles of 15 days at a time are also used.

The recent addition of a commercially available registered formulation has helped to define the use in cats. As mentioned previously, itraconazole (Itrafungol) 10 mg/ml oral solution is registered for use in cats to treat dermatophytosis (not registered in the U.S.). The treatment schedule consists of once-daily doses of 5 mg/kg for three 1-week cycles. After each week of treatment, it should be followed by a week without treatment (week-on/week-off schedule). This schedule has been evaluated in cats and maintains drug concentrations in hairs during the nontreatment phase (Vlaminck and Engelen 2004).

Itraconazole has been compared to ketoconazole, with each drug administered at doses of 10 mg/kg/day for the treatment of experimentally induced feline disseminated cryptococcosis (Medleau et al. 1990). After 3 months of therapy, the infection had been cleared by both drugs as determined by cryptococcal antigen titers and CSF culture. Three months following therapy all animals remained clinically normal, and titers and CSF cultures remained negative. Although both antifungals brought about resolution of the disease, all cats receiving ketoconazole became anorectic and lost weight, requiring dosage adjustments. This was not seen with itraconazole, and in fact the animals receiving this drug gained weight during the study. Itraconazole has also been used in naturally occurring cryptococcal infections (Medleau 1990), where an increase in treatment failure was noted in cats that were seropositive for FIV or FeLV.

Dogs. In dogs, the most extensive study has been for treatment of blastomycosis (Legendre et al. 1996). In a study of 112 dogs, 5 mg/kg/day was as effective as 10 mg/kg/day. With a 60-day course of therapy, 54% of dogs were cured. Itraconazole has been used to treat ocular and systemic blastomycosis in dogs. When given 5 mg/kg itraconazole twice a day for 60 days, 76% of eyes with posterior segment disease other than optic neuritis and 18% and 13% of eyes with anterior uveitis or endophthalmitis, respectively, recovered (Brooks et al. 1992). Pulse dosing has also been evaluated in dogs. Itraconazole doses of 5 mg/kg PO q24h for 2 consecutive days per week for 3 weeks was found to be as effective as a dose of 5 mg/kg PO q24 for 21 consecutive days in the treatment of *Malassezia* dermatitis and otitis (Pinchbeck et al. 2002).

Itraconazole has been successfully used in both the prevention and the treatment of aspergillosis in caged birds. A dose of 20 mg/kg daily for at least 30 days was used to successfully treat 5 of 12 presumed cases of *Aspergillus* infections in penguins. This same author suggests its prophylactic use in penguin chicks (Shannon 1992). A different treatment protocol was recommended for aspergillosis in raptors. Birds are treated with 10 mg/kg twice daily in combination with amphotericin B nebulization three times a day for 20 minutes. Treatment for some cases lasted as long as 6 weeks. These authors also recommend the prophylactic use of itraconazole whenever the clinician expects increased risk for the disease (Forbes et al. 1992). Other antifungal dosing regimens in birds and other exotic animal species are listed in Table 39.4.

Large Animals. Itraconazole has been reported to be effective in horses for the treatment of mycotic rhinitis, osteomyelitis, and guttural pouch mycosis (Korenek et al. 1994; Foley and Legendre 1992; Davis and Legendre 1994). A recent pharmacokinetic study showed that the oral solution at a dose of 5 mg/kg q24h will produce adequate levels in blood and tissues for successful treatment (Davis et al. 2005). However, the use of the oral liquid will require large volumes—most likely requiring gastric lavage in horses—and the drug is very expensive. The oral capsules have a lower bioavailability and higher doses or more frequent dosing intervals are recommended. There are no reports of the use of this drug in food animals, and there are no approved formulations for these species.

Adverse Effects. Itraconazole is up to 125 times more selective for fungal P450 systems than mammalian liver enzymes in certain in vitro preparations (Vanden Bossche 1987). It also does not inhibit P450 systems in the testis, adrenal, or liver in vivo (Vanden Bossche et al. 1990). In clinical studies, 100 mg of itraconazole given to humans each day for 30 days had no effect on serum testosterone

TABLE 39.4 Selected systemic antifungal drugs used in exotic animal species

Species	Drug	Disease Treated	Dosing Protocol	Reference
Passerine and Softbill Birds	Fluconazole	Candidiasis	2–5 mg/kg PO q24h for 7–10 days.	Dorrestein 2000
	Griseofulvin	Dermatophytosis	20 mg/kg PO q24h for 4–6 weeks	
	Itraconazole	Aspergillosis	5–10 mg/kg PO q12–24h in orange juice or 0.1N HCl for 14 days.	
	Ketoconazole	Dermatophytosis	20–30 mg/kg PO q12h for 14–30 days.	
	Miconazole	Candidiasis or Cryptococcosis	10–20 mg/kg IM or IV q8–24h.	
	Nystatin	Intestinal candidiasis	100,000 IU/l of drinking water or 200,000 IU/kg soft food for 3–6 weeks.	
Psittacine Birds	Fluconazole	Candidiasis	2–5 mg/kg PO q24 h for 7–10 days.	Tully 2000
	Flucytosine	Aspergillosis	60–150 mg/kg PO q12h in adults; 100–250 mg/kg PO q12h in neonates. Usually given in combination with amphotericin B.	
	Itraconazole	Aspergillosis	5–10 mg/kg q12h for 4–5 weeks; 5 mg/kg q24h in African grays.	
	Ketoconazole	Candidiasis	20–30 mg/kg q12h in orange or pineapple juice, lactulose, or methylcellulose for 14–30 days.	
	Voriconazole	Asperigillosis	12–18 mg/kg oral q12h	Flammer et al. 2008
	Miconazole	Candidiasis or Cryptococcosis	20 mg/kg IV q8h.	
	Nystatin	Intestinal candidiasis	100,000–300,000 IU/kg PO q8–12h.	
Raptors	Fluconazole	Mycelial candidiasis, systemic mycosis	5–15 mg/kg PO q12h for 14–60 days.	Huckabee 2000
		Gastrointestinal and systemic candidiasis	2–5 mg/kg PO q24h for 7–10 days.	
	Flucytosine	Aspergillosis	120 mg/kg PO q6h; 20–30 mg/kg PO q6h for 60–90 days; 50–75 mg/kg PO q8h in combination with amphotericin B.	
		Candidiasis	250 mg/kg PO q12h.	
	Itraconazole	Aspergillosis	15 mg/kg PO q12h for 4–6 weeks.	
	Ketoconazole	Candidiasis	15 mg/kg PO q12h.	
		Aspergillosis	30–60 mg/kg PO q12h for 14–30 days.	
	Nystatin	Intestinal candidiasis	100,000–300,000 IU/kg PO q8–12h.	
Pet Fish	Itraconazole	Systemic Mycoses	1–5 mg/kg q24h in feed for 1–7 days.	Mashima and Lewbart 2000
	Ketoconazole	Systemic Mycoses	2.5–10 mg/kg PO, IM or ICe.	
Ferrets	Amphotericin B	Systemic mycoses	0.4–0.8 mg/kg IV once a week to a total dose of 7–25 mg.	Williams 2000
	Griseofulvin	Dermatophytosis	25 mg/kg PO q24h for 3–4 weeks.	
	Ketoconazole	Systemic mycoses	10–30 mg/kg PO q12h–24h.	
Hedgehogs	Griseofulvin	Dermatophytosis	25–50 mg/kg PO q24h	Lightfoot 2000
	Itraconazole	Systemic mycoses	5–10 mg/kg PO q12–24h.	
	Ketoconazole	Systemic yeast/fungal infections	10 mg/kg PO q24h.	
	Nystatin	Yeast infections	30,000 IU/kg PO q8–24h.	
Marsupials	Griseofulvin	Dermatophytosis	20 mg/kg PO q24h for 30–60 days.	Johnson-Delaney 2000
	Nystatin	Candidiasis	5000 IU/kg q8h for 3 days.	
Rabbits	Amphotericin B	Systemic mycoses	1 mg/kg IV q24h.	Ivey and Morrisey 2000
	Fluconazole	Systemic mycoses	25–43 mg/kg slow IV q12h.	
	Griseofulvin	Dermatophytosis	12.5–25 mg/kg PO q12–24h for 10–42 days.	
	Ketoconazole	Dermatophytosis	10–40 mg/kg PO q24h for 14 days.	

TABLE 39.4—*continued*

Species	Drug	Disease Treated	Dosing Protocol	Reference
Rodents	Amphotericin B	Candidiasis	0.43 mg/kg PO or 0.11 mg/kg SC in mice.	Adamcak and Otten 2000
	Griseofulvin	Dermatophytosis	25 mg/kg PO q24h for 14–28 days in gerbils, guinea pigs, hamsters, and rats; 14 days in mice; 28–40 days in chinchillas.	
	Itraconazole	Systemic mycoses	5 mg/kg PO q24h in guinea pigs; 50–150 mg/kg q24h in mice; 2.5–10 mg/kg PO q24 in rats.	
	Ketoconazole	Systemic mycoses/candidiasis	10–40 mg/kg PO q24h for 14 days in all species.	
Amphibians	Amphotericin B	Systemic mycoses	1 mg/kg ICe q24h for 14–28 treatments.	Walker and Whitaker 2000
	Fluconazole	Systemic mycoses	60 mg/kg PO q24h for 7 days.	
	Itraconazole	Superficial and systemic mycoses	2–10 mg/kg PO q24h for 14–28 days.	
	Ketoconazole	Systemic mycoses	10–20 mg/kg PO q24h for 14–28 days.	
Chelonians	Amphotericin B	Aspergillosis	1 mg/kg ICe q24h for 2–4 weeks.	Bonner 2000
	Griseofulvin	Dermatophytosis	20–40 mg/kg PO q72h for 5 treatments.	
	Itraconazole	*Sceloporus* sp.	20–30 mg/kg PO q6–8h in the spiny lizard.	
	Ketoconazole	Systemic mycoses	25 mg/kg PO q24h for 2–4 weeks in turtles; 15 mg/kg PO q24h (27°C) in the gopher tortoise.	
	Nystatin	Enteric fungal infections	100,000 IU/kg PO q24h for 10 days in turtles.	
Reptiles	Amphotericin B	Systemic mycoses	1 mg/kg IT q24h for 14–28 days.	Funk 2000
	Fluconazole	Systemic mycoses	2–5 mg/kg PO q24h for 5–21 days in lizards and snakes; can also mix 100 mg with 20 ml of nystatin and give PO at 0.5–0.6 ml/kg.	
	Fluconazole		For sea turtles, a loading dose of 21 mg/kg, followed by 10 mg/kg every 5 days, injected SC (Mallo et al. 2002).	
	Griseofulvin	Dermatophytosis	20–40 mg/kg PO q72h for 5 treatments in snakes.	
	Ketoconazole	Superficial and systemic mycoses	25 mg/kg PO q24h for 3 weeks in snakes.	
	Nystatin	Enteric fungal infections	100,000 IU/kg PO q24h.	

or cortisol levels (DeCoster et al. 1987). Similarly, there were no changes in testosterone and cortisol concentrations in rats and dogs receiving daily itraconazole for at least 1 month.

The biochemical basis for the specificity of itraconazole toward fungal P450 is thought to be dependent upon the hydrophobic nonligand portion of the molecule and its affinity for the apoprotein portion of the cytochrome molecule (Vanden Bossche et al. 1990). The resulting lack of significant inhibition of liver microsomal enzymes results in itraconazole's inability to affect other drugs' metabolism. Although the clinical significance is as yet unknown, drugs that can inhibit or stimulate liver degradative enzymes are able to alter the pharmacokinetics of itraconazole. Even though itraconazole is primarily cleared by hepatic metabolism, there appears to be no need for dosage adjustments in patients with liver disease (Heykants et al. 1987). As with ketoconazole, itraconazole's oral absorption is pH dependent; therefore, dosage adjustments may be necessary when gastric pH is increased.

Because itraconazole is better tolerated than ketoconazole, it is used as the drug of choice for long-term treatment. Dogs, cats, and exotic and zoo animals have received this drug for weeks without adverse effects. The capsules have been administered for up to 6 months in horses with no reported adverse effects. Nevertheless, toxic reactions are still possible. Since most adverse effects are dose related, one is advised to lower the dose in animals in which adverse effects are observed. According to Legendre (1995) about 10% of dogs receiving recommended doses develop

hepatic toxicosis. Liver enzyme elevations may occur in 10–15% of dogs. Itraconazole has been well tolerated by clinically ill cats, although one case of fatal drug-induced hepatitis has been reported (Medleau 1990). Anorexia may occur as a complication of treatment, especially with high doses and high serum concentrations. It usually develops in the second month of therapy in dogs. In cats there seem to be dose-related GI effects of anorexia and vomiting (Mancianti et al. 1998). Drug-related cutaneous vasculitis has also been reported as a complication of itraconazole therapy in dogs (Nichols et al. 2001).

Dogs chronically administered itraconazole (2.5, 10, or 40 mg/kg daily for 3 months) had no significant alterations in mortality rate, behavior, appearance, food consumption, body weight, hematologic values, serum and urine chemistry, or gross pathology (VanCauteren et al. 1987b). Subacute toxicity studies in rats revealed increased adrenal gland weight and the accumulation of proteinaceous material in the mononuclear phagocyte system at doses of 40 and 160 mg/kg. Since the mononuclear phagocyte system is responsible for clearing the host of a fungal infection, the clinical importance of this toxic effect remains to be seen. Although not teratogenic at 10 mg/kg, maternal toxicity, embryo toxicity, and teratogenicity were observed at 40 and 160 mg/kg in rats (VanCauteren et al. 1987b); therefore, its use in pregnant animals is not recommended.

Postmarketing drug monitoring in humans has shown that itraconazole may cause or exacerbate underlying heart conditions. There is a dose-related negative inotropic effect seen in both healthy human volunteers and in anesthetized dogs. Owners should therefore be counseled to monitor the patients for signs of heart failure and to discontinue the drug if clinical signs are observed.

Mild to moderate renal failure has not been reported to change the pharmacokinetic clearance of itraconazole in humans. However, if the intravenous formulation or the oral Sporanox® solution is used, renal failure may decrease the elimination of the carrier molecule hydroxypropyl-β-cyclodextrin. Therefore, the oral capsules are recommended for use in these patients.

VORICONAZOLE. The newest triazole to be investigated in animals is voriconazole (Vfend®). Voriconazole is similar in structure to fluconazole (Figure 39.4); however, the substitution of a fluoropyrimidine ring for one of the triazole moieties and the additional of a methyl group to the propanol backbone increases the spectrum of activity and potency as well as the fungicidal activity against some species of molds, including *Aspergillus* and *Fusarium* spp. In a survey of fungal pathogens, itraconazole inhibited greater than 95% of *Aspergillus* with a concentration less than or equal to 1 μg/ml (Diekma et al. 2003). It is more lipophilic than fluconazole, more water soluble than itraconazole or ketoconazole, with intermediate protein binding. These properties allow for excellent oral bioavailability and tissue distribution. In people, the plasma concentrations were highly variable among individuals, which is caused by variations in hepatic metabolism, other medications coadministered, and nonlinear elimination. Such a variation is likely in animals, but there have not been enough studies reported to assess the degree of variability among patients. The concentration associated with clinical cure has been an AUC/MIC plasma concentration of 20–25, or a plasma concentration above 2 μg/ml.

Clinical Use

Dogs and Cats. Clinical experience with this drug is limited at this time. Experimental studies in dogs have shown rapid and complete absorption of the drug following oral administration (Roffey et al. 2003). Voriconazole exhibits nonlinear pharmacokinetics in this species, with a ninefold increase in plasma concentrations seen following a fourfold increase in dose. Interestingly, autoinduction of drug metabolism was shown to occur in dogs, requiring an increase in dose with multiple administrations. Its safety in cats remains to be investigated. In one anecdotal account by the authors, one cat being treated for cryptococcosis developed gastrointestinal side effects from oral voriconazole administration. The drug concentrations in this cat were extremely high and the elimination of the drug was very prolonged (half-life >4 days). Whether this caution should be extended to all cats or whether this was an idiosyncratic reaction in this individual is not known.

Horses. Recently, the pharmacokinetics of voriconazole have been studied following single and multiple dose administration in the horse (Davis et al. 2006; Colitz et al. 2007). In these cited equine studies, voriconazole had excellent oral absorption (95% and 100%) and a long half-life (8–13 hrs) following oral administration, as well as good distribution into the aqueous humor, CSF, synovial fluid, urine, and periocular tear film. The concentrations in plasma, tissues, and other fluids exceed the minimum concentration recommended for successful therapy (Goodwin and Drew 2008). The oral dose used

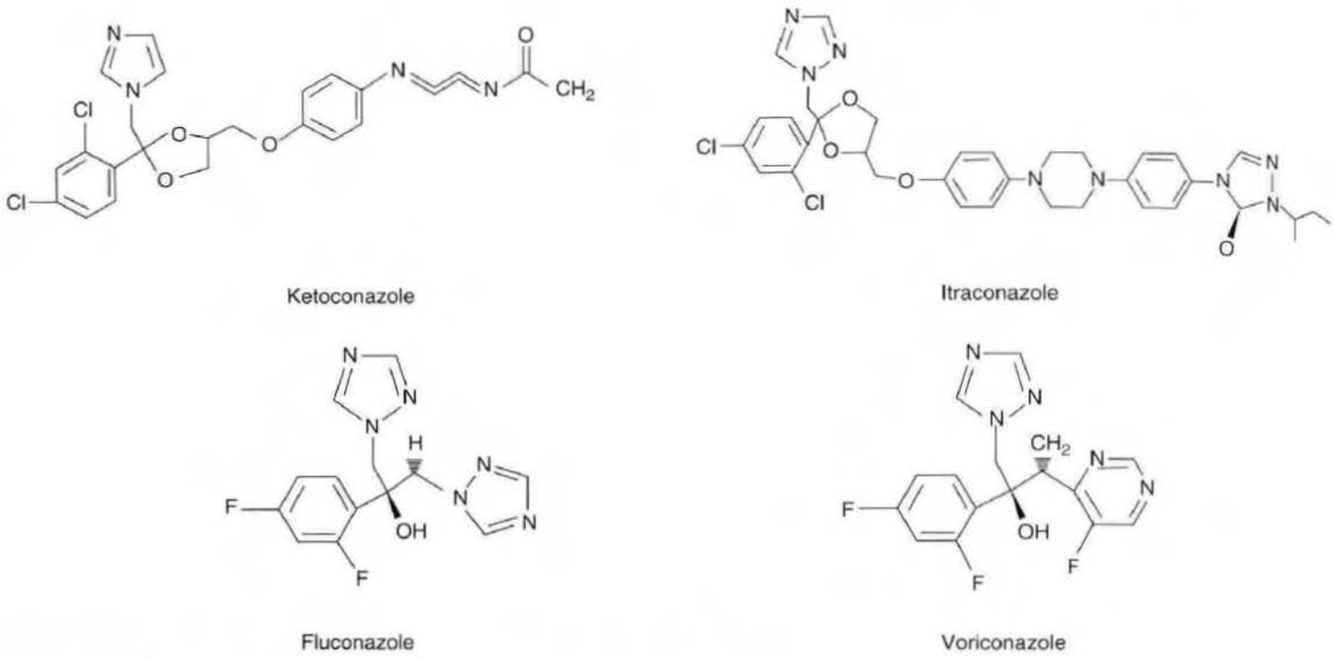

FIG. 39.4 Chemical structures of commonly used systemic azole antifungal drugs.

in the study by Davis et al.(2005) was 4 mg/kg and produced plasma concentrations were higher than necessary for the treatment of most common veterinary pathogens, with the exception of *Fusarium* sp. The study by Colitz et al.(2007) used 3 mg/kg orally twice daily and produced concentrations above the minimum level necessary for successful treatment. Follow-up clinical experience with therapeutic drug monitoring by the authors cited above (Davis et al.) suggests that a dose of 2 mg/kg orally once a day would be sufficient for most fungal infections.

Birds. The experience with voriconazole in birds has been reported by Flammer et al. (2008). After oral administration of single doses ranging from 6 to 18 mg/kg in parrots, a follow-up study examined multiple doses at the highest dose (18 mg/kg every 12 hours for 9 days). Compared to mammals, the elimination half-life was short at 1.1 to 1.6 hours. With multiple doses the half-life decreased, suggesting induction of the hepatic metabolism as mentioned for dogs above. Polyuria was observed in the treated birds, but no other adverse reactions were reported. On the basis of this study, the authors concluded that 12–18 mg/kg orally twice daily would be sufficient for treatment of some *Aspergillus* infections; higher doses may be needed for some infections and to maintain concentrations during long-term treatment.

Adverse Effects. Except for the single anecdotal account in a cat cited above, and the polyuria observed in birds, there have been no other adverse effects reported for voriconazole in animals. In people, increased liver enzymes and hepatotoxicity have been observed. Liver adverse reactions are more likely in people at high plasma concentrations. In experimental animals and people, visual disturbances have been reported. In experimental dogs, the visual problems were transient. The incidence of ocular problems in people is very low.

POSACONAZOLE. Posaconazole (Noxafil®) is one of the newest azole antifungal drugs introduced. It was registered for use in people but its clinical use in animals has been limited to just a few case reports. Posaconazole resembles itraconazole in structure. It is used for invasive fungal infections, including those caused by *Aspergillus* and *Candida*. It is also active against dermatophytes, *Histoplasma capsulatum, Blastomyces dermatitidis, Coccidioides immitis*, and *Cryptococcus neoformans*. Its advantage over

other azole drugs is the activity against Zygomycetes. As with other azoles, the pharmacokinetic/pharmacodynamic parameter that best correlates with clinical success is the plasma concentration AUC/MIC. For treating *Aspergillus* this ratio was above 200; for treating *Candida* the ratio was only 15. If AUC/MIC ratios cannot be monitored, it is suggested to maintain plasma concentrations above (C_{MAX}) 1.48 µg/ml or an average concentration at least 1.25 µg/ml (Goodwin and Drew 2008). Additional information has indicated that prophylactic efficacy for invasive fungal infections is optimal when plasma concentrations of posaconazole exceed 0.7 µg/ml 3–5 hours after dosing in a multiple-dose regimen. It is available as an oral suspension containing 40 mg/ml posaconazole. The dose in people is 400 mg twice a day with a meal. If not given with a meal, dosage of 200 mg four times a day is recommended.

No dose ranges have been established for animals, but in two case reports on its use in cats with successful treatment, a dose of 5 mg/kg orally, every 24 hours was used without ill effects (Wray et al. 2008). In dogs, the oral absorption is good and the half-life is 23 hours. In dogs, there is a food effect on absorption with oral systemic availability of 11% and 27% in fasted and fed dogs, respectively. It is highly protein bound with binding greater than 97% in dogs. In toxicity studies, dogs have tolerated 30 mg/kg/day for 1 year without any clinical signs. However, histologically some neuronal vacuolation was observed at this dose. It should not be used during pregnancy because of inhibition of steroidogenesis.

OTHER AZOLE ANTIFUNGAL DRUGS. There are no other azole drugs reported to be used in animals systemically. However, newer drugs are in development and may be considered in the future. Drugs currently being evaluated include triazoles such as isavuconazole, ravuconazole, and albaconazole. These drugs, with modifications of the triazole structure have advantages in pharmacokinetic properties and spectrum of action compared to older drugs.

OTHER ANTIFUNGAL AGENTS

TERBINAFINE. Terbinafine (Lamisil®) is a highly fungicidal agent. It is a synthetic drug of the allylamine class. A closely related drug of the same class is naftifine (Naftin®), which is used as a topical cream for dermatophyte infections in people. Terbinafine inhibits squalene epoxidase to decrease synthesis of ergosterol. Fungal cell death results from disruption of cell membrane (Balfour and Faulds 1992).

Spectrum of Activity. Terbinafine is active against yeasts and a wide range of dermatophytes. It is fungicidal against *Trichophyton* spp., *Microsporum* spp., and *Aspergillus* spp. It is also active against *Blastomyces dermatitidis, Cryptococcus neoformans, Sporothrix schenckii, Histoplasma capsulatum, Candida*, and *Malassezia* (*Pityrosporum*) yeast. In people, it was more effective than griseofulvin for treating dermatophytes, with fewer relapses (Hoffman et al. 1995). There may also be some activity against protozoa (e.g., *Toxoplasma*).

Pharmacokinetics. Oral bioavailability in most species is high, ranging from >46% in the dog to >85% in mice (Jensen 1989). Its lipophilic nature results in high concentrations in tissues such as stratum corneum, hair follicles, sebum-rich skin, and nails. In people, after 12 days of therapy, the concentrations in stratum corneum exceed those in plasma by a factor of 75. Concentrations in skin may be detected in people as early as 24 hours after oral administration, but maximum concentrations are reached at 7 days. Fungicidal concentrations in nails may require 3 weeks of treatment. Concentrations of terbinafine in the hair of cats being treated for dermatophytosis reach approximately 3.62 µg/g after 120 days of treatment with a dose of 30–40 mg/kg. Like itraconazole, terbinafine is highly protein bound, with values reaching >99% in dogs and rabbits (Jensen 1989).

Clinical Use. Terbinafine has been reported to be efficacious in the treatment of dermatophytosis in dogs and cats, as well as *Malassezia* dermatitis in dogs (Chen 2000). For dermatophytosis, doses of 30–40 mg/kg PO q24h are recommended (Moriello et al. 2004). In both experimental and clinical trials, terbinafine was well tolerated in dogs and cats, and the average treatment length lasted approximately 60 days. Most treatments in cats are for at least 14 days, but may extend to 60 days. For treatment of *Malassezia* dermatitis, terbinafine (30 mg/kg) is as effective as ketoconazole in reducing yeast counts on the skin (Rosales et al. 2005). There are no reports of the use of terbinafine

for the treatment of systemic mycoses or of use in large animals.

It should be noted that doses in people are much different. By comparison, doses in people are only 125 mg twice daily (approx. 1.8 mg/kg q12h). Pediatric dose has been in the range of 4–8 mg/kg, once a day, but most often is at the lower dose of 4 mg/kg (Jones 1995). Terbinafine is available as a 1% topical cream (Lamisil, available over the counter) and 125 and 250 mg tablets.

Adverse Effects. In dogs treated with 30 mg/kg, serum ALT concentrations were mildly to moderately elevated in 4 of 10 dogs and ALP was increased in 2 of 10 dogs. Terbinafine does not bind to P450 enzymes as do other antifungal drugs; therefore, it does not cause drug interactions or inhibition of steroid synthesis in animals. In cats facial dermatitis and pruritus has also been reported. This reaction is a problem because it may be confused with an ongoing dermatophyte infection. In people, there is a rare incidence of severe hepatitic failure and death. No teratogenic effects of the drug have been noted in people.

LUFENURON. Lufenuron (Program®), is an orally active inhibitor of chitin synthesis that is commonly used in dogs and cats for control of flea infestations. It has recently been evaluated as an antifungal agent, since fungi also have chitin in their outer cell wall. Although there are reports of successful treatment of dermatophytosis in dogs and cats, the success of this treatment has been controversial.

In the original paper by Ben-Ziony and Arzi (2000), lufenuron provided an effective and rapid treatment of dermatophyte infections in dogs and cats. The effect on fungi is presumably because it also inhibits the cell wall of these fungi, which contains chitin, as well as other complex polysaccharides. A follow-up recommendation by Ben-Ziony and Arzi (2001) suggests that cats should be treated with a minimum dose of 100 mg/kg orally combined with environmental treatment to decrease the spread of fungal spores. House cats and dogs should be treated with 80 mg/kg. Animals that are reexposed to dermatophytes should be retreated 2 weeks after the first treatment. Lufenuron is a highly lipophilic drug and is absorbed best with a meal. If cats have free access to their food, withhold their food until such time that a meal will be consumed readily before administering the lufenuron oral dose.

The experience with lufenuron is still limited and the true efficacy still has to be determined with controlled studies. Some dermatologists are skeptical of lufenuron's efficacy for treatment of dermatophytes. Poor efficacy in some animals has been attributed to inadequate dosing or reexposure from the environment. As a pretreatment for prevention of dermatophyte infection in cats, it was not shown to be effective (Moriello et al. 2004; DeBoer et al. 2003). More recent studies have shown no effect in vitro or in vivo of lufenuron against dermatophytosis. There was a good effect of lufenuron against dermatologic disease not caused by fungi in this study, however, and an immunomodulatory effect was hypothesized (Zur and Elad 2006).

If used for dermatophyte treatment, antifungal doses of lufenuron are higher than those recommended for flea control and have ranged from 50 mg/kg to greater than 250 mg/kg. Most authors recommend treatment with 80–100 mg/kg orally, once every 2 weeks until mycological cure (Ben-Ziony and Arzi 2001).

Topical or local use of lufenuron may be more efficacious. It has been successfully used to treat fungal endometritis caused by *Candida* or *Aspergillus* spp. in horses (Hess et al. 2002). However, this too is controversial because in a study on efficacy and oral absorption (Scotty et al. 2005) lufenuron had no antifungal activity against pathogens important to horses (*Aspergillus* and *Fusarium*). If administered orally, absorption is poor and an oral dose cannot be recommended. Lufenuron may also be used in water baths for the treatment of aquatic species and amphibians (Woolfe et al. 2001).

FLUCYTOSINE. Flucytosine (5-Fluorocytosine, 5-FC, Ancobon) is a synthetic antifungal agent available as an oral preparation. Flucytosine must be taken into the fungal cell by cytosine permeate and then converted to the active form, 5-fluorouracil (5-FU), by a fungal cytosine deaminase enzyme. The 5-FU either is incorporated into RNA, disrupting protein synthesis, or is converted to a related compound that inhibits DNA synthesis. Mammalian cells do not have cytosine deaminase, which results in a selective toxicity of this compound; however, conversion to 5-FU may occur by microbes in the gastrointestinal (GI) tract resulting in 5-FU being taken up by mammalian cells, leading to anemia, leukopenia, and thrombocytopenia (Bennett 1990).

Fungal mutations leading to alterations in the permease or deaminase enzyme activity has led to the development of resistance to flucytosine, both in vitro and during

therapy. As a result of this, the therapeutic indications for flucytosine are limited to adjunct therapy with amphotericin B in systemic infections caused by *Candida* or *Cryptococcus neoformans*. Synergy between these two medications, seen as a fourfold reduction in the MIC, has been demonstrated, and combination therapy has been successful, particularly in the treatment of cryptococcal meningitis (Medoff et al. 1971; Utz et al. 1975; Bennett et al. 1979). One explanation of this synergism involves the membrane-permeabilizing effects of amphotericin B facilitating flucytosine's entrance into the cell cytoplasm (Medoff et al. 1972). This combination of antifungal drugs is more effective than amphotericin B alone in the treatment of cryptococcal meningitis (Bennet et al. 1979; Utz et al. 1975). Advantages of this combination include a reduction in the amphotericin B dose, thereby limiting nephrotoxicity, as well as prevention of mutants to flucytosine (Drouhet and Dupont 1987). This combination has also been suggested for therapy of acute hematogenously disseminated candidiasis (Horn et al. 1985). Although flucytosine is synergistic with amphotericin B, there is not evidence of synergism for azole antifungal drugs and this combination should not be used. The combination of flucytosine and ketoconazole proved toxic to cats (Pukay and Dion 1984).

SODIUM OR POTASSIUM IODIDE. Iodide compounds were one of the first antifungal drugs used and they are still used today in veterinary medicine. They are inexpensive and can be administered orally which makes them useful for long-term treatment. The mechanism of action of iodide compounds against fungal organisms is largely unknown, but it may involve stimulating the host's immune response or increasing the elimination of the fungi through the skin or hair. Iodide compounds have been used to treat sporotrichosis in dogs, cats, and donkeys, as well as nasal fungal granulomas caused by *Basidiobolus*, *Conidiobolus*, and *Pseudallescheria* spp. in horses (Koehne et al. 1971; Gonzales Cabo et al. 1989; Irizarry-Rovira et al. 2000; Owens et al. 1985; Zamos et al. 1996; Davis et al. 2000). These drugs are seldom used as a sole therapy, but rather are used as an adjunct to surgical excision, intralesional injection of other antifungals, or systemic antifungal therapy. Toxic effects are possible (iodism) and may occur secondary to excessive iodide levels. Clinical signs attributable to excess iodine include lacrimation, salivation, coughing, anorexia, dry scaly skin, and tachycardia. Abortion and infertility may also be observed, therefore care should be taken when administering this drug to breeding animals. The recommended doses of 20% sodium iodide solution for dogs is 44 mg/kg PO q24h, for cats is 22 mg/kg PO q24h, and for horses is 125 ml IV q24h for 3 days followed by 30 grams PO q24h. Treatment is recommended to extend 30 days beyond the resolution of clinical signs. Iodoject IV is labeled for use in cattle for the treatment of actinomycosis and actinobacillosis at 66 mg/kg IV once a week. The use of this product for fungal infections is considered off label.

TOPICAL ANTIFUNGAL AGENTS

ENILCONAZOLE. Enilconazole (Imaverol®) is also called *imazalil* in some countries. It is an azole antifungal that has excellent activity against dermatophytes and filamentous fungi and it has a residual effect after application. It has been used in some countries for the topical treatment of dermatophyte infections in dogs and horses. For this treatment, a 10% solution is diluted 50:1 to form an emulsion. It may be sponged on the animal every 3 or 4 days for 4 treatments. It may be applied to the premises as well to prevent recurring infections. In an evaluation of topical therapies for treatment of dermatophyte infections in dogs and cats (White-Weithers and Medleau 1995), enilconazole was more effective than chlorhexidine, povidone iodine, ketoconazole, sodium hypochlorite, and Captan. The safety of enilconazole has been demonstrated in dogs, even at high doses. One study also showed that enilconazole is safe for treatment of dermatophytes in Persian cats (deJaham 1996). Enilconazole also has been used to treat nasal aspergillosis in dogs. It has a unique vapor effect and, if instilled into the nasal cavity of dogs, will control fungal growth (Sharp et al. 1991; Sharp and Sullivan 1992). A dose of 10 mg/kg in a volume of 5–10 ml is infused twice a day for 7–14 days. In one study using this protocol (Sharp et al. 1993) 26 of 29 affected dogs became asymptomatic. A similar protocol has been used for the successful medical treatment of guttural pouch mycosis caused by *Aspergillus* spp. in the horse (Davis and Legendre 1994).

In the United States, enilconazole is available as Clinafarm®-SG or Clinafarm®-EC. Both are approved for use in poultry hatcheries to control *Aspergillus* organisms on facilities and equipment. Clinafarm®-SG comes in a

canister used for smoke generation. Clinafarm-EC is available in a 750 ml bottle containing 13.8% (138 mg/ml) enilconazole. The other ingredients listed on the Material Safety Data Sheet are benzyl alcohol and dioctyl sodium sulfosuccinate. It also contains ethoxylated castor oil. The Canadian formulation of Imaverol contains polysorbate 20 and sorbitan monolaurate as its inert ingredients with 10% enilconazole as the active drug. The Clinafarm-EC formulation is registered for controlling *Aspergillus* organisms in poultry facilities and equipment by making a 1:100 dilution and spraying or fogging the area to be treated. Although there are no published toxicology studies on this particular solution in animals, it has been used in a 50:1 dilution applied topically to dogs and cats without adverse effects. One study applied 100 ml of a 2 mg/ml formulation of Clinafarm-EC to cats and was judged to be safe (Hnilica et al. 2000). However, monitoring of liver enzymes was recommended by these authors.

CLOTRIMAZOLE. Clotrimazole (Lotrimin®) is an imidazole antifungal. It is limited to topical use because after oral administration, the metabolism produces undetectable concentrations of the drug in plasma following repeated dosing. In veterinary medicine, it has been used for treatment of nasal aspergillosis in dogs following infusion of a 1% solution over 1 hour through a nasal catheter (Matthews et al. 1998). It has also been infused into the bladder of dogs and cats with fungal candiduria (Toll et al. 2003, Forward et al. 2002). Clotrimazole can be found in combination with gentamicin sulfate and betamethasone valerate as the product Otomax® and other generic forms that are labeled for the treatment of otitis externa caused by *Malassezia pachydermatitis* or susceptible bacteria in dogs.

MICONAZOLE. Miconazole (Conofite® cream) is an imidazole antifungal effective against some fungi refractory to amphotericin B. Rapid clearance and poor oral absorption necessitated frequent IV infusions during hospitalization. In addition, the solubilizing agent in the parenteral form induces histamine-related toxic side effects, making its use hazardous. The intravenous formulation is no longer marketed in the United States. In veterinary medicine, miconazole is used as a 1% solution for topical treatment of keratomycosis. It is also available as 2% cream or 1% spray or lotion for the treatment of dermatophytosis in dogs and cats. It can also be found combined with chlorhexidine as a shampoo for the adjunct treatment of dermathophytosis in animals.

NATAMYCIN. Natamycin (Natacyn®), is a polyene antifungal with a mechanism of action similar to amphotericin B. It is approved for use in humans as a 5% ophthalmic suspension. Natamycin has excellent activity against yeasts and filamentous fungi, and it is considered the treatment of choice for *Fusarium* keratomycosis in the horse. It is most commonly used in veterinary medicine for treatment of keratomycosis in horses, although it has also been reported as a topical therapy for nasal aspergillosis as well as guttural pouch mycosis and dermatophytosis in these species (Brooks et al. 1998; Greet 1987, 1981; Oldenkamp 1979). Its systemic use is prohibited by expense, as well as toxicity.

NYSTATIN. Nystatin (Mycostatin®) is also a polyene antifungal that is limited to topical use due to systemic toxicity. Nystatin is not absorbed well from the gastrointestinal tract; therefore, it can be given orally as a "topical" treatment for oral and intestinal candidiasis, particularly in exotic animal species (see Table 39.4). In veterinary medicine, it is most commonly used in combination with antibiotics (neomycin, thiostrepton) and antiinflammatory (triamcinolone) drugs in ointments such as Panalog® and other generic formulations.

ANTIVIRAL THERAPY

The use of antiviral drugs in veterinary medicine has been limited. In human medicine, these drugs have gained greater importance and use because of treatment of human immunodeficiency virus (HIV) and associated AIDS, and for treatment of herpesvirus infections, influenza, and other diseases. In veterinary medicine, the use has primarily been limited to treatment of herpesvirus infections. Some are only used topically for treatment of ocular lesions. Consequently, compared to a human textbook, the consideration of these agents in this book is limited. Readers are encouraged to consult a human pharmacology textbook for more in-depth discussion of mechanism of action and antiviral spectrum of these agents.

The antiviral drugs are aimed at preventing or eliminating one of the steps involved in the viral replicative cycle.

IDOXURIDINE AND TRIFLURIDINE

Idoxuridine (5-iodo-2′-deoxyuridine, Herplex®, Stoxil®) and trifluridine (5-trifluoromethyl-2′-deoxyuridine, Viroptic®) are thymidine analogs that are only active against DNA viruses, primarily herpesvirus and poxvirus. The compound is phosphorylated inside the host cell and is then incorporated into growing mammalian and viral DNA strands. This DNA is thought to be more susceptible to breakage and results in faulty proteins if transcribed. Both compounds are commercially available as topical ophthalmic preparations for the treatment of herpetic keratitis. Trifluridine (also known as trifluorothymidine) is thought to have higher affinity for viral DNA than mammalian, as well as being more active; however, it also causes the most conjunctival irritation in vivo (Nasisse et al. 1989). Because of the high cost of these medications, idoxuridine should be used initially, and if no response is seen within 1 week, trifluridine therapy should be initiated (Martin 1990). Toxic side effects, including leukopenia, hepatotoxicity, and GI signs, have precluded their systemic use.

CYTARABINE AND VIDARABINE

Cytarabine (Ara-C®) and vidarabine (Ara-A®), are nucleoside analogs of cytosine and adenine, respectively. They have in vitro activity against certain DNA viruses, including herpesviruses, poxviruses, vaccinia, rabies, cytomegalovirus, and probably hepatitis B virus. Cellular enzymes convert these compounds to the triphosphate form, which then act as competitive inhibitors of DNA polymerase. Herpes-induced DNA polymerase seems to be more sensitive to this inhibition than the mammalian cellular counterpart.

Vidarabine is poorly soluble so must be given intravenously in large fluid volumes over 12 hours. Vidarabine and its active metabolite, hypoxanthine arabinoside, are widely distributed in body fluids and tissues, including the brain and cerebrospinal fluid. Cytarabine is biotransformed to an inactive metabolite and is therefore less effective than vidarabine. Major side effects include GI, neurologic, and hematologic toxicity and teratogenicity.

Vidarabine is used topically in the treatment of herpes keratitis, although it exhibits less potency against feline herpesviruses than does idoxuridine or trifluridine (Nasisse et al. 1989). Vidarabine demonstrated significant antiviral activity in vitro against the feline infectious peritonitis virus. However, this effect was seen only if the compound was used as a pre- or cotreatment with viral inoculation (Barlough and Scott 1990). It also has demonstrated in vitro activity against equine and feline rhinopneumonitis viruses (Babiuk et al. 1975).

Use of these compounds as systemic antiviral drugs in veterinary medicine is not reported. Cytarabine is used as an antineoplastic agent in dogs and cats for treatment of leukemia and lymphoma and is known to cause bone marrow suppression, which would limit its use as an antiviral agent. Its use as an anticancer drug is discussed in more detail in Chapter 45.

RIBAVIRIN

Ribavirin (Virazole®) is a triazole purine nucleoside analog that inhibits the replication of a wide range of RNA and DNA viruses in vitro. Its strongest antiviral activity is against RNA respiratory viruses (influenza A and B) and herpesviruses but also includes myxoviruses, paramyxoviruses, arenaviruses, bunyaviruses, retroviruses, adenoviruses, and poxviruses. Ribavirin is thought to have multiple sites of action. After being monophosphorylated to ribavirin 5′-monophosphate (RMP) by adenosine kinase, it is able to indirectly inhibit synthesis of guanine nucleotides. Further phosphorylation to RTP allows it to competitively inhibit ATP and GTP binding to RNA polymerase.

Ribavirin can be administered by oral, intravenous, and aerosol routes. When administered by the first two routes, anemia due to extravascular hemolysis, bone marrow suppression, GI toxicity, and central nervous signs may occur. In addition, these two routes have been shown to be ineffective in the treatment of influenza A infection (Smith et al. 1980). Aerosolized ribavirin is generally well tolerated (Hall et al. 1983) and is therefore the preferred route for treating susceptible respiratory infections.

Oral ribavirin was seen to worsen the condition of cats experimentally infected with calicivirus. Bone marrow suppression, weight loss, increased hepatic enzymes, and icterus were seen (Povey 1978). These side effects were also seen in healthy cats given the drug (Weiss et al. 1993a); however, they were not seen in dogs when given 60 mg/kg for 2 weeks (Canonico 1985). Ribavirin was shown to have in vitro antiviral activity against the FIP virus at concentrations of 150 μg/ml (Barlough and Scott 1990). Kittens experimentally infected with FIP virus had no significant difference in outcome when compared to those treated

with placebo (Weiss et al. 1993b). In fact, similar to the cats infected with calicivirus, the ribavirin treated FIP kittens had a worsening of clinical signs. In vitro activity against bovine rhinotracheitis and bovine viral diarrhea has also been demonstrated, but there are no reports of the use of this compound in infected animals (Glotov et al. 2004).

ACYCLOVIR, PENCICLOVIR, AND RELATED PRODRUGS (VALACYCLOVIR AND FAMCICLOVIR)

ACYCLOVIR. Acyclovir (Zovirax®) is a synthetic nucleoside analog of the purine deoxyguanosine that has antiviral activity restricted to herpesviruses. Acyclovir is particularly active against herpes simplex 1 and 2 viruses and varicella-zoster virus but is less active against Epstein-Barr and cytomegaloviruses (CMV). Herpesvirus infections (feline herpesvirus type-1, FHV-1) in cats have been described (Thomasy et al. 2007; and in review by Gaskell et al. 2007). Infections consist of respiratory illness, upper respiratory disease, and ocular lesions. Unfortunately, some of the drugs used for herpesvirus infection in people are not as active against the feline virus (Maggs et al. 2004; Gaskell et al. 2007). Administration of valacyclovir to cats did not suppress FHV-1 and produced toxicity (see adverse effects below) (Nasisse et al. 1997).

Herpesvirus infections are particularly important in horses. In horses, the equine herpesvirus type 1 (EHV-1) causes myeloencephalopathy, respiratory disease, abortion, and neonatal infections. The sensitivity of EHV-1 to acyclovir is similar to humans with an inhibitory concentration (IC_{50}) of 0.3 μg/ml, although one study cited effective concentrations (EC_{50}) of 1.7 to 3.0 μg/ml (Garré et al. 2007).

Acyclovir is monophosphorylated by viral thymidine kinase 200 times easier than by the similar mammalian enzyme, which contributes to its good selective toxicity and high therapeutic index. Cellular enzymes then form the di- and triphosphate form, which selectively inhibit the viral DNA polymerase by competing with deoxyguanosine triphosphate. Acyclo-GTP that is incorporated into viral DNA strands causes termination of elongation. Virally infected cells are 40–100 times more efficient in converting acyclo-GMP to acyclo-GTP than are noninfected cells. Penciclovir (discussed below) and ganciclovir have similar mechanisms of action against herpesvirus. Ganciclovir has better activity than acyclovir against FHV-1 (Maggs et al. 2004) and also has activity against cytomegalovirus (CMV), but its use in animals has not been reported.

Pharmacokinetic data for acyclovir are available for horses, dogs, and cats, as well as Quaker parakeets and pheasants and other species (de Miranda et al. 1982, 1981). Oral bioavailability of the drug is high in dogs (>80%), moderate in people (10–30%), but low and variable in horses (<5%). In horses, the oral absorption was undetectable in one study (Wilkins et al. 2005), and only 2.8–4% in other studies (Garré et al. 2007; Benz et al. 2006), but when administered IV the half-life of approximately 5, 7, or 9 hours, depending on the study (Garré et al. 2007; Wilkins et al.; Bentz et al. 2006) was longer than in other species (half-life 2.3 hours in dogs and 2.6 hours in cats). An IV infusion of 10 mg/kg for 1 hour produced effective concentrations in horses for 8 hours and they concluded that this treatment could be administered twice daily for EHV-1 (Wilkins et al. 2005).

Orally administered acyclovir at 80 mg/kg IM 24 hours after herpesvirus infection in Quaker parakeets was shown to be more effective in preventing death than either low- or high-dose (40 or 250 mg/kg) intramuscular injections. At the highest dose tested, acyclovir toxicity, as seen by local muscular necrosis, was thought to contribute to bird mortality (Norton et al. 1991). Acyclovir has been shown to decrease mortality in psittacine birds with herpesviral infections if the drug is administered prior to the onset of clinical signs (Smith 1987).

Acyclovir has been used as a treatment for equine herpesvirus encephalitis. In one herd outbreak of EHV-1 neurologic disease, 7 of 19 horses were treated with acyclovir. Only one of the treated horses was euthanized; however, none of the untreated horses was euthanized (Friday et al. 2000). Given the low oral bioavailability of this drug in adult horses, its usefulness is questionable and other drugs have been considered as alternatives (see valacyclovir and penciclovir, below). Doses recommended in the literature include 10 mg/kg PO q4h and 20 mg/kg PO q8h. Acyclovir may be more useful as a treatment of neonatal herpesvirus infection. In one herd outbreak of EHV-1 in foals, 2 of 3 foals treated with acyclovir survived, whereas the 2 foals not treated died (Murray et al. 1998). Since this disease is almost universally fatal in foals, acyclovir shows promise as a therapeutic agent. The pharmacokinetics have not been studied in neonatal foals, but oral absorption may be higher, as has been seen with several other compounds.

In dogs, acyclovir is well absorbed (80–90%), but oral absorption may become saturated at high doses (Krasny et al. 1981). The elimination half-life in dogs is 2.2–3.6 hours and clearance in dogs appears to be primarily via glomerular secretion (de Miranda et al. 1981, 1982; Krasny et al. 1981).

In birds, herpesvirus infections can be an important cause of morbidity. When acyclovir was administered orally to pheasants (Rush et al. 2005), the half-life of acyclovir was approximately 3 hours. A range of doses were examined in this study, from 40 to 120 mg/kg. It was concluded that, to maintain concentrations necessary to produce antiviral effects (>1.0 μg/ml), a dose of 120 mg/kg orally every 12 hours should be used.

Valacyclovir (Valtrex). Acyclovir is absorbed poorly and inconsistently. Therefore, the prodrug valacyclovir is used to produce more effective and consistent blood concentrations. Valacyclovir (500 mg and 1 gram tablets) is much more expensive than acyclovir. As long as the expense remains high, the application for some animals, especially horses, will be uncommon. Nevertheless, valacyclovir has important advantages. It is absorbed as the prodrug, and then converted to the active drug—acyclovir—in the patient. Compared to 10–30% oral absorption of acyclovir in people, it is increased to 55% if administered as the prodrug. In horses, valacyclovir also appears to have good absorption compared to acyclovir and may potentially be used in horses to treat and prevent infections caused by EHV-1 (Garré et al. 2007). This study showed that compared to acyclovir oral absorption of 3%, oral absorption from valacyclovir was 26% in horses. These authors predicted that a dose of 40 mg/kg every 8 hours orally to horses would maintain concentrations above an effective level of 1.7 to 3.0 μg/ml for EHV-1 infections.

Valacyclovir should not be administered to cats because it does not suppress FHV-1 and is toxic, which is discussed in more detail below in the section "Adverse Effects" (Nasisse et al. 1997).

PENCICLOVIR AND FAMCICLOVIR. Penciclovir is administered topically (cream) for herpesvirus infections in people (Denavir). After topical application of the cream, the systemic absorption of penciclovir is negligible. Oral absorption of penciclovir is poor; therefore, the oral prodrug famciclovir—an ester of penciclovir—is administered instead. Penciclovir has a similar mechanism of action as acyclovir, but the half-life in virus-infected cells is 10–20 times longer (Gill and Wood 1996). In people, oral absorption of penciclovir, administered as the prodrug famciclovir, is 60% and 77% (depending on the study) (Gill and Wood 1996). After administration of famciclovir, there is extensive first-pass metabolism in people to produce the active drug. In cats, famciclovir has been used but the activity is questionable. The activity of penciclovir is not as high against the feline virus as it is against the human herpesvirus. The effective concentration (EC_{50}) has been reported as 3.5 μg/ml (Thomasy et al. 2007). When famciclovir was administered to cats at a dose of 15 mg/kg plasma concentrations were highly variable, but no adverse effects were observed. There appeared to be nonlinear (saturable) pharmacokinetics that is a potential problem for extrapolating doses and effects from multiple administrations. Plasma concentrations were much lower than reported for people, which indicates either a lack of intestinal absorption in cats, or a deficiency in cats for conversion of famciclovir to the active drug. The enzyme needed for conversion is hepatic aldehyde oxidase, which is deficient in cats (Dick et al. 2005). The half-life of penciclovir in cats was 3–4 hours and produced concentrations of 0.3 to 0.7 μg/ml (depending on the interval) but these were only 1/5 to 1/11 of the concentration needed to inhibit feline herpesvirus (Thomasy et al. 2007). Despite some of these drawbacks famciclovir has been used to treat feline herpesvirus-1 associated disease in cats (Malik et al. 2009). In the report by Malik et al. (2009) ten cats were treated with famciclovir at a dose of 62.5 mg per cat twice daily or 125 mg per cat three times daily. Although the study was not controlled, the drug was well tolerated in the cats and it appeared to have a positive effect on resolution of conjunctivitis, keratitis, rhinosinusitis and FHV-1 associated dermatitis. Absorption in dogs is higher than in cats (Filer et al. 1995). When a dose of 25 mg/kg was administered to dogs, plasma penciclovir concentrations were similar to those achieved in people. Although the conversion of famciclovir to penciclovir was slower than in other species, the pharmacokinetics are otherwise similar to people.

Adverse Effects. The adverse effects of acyclovir and related drugs have not been well-documented in animals because of their infrequent use. In people, CNS effects are the most common and consist of headache, dizziness, depression, and other CNS-related problems. When acyclovir is administered, the IV infusion should be given over 1 hour to diminish the risk of CNS problems.

When famciclovir was administered to cats, no adverse effects were reported, but absorption and conversion to

the active drug was low (Thomasy et al. 2007). However, when valacyclovir was administered to cats at a dose of 60 mg/kg orally every 6 hours there were serious adverse reactions (Nasisse et al. 1997). Cats in this study became depressed and dehydrated, developed severe bone marrow suppression, and developed hepatic and renal necrosis.

ZIDOVUDINE

Zidovudine (Azidothymidine®, AZT®, Retrovir®) is a thymidine analog in which the 3′ hydroxy of the deoxyribose sugar has been replaced with an azido group. Zidovudine is more commonly known as *AZT*. AZT is phosphorylated by cellular enzymes to the triphosphate analog. This form inhibits viral reverse transcriptase (RNA-dependent DNA polymerase) as well as causing chain termination due to the unavailability of a 3′-hydroxyl moiety. AZT inhibits the viral enzyme with greater affinity (~100 times) than mammalian DNA polymerases, resulting in selective activity and low mammalian toxicity.

AZT can be given orally or IV in humans. Its oral bioavailability is 60–65%, and peak concentrations are achieved in about 1 hour. Only 25% of the drug is bound to plasma, and concentrations in the cerebrospinal fluid are similar to plasma concentrations. AZT is quickly metabolized to the 5′glucuronide, and both the metabolite and parent compound are eliminated in urine with a half-life of approximately 1 hour. The pharmacokinetics of AZT at a dose of 25 mg/kg have recently been studied in cats following IV, PO, or intragastric (IG) administration through a gastrostomy tube (Zhang et al. 2004a). Absorption following PO administration (95%) was higher than IG administration (70%), but effective plasma concentrations, as determined by the in vitro EC_{50}, were maintained for at least 12 hours following administration by all three routes. As in humans, half-life was short (1.4 hr). No adverse effects, other than hemolysis after IV injection, were observed in this study; however, only single doses were administered. These same investigators also studied the pharmacokinetics of a related compound, lamivudine, in cats (Zhang et al. 2004b). This drug was studied because it has a higher safety profile than AZT, probably because it does not get transported into the mitochondria of the cells. Additionally, lamivudine was more potent against FIV in vitro compared to other antiviral agents, including AZT. The pharmacokinetics were similar to those of AZT in cats, with a high bioavailability, short half-life, and plasma concentrations maintained above the predicted EC_{50} for 12 hours following either IV, PO, or IG dosing of 25 mg/kg.

Major toxicities of AZT include anemia and granulocytopenia, which occur in up to 45% of treated human patients (Richman et al. 1987). Dose escalation studies have demonstrated a dose-dependent and progressive anemia and neutropenia in cats chronically administered >30 mg/kg/day PO divided into three doses for 32–34 days. Marked bone marrow hypercellularity and extramedullar hematopoeisis were observed on postmortem examination (Haschek et al. 1990).

The use of AZT has been investigated in cats both as a clinical therapy for FIV and experimentally, using FIV as an animal model of HIV infection. Reverse transcriptase from FIV and HIV-1 viruses was shown to be nearly identical in sensitivity to several antiviral agents, including AZT. In addition, similar concentrations of AZT were required to inhibit replication of these viruses (North et al. 1989). Bovine leukemia virus has also been suggested as a possible animal model for investigation of retroviral infection. AZT inhibition of BLV reverse transcriptase was similar to that of FIV-RT (Reimer et al. 1989).

AZT has been shown to reduce clinical signs when given to two FIV-positive cats at a dose of 10 mg/kg twice a day subcutaneously for a period of 3 weeks (Egberink et al. 1991). Although it did not eradicate the infection, the authors suggest it is of clinical benefit and should extend the life of FIV-infected cats. In experimental FeLV infections, when treated with AZT within 1 week after virus challenge, cats are protected from bone marrow infection and viremia. Viremia persisted in cats treated between 1 and 3 weeks; however, antigen load in the blood was reduced (Tavares et al. 1987). AZT alone, or in combination with interferon or interleukin, was shown to prevent infection in cats challenged with virulent FeLV virus for a period of 6 weeks (Zeidner et al. 1989).

FOSCARNET

Foscarnet (trisodium phosphonoformate hexahydrate; PFA) is a pyrophosphate analog that exhibits antiviral activity against a variety of DNA and RNA viruses. It inhibits DNA and RNA polymerases as well as reverse transcriptase. The mechanism of foscarnet activity differs from that of the preceding antiviral agents in that it inhibits these enzymes by binding at the pyrophosphate binding site rather than at a base binding site. Thus, inhibition is noncompetitive rather than competitive (Oberg 1989).

Because phosphorylation by viral kinases is unnecessary for antiviral activity, it has potential for use in thymidine kinase-deficient herpesvirus infections (Teich et al. 1992); however, in vitro it demonstrates no antiviral activity against FHV-1 (Maggs and Clarke 2004). Viruses inhibited include avian myeloblastosis, Moloney murine leukemia, Rauscher leukemia, visna, influenza, bovine leukemia, African swine fever, baboon endogenous virus, simian sarcoma, human herpes, and human immunodeficiency viruses (Swenson et al. 1991a).

Although viral replication has been shown to be inhibited at concentrations achievable in plasma, these concentrations often vary widely. In addition, variable interindividual pharmacokinetics in humans makes optimal dosage regimens difficult to identify (Lietman 1992). The pharmacokinetics of PFA have been investigated in the cat (Straw et al. 1992). PFA was only 8% bioavailable, had a terminal half-life of approximately 3 hours, and was not metabolized, resulting in a total clearance of 1.88 ml/min/kg. The related compound thiofoscarnet (thiophosphonoformate, TPFA) had greater bioavailability (22–44%) and a shorter plasma half-life (42 minutes) and was metabolized to the active PFA, suggesting its possible use as a prodrug. The percutaneous absorption of PFA was studied in rabbits and dogs to ensure its safe topical use in herpetic mucocutaneous conditions. Systemic absorption after vaginal application was found to be 14% in the rabbit and 34% in the dog, whereas 12% (rabbit) and 3% (dog) of the dose entered the systemic circulation after topical administration (Hussain and Ritschel 1989).

The prophylactic and therapeutic use of PFA has been suggested in the cat (Swenson et al. 1991a). It is thought that long-term PFA administration to FeLV-infected cats may limit spread of infection within and between hosts via extracellular inactivation of newly produced virus particles. The authors also suggest PFA may have a role as a viral disinfectant for blood, blood products, supplies, and equipment. Toxicities associated with PFA include alterations in calcium/phosphorus homeostasis, as well as rickettslike lesions in young cats (Swenson et al. 1991b). Older cats do not show any significant changes in blood calcium levels, however osteomalacia can be seen.

AMANTADINE AND RIMANTADINE

Amantadine hydrochloride (1-adamantanamine hydrochloride, Symmetrel®) and rimantadine (Flumadine®) are water-soluble cyclic amines with antiviral activity against a narrow range of RNA viruses, including myxoviruses, paramyxoviruses, togaviruses, and most strains of influenza A virus. Rimantadine has approximately 3–4 times greater *in vitro* activity against influenza A than amantadine (Betts 1991). The mechanism of these two related compounds has been debated. They were thought at one time to prevent viral penetration and uncoating (Hoffman et al. 1965), but this was later refuted (Couch and Six 1986). Their antiviral activity is now thought to involve inhibition of late-stage assembly of the virus.

Both amantadine and rimantadine are absorbed well from the human GI tract. Serum concentrations of amantadine are greater than those of rimantadine, but the latter achieves greater concentrations in secretions (Hayden et al. 1985). The volume of distribution of amantadine is significantly less than that of rimantadine. Amantadine is excreted unchanged in urine, with an elimination half-life of ~16 hours, whereas rimantadine is 85% metabolized and eliminated with a 24–36 hour half-life. Neither agent has bone marrow, renal, or hepatic side effects, but amantadine may be neurotoxic, causing jitters, difficulty in concentrating, and seizures in certain patient populations. CNS side effects are less frequent with rimantadine. The combination of greater in vitro efficacy, greater distribution and terminal half-life, and less toxicity suggests rimantadine has greater clinical potential.

Both compounds are equally effective in the prophylactic prevention of respiratory infections caused by influenza A virus, although not as effective as vaccination. They have also been used to treat flu outbreaks, resulting in shorter duration fever and more rapid resolution of symptoms (VanVoris et al. 1981). Experimentally infected chicks that received amantadine via the drinking water were one-half as likely to die as untreated controls (Obrosova-Serova et al. 1976). However, the use of amantadine in poultry is thought to be responsible for the amantadine resistant influenza strains seen in the Chinese pandemic in 2005 (Ilyushina et al. 2005). The use of this drug in poultry should therefore be discontinued due to the potential human health risk. Amantadine had no inhibitory effect on FIP virus replication in vitro at the highest concentration tested (Barlough and Scott 1990).

These two compounds have been recently investigated for the treatment of influenza in the horse. In vitro testing suggests that amantadine suppresses viral replication at concentrations of 300 ng/ml while rimantadine is more

potent and has activity at concentrations as low as 30 ng/ml (Rees et al. 1997, 1999). Amantadine caused serious adverse effects, including fatal seizures, in horses at doses of 10–15 mg/kg IV. Absorption of the drug following oral administration was highly variable between individual horses; therefore, a dose could not be recommended (Rees et al. 1997). Rimantadine shows greater promise as an antiviral drug in horses. A multiple dose study examining the effects of oral rimantadine at a dose of 30 mg/kg q12h showed adequate absorption of the drug with plasma concentrations maintained above the estimated effective concentration (30 ng/ml) throughout the dosing interval. No side effects were reported. In challenge studies using influenza virus A2, prophylactic rimantadine administration caused a significant decrease in rectal temperature and lung sounds (Rees et al. 1999).

TREATMENT OF PAIN. An additional use of amantadine is for treatment of pain syndromes in animals. The proposed mechanism of action for amantadine is via inhibiting the neurotransmitter N-methyl-D-aspartate (NMDA) (Pozzi et al. 2006). NMDA produces central sensitization and pain in animals. Blocking of the NMDA central receptor by amantadine has been associated with relief of pain syndromes. Amantadine is well absorbed orally in practically all animals, but the precise duration of action and dosing regimens have not been fully investigated in animals. In one study, it was used—in combination with nonsteroidal antiinflammatory drugs (NSAIDs)—for treatment of pain in dogs (Lascelles et al. 2007). At a dose of 3–5 mg/kg orally, once daily, with meloxicam, dogs responded better than if administered meloxicam alone. Other doses that have been cited for pain are 2–10 mg/kg orally every 8–12 hours in dogs and 2 mg/kg orally every 24 hours in cats (Pozzi et al. 2006).

INTERFERON

A complete discussion of the biochemistry, physiology, and immunological function of interferon-$\alpha_{2a,2b}$ (Roferon-A, Intron A) is beyond the scope of this chapter. Interferons are glycopolypeptide molecules produced by certain mammalian cells in response to viral infections as well as other stimuli. They are potent cytokines that possess antiviral, immunomodulating, and anticancer properties (Pestka et al. 1987). At least four classes of interferons (IFNs) exist: alpha, beta, omega, and gamma, with the last being produced solely by T lymphocytes. Subtypes can exist within each class. The antiviral activities of interferons are indirect. They cause the induction of a variety of antiviral enzyme systems within the host cells that, in turn, inhibit protein synthesis and degrade viral RNA (Moore 1996). Two of these proteins, MxA and 2′,5′ oligoadenylate synthetase, are often used as a marker protein for IFN activity, since blood concentrations of IFN may not be measurable. An interesting property of IFNs is that once they induce an antiviral state in one cell, that cell can then transfer this antiviral activity to other cells through cell-to-cell contact without requiring additional IFN. This has been demonstrated in vivo using IFN-α stimulated lymphocytes. This results in an amplification of the antiviral effect, which may explain why IFNs are efficacious despite low to undetectable plasma levels (Stanton et al. 1989). Interferons are highly conserved between species and therefore their actions are not species-specific. Natural, bacteria-derived IFNs appear to be more potent than recombinant IFNs, possibly because they contain more than one subtype, thereby providing a broader effect. In people, multiple interferons have been used for treatment of AIDS-related diseases, and cancer-associated diseases.

Interferons have been administered parenterally, intranasally, and orally. Parenteral and intranasal administration lead to an increased risk of adverse effects, including formation of neutralizing antibodies to IFN, as well as clinical signs of hyperthermia, anorexia, and malaise (Roney et al. 1985). Being peptides, interferons are inactivated by the digestive enzymes in the gastrointestinal tract, yet orally administered IFN has been shown to be an effective treatment for viral diseases in a number of species. The probable mechanism for this is uptake of IFN by the oropharyngeal-associated lympoid tissue, which sensitizes the lymphocytes in these organs. The lymphocytes are then released into the circulation where they can confer antiviral activity to cells at the site of infection (Bocci 1991).

In vitro studies have demonstrated that FHV-1 is susceptible to feline interferon or human interferon. Most of the use has been anecdotal with few clinical trials to demonstrate efficacy for treating FHV-1 infections (Gaskell et al. 2007). Interferons are licensed for use in the treatment of viral disease of dogs and cats in Japan and other countries. A summary of some of the reports of interferon use in natural and experimental viral disease of different species is presented in Table 39.5.

TABLE 39.5 Clinical and experimental uses of interferon in veterinary species

Species	Disease Treated	IFN Subtype	Dose and Route of Administration	Results	Reference
Feline	FIP (coronavirus)	Recombinant feline IFN-γ	1 million U/kg SC EOD until remission followed by weekly injections of the same dose	Produce complete remission (>2 years) in 4/12 cats, and partial remission (2–5 months) in 4/12 cats; only cats with the effusive form of FIP responded.	Ishida et al. 2004
	FeLV or FeLV/FIV coinfection	Recombinant feline IFN-ω	1 million U/kg SC q24h for 5 consecutive days in 3 series (day 0, 14, and 60)	Placebo controlled study; treated cats had significantly lower clinical scores in the first 4 months and significantly lower mortality rates at 9 and 12 months.	de Mari et al. 2004
	FeLV	Human IFN-α with or without *Staphylococcus* Protein A (SPA)	30 U/cat PO once daily on weeks 1,3,5,7, and 9	Placebo controlled study; no significant improvements seen in animals treated with IFN compared to controls; mild improvement noted based on owner perception in cats treated with SPA alone.	McCaw et al. 2001
	FIV	Natural human IFN-α	10 IU/kg PO q24h on alternating weeks for 6 months	Treated cats had a significant improvement in clinical signs and a longer survival than controls; no correlation with plasma viremia or viral load in leukocytes was noted.	Pedretti et al. 2005
Canine	Parvovirus (CPV-2)	Recombinant feline IFN-ω	1 million U/kg IV q24h for 3 consecutive days starting 4 days after viral inoculation	Placebo controlled study; treatment significantly reduced the severity of the enteritis within 12 hours of administration of the first dose; all dogs received standard supportive therapy.	Ishiwata et al. 1998
	Parvovirus	Recombinant feline IFN-ω	2.5 million U/kg IV q24h for 3 consecutive days	Multicentric, double-blind, placebo controlled field trial; treated dogs showed a significant improvement in clinical signs; mortality rate was 7% in treated dogs and 29% in controls; all dogs received standard supportive therapy.	de Mari et al. 2003
Bovine	Vaccinia (Smallpox)	Natural human IFN-α2	10 million U/kg IM q24h starting 24 hours prior to viral inoculation	Placebo controlled study; complete protection was obtained at this dose.	Werenne et al. 1985
	IBR	Recombinant human IFN-α	0.05–5 U/kg PO q24h for 4 days starting 48 hours prior to intranasal viral inoculation	Placebo controlled study; the 0.05 and 0.5 U/kg groups showed significant improvement in mean rectal temperature and duration of antibiotic therapy; the 0.05 U/kg group also had significantly better weight gain.	Cummins et al. 1993

TABLE 39.5—*continued*

Species	Disease Treated	IFN Subtype	Dose and Route of Administration	Results	Reference
	IBR	Recombinant bovine IFN-α1	10 mg/animal intranasally 48 hours prior to viral inoculation	Significant reduction in morbidity and mortality in treated animals was noted, although treatment did not prevent clinical signs or affect viral shedding.	Babiuk et al. 1987
Equine	EHV-1	Recombinant human IFN-α2a	0.22 or 2.2 U/kg PO 48 and 24 hours prior to viral inoculation and 24 hours after inoculation	No significant effects on clinical disease or duration of viral shedding were noted.	Seahorn et al. 1990
	Inflammatory airway disease	Recombinant and natural human IFN-α	90 U/horse (recombinant) or 50 U/horse (natural) PO q24h for 5 days	Placebo controlled study; all horses had a significant decrease in cough and nasal discharge; significantly fewer horses treated with either IFN product had a relapse after 4 weeks; viral etiology in this disease not proven.	Moore et al. 2004

VIRBAGEN OMEGA. Recombinant omega interferon contained in Virbagen omega is produced by silkworms previously inoculated with interferon-recombinant baculovirus resulting in the synthesis of pure interferon. Omega interferon of feline origin, produced by genetic engineering, is a type 1 interferon closely related to α interferon.

After injection, omega interferon has a half-life of 1.4 hours in dogs and 1.7 hours in cats. It is bound to receptors in cells infected by virus. Interferon has been used to stimulate immune cells in dogs with parvovirus and in cats with feline retrovirus (Feline Leukemia Virus, *FeLV*, and Feline Immunodeficiency Virus, *FIV*).

ADVERSE REACTIONS. In people, injections of interferon α have been associated with influenzalike symptoms. Other effects also have been reported in people, such as bone marrow suppression. In animals, interferon has been generally well tolerated, but may induce vomiting and nausea. In some animals it may induce hyperthermia 3–6 hours after injection. In cats, it may produce soft feces to mild diarrhea. A slight decrease in white blood cells, platelets, and red blood cells, and rise in the concentration of alanine aminotransferase may be observed. These parameters usually return to normal in the week following the last injection. In cats, it may induce transient fatigue during the treatment. Do not vaccinate dogs or cats receiving interferon.

Doses and indications for animals have primarily been based on extrapolation of human recommendations, experimental studies in animals, or specific studies in cats with viral infections.

The formulation used in veterinary medicine is available in 5 and 10 million units/vial, which is reconstituted before use. In dogs, administer 2.5 million units/kg IV once daily for 3 consecutive days. In cats, administer 1.0 million units/kg IV once daily for 5 consecutive days. Three separate 5-day treatments must be performed at day 0, day 14, and day 60.

L-LYSINE

L-lysine is an essential amino acid that blocks the availability of arginine, which is necessary for the replication of herpesviruses. In vitro testing has demonstrated an inhibitory effect of L-lysine on FHV-1 replication in the presence of arginine (Maggs et al. 2000). Additionally, a dose of 400 mg per day, given in food, reduced viral shedding following the stress of changes in housing and husbandry (Maggs et al. 2003). This beneficial effect was blocked when the cats were given methylprednisolone to

induce viral shedding; however, L-lysine may also be efficacious in cases of herpesvirus keratitis in cats. When given prophylactically at a dose of 500 mg 6 hours prior to viral challenge, and then continued at 500 mg PO q12h, it decreased the severity of the ocular lesions compared to controls; however, it had no effect on virus isolation (Stiles et al. 2002). Despite the positive results cited above, a clinical study in shelter population cats did not show a benefit of treatment (Rees and Lubinski 2008). When 144 treated shelter cats were compared to 147 controls, there was no difference in prevention of upper respiratory infection or conjunctivitis when cats were supplemented with 250 or 500 mg daily oral L-lysine.

PMEA

The acyclic purine nucleoside analog 9–2(phosphonomethoxyethyl) adenine (PMEA) has been studied in the treatment of both FeLV and FIV infections in cats. PMEA was found to inhibit replication of FeLV in vitro and prevented the development of persistent antiginemia and the induction of the immunodeficiency disease in cats exposed to the virus (Hoover et al. 1991). PMEA exhibited similar effects against FIV infection. Seropositive cats with symptoms of opportunistic infection showed improvement of clinical signs during PMEA therapy at 5 mg/kg/day (Egberink et al. 1990). A comparative study on the effects of PMEA and AZT on FIV- or FeLV-positive cats showed that PMEA was superior to AZT in diminishing the clinical signs of disease; however, the adverse effects (mainly hematological) were more severe with PMEA than AZT, which would limit its use (Hartmann et al. 1992).

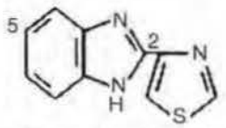
Concluding Remarks	**1090**

The economic importance of helminth infections in livestock has long been recognized, and it is probably for this reason that the most important advances in the chemotherapy of helminthiasis have come from the animal health area (Horton 1990). Anthelmintics are used in all animal species and man. A significant part of the economic impact of parasitism in animal production is represented by the investment in control measures. Although alternative methods have been developed, chemically based treatments are the most important tool to control parasitism. A more complete understanding of the pharmacological properties of existing antiparasitic drugs should assist with more efficient parasite control both in livestock and companion animals. The development of highly efficient analytical techniques to quantify drug/metabolites concentrations in various host tissues and target parasites has significantly contributed to understanding the pharmacokinetic and metabolic features of the available

anthelmintic drugs. Unfortunately, the investment in control measures does not always result in the expected therapeutic success. Among factors responsible for that therapeutic failure are 1) inadequate integration between management strategies and chemotherapy, 2) incorrect use of anthelmintic drugs due to insufficient knowledge of their pharmacological features, 3) insufficient understanding of the relationship between pharmacological properties, and 4) several host-related factors that could lead to modifications on the pharmacokinetic behavior and to a decreased antiparasite efficacy of the chosen drug. In addition, the availability of many compounds with a common mode of action and the indiscriminate use of these drugs have accounted for the widespread development of drug resistance, mainly in parasites of sheep and goats, but also in parasites of pigs, horses, and cattle. This chapter covers the information available for the different specific antinematodal drug families used in veterinary therapeutics. However, special consideration is given to the description of the large body of pharmacological knowledge generated for the benzimidazole compounds, the most intensively studied anthelmintic chemical group together with the endectocide macrocyclic lactones (see Chapter 42).

BENZIMIDAZOLES AND PROBENZIMIDAZOLES

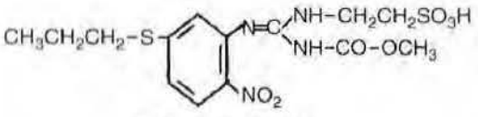
Benzimidazole (BZD) and probenzimidazole (pro-BZD) anthelmintics are widely used in veterinary and human medicine. The pro-BZDs are inactive prodrugs metabolically converted into anthelmintically active BZD molecules in the host. The remarkable overall safety of BZD compounds has been a major factor in their successful worldwide use over 4 decades. BZDs were introduced into the animal health market primarily for the control of gastrointestinal (GI) nematodes, not only for use in livestock animals (cattle, sheep, goats, swine, and poultry), but also for horses, dogs, and cats. The use of BZD compounds quickly became widespread because they offered major advantages over previous available drugs in terms of spectrum, efficacy against immature stages, and safety for the host animal.



CHEMISTRY. Since the discovery of thiabendazole (TBZ) in 1961 (Brown et al. 1964), several thousand BZD molecules have been synthesized and screened for anthelmintic activity. However, no more than twenty of them have been commercially developed for use in domestic animals and man, either as BZD or pro-BZD. The BZD structure is a bicyclic ring system in which benzene has been fused to the 4- and 5- positions of the heterocycle (imidazole) (see Fig. 40.1). Most of the BZD compounds are white crystalline powders, with a fairly high melting point and which are insoluble or slightly soluble in water. BZD's aqueous solubility is markedly higher at low acidic pH values with the stomach/abomasum being the appropriate site for the dissolution of BZD drug particles after oral treatment. The BZD compounds can be grouped as follows:

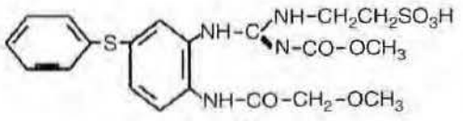
1. *BZD thiazolyls:* thiabendazole (TBZ), cambendazole
2. *BZD methylcarbamates:* parbendazole, mebendazole (MBZ), flubendazole (FLBZ), oxibendazole (OBZ), luxabendazole, albendazole (ABZ), ABZ sulphoxide (ABZSO), also known as ricobendazole (RBZ), fenbendazole (FBZ), oxfendazole (OFZ)
3. *Halogenated BZD thiols:* triclabendazole
4. *Pro-BZDs:* thiophanate, febantel (FBT), netobimin (NTB)

Different modifications at positions 2- and 5- of the BZD ring system (see Fig. 40.1) have provided the most anthelmintically active drugs, especially with the discovery of sulfur-containing methylcarbamate derivatives such as ABZ and FBZ, which exhibit high efficacy against lungworms and inhibited larval stages of most GI nematodes. The BZD methylcarbamates are largely the most used BZD compounds. ABZ, FBZ, and their sulphoxide derivatives (ABZSO and OFZ, respectively) ruminants; FBZ and OFZ horses; FBT, FBZ, and MBZ companion animals; and FBZ and FLBZ (poultry and pigs) are currently among the most extensively used BZD methylcarbamate anthelmintics in veterinary medicine.



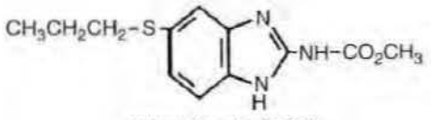
PHARMACODYNAMICS: MODE OF ACTION. Microtubules are hollow tubular organelles that exist in a dynamic equilibrium with tubulin, the microtubule subunit. Tubulin exists as a dimeric protein comprised of α- and β-subunits. The BZD and pro-BZD pharmacological activity is based on the binding to parasite β-tubulin, which produces subsequent disruption of the tubulin-microtubule dynamic equilibrium (see Lacey 1990 for detailed information). Competitive binding experiments using tubulin from mammalian, invertebrate, or fungal cells indicate that BZD compounds bind within the colchicine (a well-recognized microtubule inhibitor) binding domain on tubulin. Thus,

BENZIMIDAZOLE THIAZOLYLS



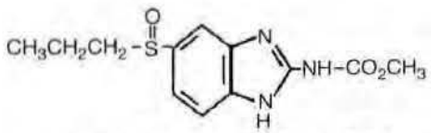
Thiabendazole (TBZ)

PRO-BENZIMIDAZOLES

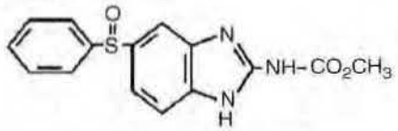


Netobimin (NTB)

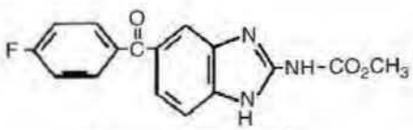
Febantel (FBT)



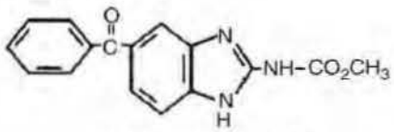
BENZIMIDAZOLE METHYLCARBAMATES



Albendazole (ABZ)



Fenbendazole (FBZ)



Albendazole sulphoxide (ABZSO)

Oxfendazole (OFZ)

Flubendazole (FLBZ)

Mebendazole (MBZ)

FIG. 40.1 Chemical structures of the main benzimidazole (BZD) anthelmintics used in veterinary medicine. The positions -2 and -5 (main substitution sites) are shown in the thiabendazole structure. ABZSO is also known as *ricobendazole (RBZ)*. Triclabendazole (a halogenated flukicidal BZD) is not included here (see Chapter 41).

all the functions ascribed to microtubules at the cellular level are altered (cell division, maintenance of cell shape, cell motility, cell secretion, nutrient absorption, and intracellular transport) (Lacey 1988). Microtubules are found in animal, plant, and fungi cells. However, the rate constant for the dissociation of BZD from parasite tubulin is much lower than the rate constant for the dissociation from mammalian tubulin. These differences in dissociation rates between

BZD and tubulin in host and parasites may explain the selective toxicity of BZD compounds to parasites and its wide safety margin in the mammalian host. The microtubule loss observed at tegumental and intestinal level in cestodes and nematodes after BZD treatment is followed by loss of transport of secretory vesicles and decreased glucose uptake. A prolonged storage of secretory material within the cells is followed by cell disintegration. Cell autolysis requires a period of 15–24 hours posttreatment. Additionally, the inhibition of secretion of nematode acetylcholinesterase and inhibition of some enzymatic activities (such as fumarate reductase, malate dehydrogenase, phosphoenol pyruvate reductase, and succinate dehydrogenase) have been associated with the BZD anthelmintic action. However, all these effects may be related to the primary underlying BZD mechanism: the disruption of the tubulin-microtubules dynamic equilibrium. The effects of structural modifications to BZD-like molecules on microtubule inhibitory activity have been intensively investigated (reviewed by Lacey 1988). It has been postulated that the presence of a carbamate group in the 2- position is essential for potent microtubule inhibitory activity. Additionally, regardless of the size of the substituent in the 5- position, the pharmacological effect heavily depends on the nature of the molecule adjacent to the BZD ring system. Different studies suggest that not only the chemical substitution in the position 5- of the BZD ring, but also its conformational arrangement, are relevant in the access of the drug to the active site and in the resultant anthelmintic activity.

Pharmacokinetic Behavior. The anthelmintic activity of BZD compounds not only depends on their binding to β-tubulin, but it also depends on the ability of the compounds to reach high and sustained concentrations at the site of parasite location that allow the delivery of effective concentrations of the compound at the receptor within the parasite cells, in sufficient time, to cause the therapeutic effect (Thompson et al. 1993) (see Fig. 40.2). As a chemical class, the BZD methylcarbamates have only limited water solubility, and small differences in drug solubility may have a major influence on their absorption and resultant pharmacokinetic behavior. The lack of water solubility is an important limitation for the formulation of BZD compounds, which mainly allows their preparation as suspensions, pastes, or granules for oral or intraruminal administration. Poor/erratic GI absorption is a common inconvenience for the systemic availability of enterally administered BZD suspensions in most species. The mucous surface in the GI tract behaves as a lipid barrier for the absorption of active substances, so absorption depends on lipid solubility and degree of ionization at GI pH levels. However, drug particles must dissolve in the enteric fluids to facilitate absorption of the BZD molecule through the GI mucosa. The dissolution rate of an enterally delivered compound influences the rate and extent of its absorption (systemic bioavailability), its maximal plasma concentration, its subsequent distribution to target tissues and its overall disposition kinetics. The BZD methylcarbamates show only limited GI absorption due to their poor solubility in water. Their dissolution rate, passage along the GI tract, and absorption into the systemic circulation are markedly slower than those observed for the more hydrosoluble BZD thiazolyls (TBZ). Such a phenomenon also results in extended residence times for the active metabolites of the BZD methylcarbamates compared to those of TBZ. This differential pharmacokinetic behavior accounts, in part, for the greater anthelmintic potency of FBZ and ABZ compared with TBZ.

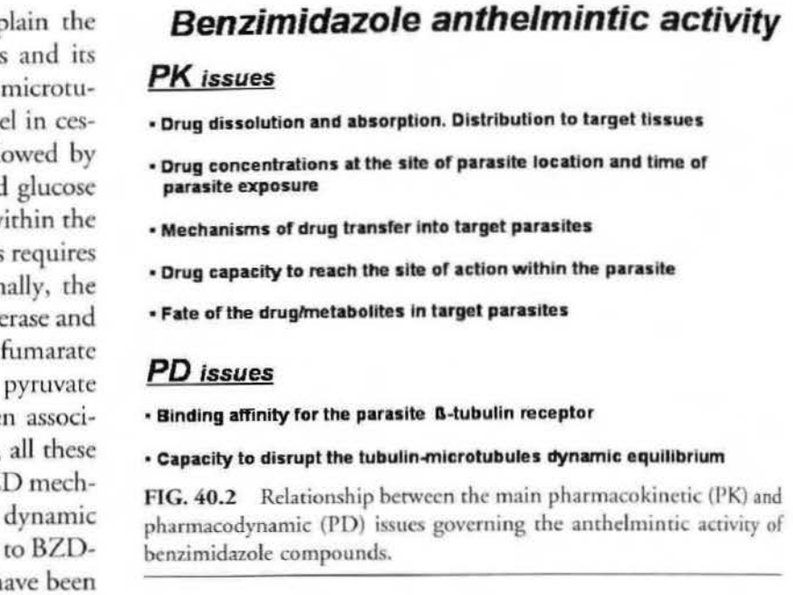


FIG. 40.2 Relationship between the main pharmacokinetic (PK) and pharmacodynamic (PD) issues governing the anthelmintic activity of benzimidazole compounds.

PHARMACOKINETICS AND METABOLISM IN RUMINANT SPECIES

Absorption. The complexity of the ruminant digestive tract in comparison to that of the monogastric animal creates unique problems and opportunities as concerns the absorption of drugs administered orally. The rumen may substantially influence the absorption pattern and the resultant

pharmacokinetics and antiparasite activity of enterally delivered BZD anthelmintics. The rumen accounts for about 20% of the animal's volume and never empties. When a BZD suspension is deposited in the rumen, solid particles mix and distribute through the digesta volume. The adsorption of BZD particles to digesta solid content, the slow mixing and long digesta residence time, and the large rumen volume assists absorption by delaying the rate of passage of drug down the GI tract (Hennessy 1993a). The rumen may act as a reservoir and prolong the duration of drug absorption and/or outflow down the GI tract. On the other hand, dissolution of BZD particles given as drug suspensions is greater at the acid abomasal pH. Thus, the time of residence of the administered BZD suspension at the abomasal level may notably affect the dissolution rate and the subsequent absorption of the drug in the gut. The rumen acts as a drug reservoir by slowing the digesta transit time throughout the abomasum, which results in improved systemic availability of BZD compounds as a consequence of a greater dissolution of drug particles in the acid pH of the abomasums (Lanusse and Prichard 1993b). The influence of the rumen on BZD absorption is evidenced by the higher and more sustained concentration of FBZ, OFZ, ABZ and their metabolites recovered in the bloodstream after oral/intraruminal treatments compared to intraabomasal administration of the same compounds in sheep (Prichard et al. 1978; Marriner and Bogan 1981).

Although the distribution of the drug in the stratified ruminal content may slow absorption and outflow down to the abomasum, the BZD methylcarbamates are less water soluble at ruminal pH than at abomasal pH. The dissolution of the sulphides ABZ and FBZ in the ruminal fluid, or at least the delay of its outflow down to the abomasum, may be important in the resultant plasma bioavailability of the sulphoxide metabolites. This relationship among drug dissolution, GI absorption, and systemic availability may be a critical issue to be considered in the development of successful BZD formulations for use in ruminants.

Metabolism and Elimination. BZD and pro-BZD anthelmintics are extensively metabolized in all mammalian species studied. As a common pattern among different BZD compounds, the parent drug is short-lived and metabolic products predominate in plasma and all tissues and excreta of the host, as well as in parasites recovered from BZD-treated animals (Fetterer and Rew 1984; Alvarez et al. 1999, 2000). The primary metabolites usually are products of oxidative and hydrolytic processes and are all more polar and water soluble than the parent drug. In addition, phase II conjugative reactions are highly important in the detoxification of BZD-derived products. The oxidized and hydrolyzed metabolites are conjugated with glucuronide and/or sulphate to increase their polarities, which facilitates urinary or biliary excretion. Since BZD anthelmintics are mainly administered by the oral route, "first-pass" metabolism is relevant in the kinetic behavior of these compounds. Intestinal, liver, and lung metabolism have been implicated in this phenomenon in most animal species. Additionally, GI metabolism is an important concern in ruminant species.

NTB (pro-BZD) is an anthelmintically inactive nitrophenylguanidine prodrug. NTB is nitroreduced and cyclized into ABZ in a microflora-mediated reductive reaction in the GI tract (Lanusse et al. 1993a). The nitroreduction and cyclization of NTB into ABZ in the host are crucial for the pharmacokinetic profile of its active metabolites and resultant anthelmintic activity. Both formulation and route of administration may dramatically affect the rate of NTB conversion and the bioavailability and disposition of its main plasma metabolites, ABZSO and $ABZSO_2$. Both sheep and cattle ruminal and ileal fluids can convert NTB into ABZ under in vitro conditions (Lanusse et al. 1992b). However, the subcutaneous administration of NTB resulted in lower plasma concentrations of active metabolites compared to those measured after oral administration of the prodrug in sheep and cattle (Lanusse et al. 1990). In conclusion, the oral administration results in an improved pharmacokinetic profile of NTB metabolites, which accounts for some advantageous anthelmintic efficacy after the oral/intraruminal compared to the parenteral treatment.

FBT is a phenylguanidine prodrug that is hydrolyzed by removal of a methoxyacetyl group and then cyclized to FBZ. FBZ is then converted to OFZ and $FBZSO_2$ in subsequent oxidative metabolic steps. Following FBT administration in both sheep and cattle, the parent drug is not found in plasma, or is detected in low concentrations for only a short period. In contrast to the extensive GI metabolism described for NTB, only a low proportion of FBT is bioconverted by sheep and cattle ruminal fluids (Beretta et al. 1987). Hepatic metabolism appears to be the main site of FBT conversion into FBZ after its oral administration to different animal species. The active molecule of the pro-BZD thiophanate is an ethyl BZD carbamate metabolite known as lobendazole (Delatour et al. 1988), formed in the liver with conversion rates of 34% (sheep), 52% (goats), and 57% (cattle).

Thiophanate is currently used as an antifungal agent (TPT-methyl) for plants.

Hepatic and Extrahepatic Oxidative Metabolism. The metabolism of BZD heavily depends on the substituent present at position 5- of the BZD ring system and involves a variety of reactions. Phase I reactions have been observed at position 5-. Hydroxylations of TBZ, ABZ, and FBZ have been demonstrated in different animal species. The sulphoxidation of ABZ and FBZ at the sulfur atom of the substituent group at the carbon 5- of the BZD nucleus have been widely investigated (see Fig. 40.1). In fact, the oxidations of ABZ to ABZSO and FBZ to OFZ have been shown to be catalyzed by the liver microsomal mixed function oxidases in different species (Galtier et al. 1986a; Souhaili El Amri et al. 1987; Montesissa et al. 1989; Lanusse et al. 1993b; Virkel et al. 2004). Additionally, the anthelmintically active sulphoxide derivatives undergo a second, slower, and irreversible oxidative step that forms the inactive sulphone ($ABZSO_2$ and $FBZSO_2$) metabolites, which are also found in the bloodstream and tissues after administration of their respective parent sulphides.

The substitution of the BZD ring in position 5- has been particularly important in determining the metabolic fate of BZD methylcarbamates. This position is metabolically labile and has permitted retardation of the biotransformation of 5-substituted BZD anthelmintics as well as improvement of their efficacy (Hennessy et al. 1989). The nature of this substitution at position 5- markedly influences the sequence of BZD liver metabolism. Aromatic BZD derivatives such as FBZ and OFZ require more extensive hepatic oxidative metabolism than aliphatic derivatives (ABZ and ABZSO) to achieve sufficient polarity for excretion (Hennessy 1993). Consequently, the rates of ABZ liver microsomal sulphoxidation in sheep and cattle were higher than those observed for FBZ (Virkel et al. 2004). Indeed, pharmacokinetic differences between ABZ and FBZ are highly based on their different oxidative metabolism. For this reason, low FBZ concentrations are recovered in plasma following its oral/intraruminal administration to sheep and cattle, while ABZ is not detected in the bloodstream after its administration as parent drug in both species. Moreover, longer plasma mean residence times and elimination half-lives for FBZ and its metabolites, compared to those of ABZ metabolites, were observed in sheep and cattle (Lanusse et al. 1995) (see Fig. 40.3).

The involvement of the cytochrome P450 (CYP) and flavin monooxygenase (FMO) systems on the liver sulphoxidation of ABZ have been demonstrated in different animal species, including sheep (Galtier et al. 1986a) and cattle (Lanusse et al. 1993b). Up to 30% of ABZ sulphoxidation in human liver is mediated by FMO, while the CYP system is the major contributor (~70%) (Rawden et al. 2000). Similarly, CYP is primarily involved (~60%) in ABZ hepatic sulphoxidation in rats, although the FMO enzymatic system is also implicated (Moroni et al. 1995). Similar in vitro studies demonstrated the relative involvement of liver FMO (~32%) and CYP (~68%) on the liver sulphoxidation of FBZ in rats (Murray et al. 1992). Inhibition of CYP-mediated sulphoxidation by piperonyl butoxide demonstrated the participation of this enzymatic system in the hepatic metabolism of FBZ in horses (McKellar et al. 2002). Conversely, it has been demonstrated that FMO is primarily involved in ABZ hepatic sulphoxidation in sheep (Galtier et al. 1986a) and cattle (Lanusse et al. 1993b). Recently, it has been demonstrated that FMO-mediated sulphoxidation accounted for up to 60% of ABZSO production from ABZ, while CYP contributed 40% in both sheep and cattle liver microsomes (Virkel et al. 2004). Similarly, FMO was estimated to be the main enzymatic system involved in the liver sulphoxidation of FBZ (~80%) in both species (Virkel et al. 2004).

Both sulphoxide metabolites (ABZSO and OFZ) have an asymmetric center in the sulfur atom of its side chain. This nucleophilic sulfur atom is attached to four different functional groups, which results in an asymmetric molecule nonsuperimposable with its mirror image. Thus, two different enantiomers of ABZSO and OFZ have been identified (by chiral separation) in the plasma of sheep and cattle treated with ABZ and FBZ (prochiral molecules), respectively (Delatour et al. 1990a; Sánchez et al. 2002) (see Fig. 40.4). It has been shown that (+)ABZSO is the main enantiomeric form recovered in plasma and tissues of parasites location (Alvarez et al. 2000) following ABZ treatment to sheep (see Fig. 40.5). The same pattern was observed after ABZSO administration to cattle (Cristofol et al. 2001). Similarly, (+)OFZ prevails in the systemic circulation after both FBZ and OFZ administrations to sheep (Delatour et al. 1990a; Sánchez et al. 2002) and cattle. The observed differences on the plasma/tissue availabilities of the (+) and (–) enantiomeric forms were attributed to the relative contribution of the FMO and CYP-dependent oxygenases to ABZ and FBZ hepatic sulphoxidation. Many steps in drug metabolism have been shown to be chiral-dependent. Enantioselectivity of

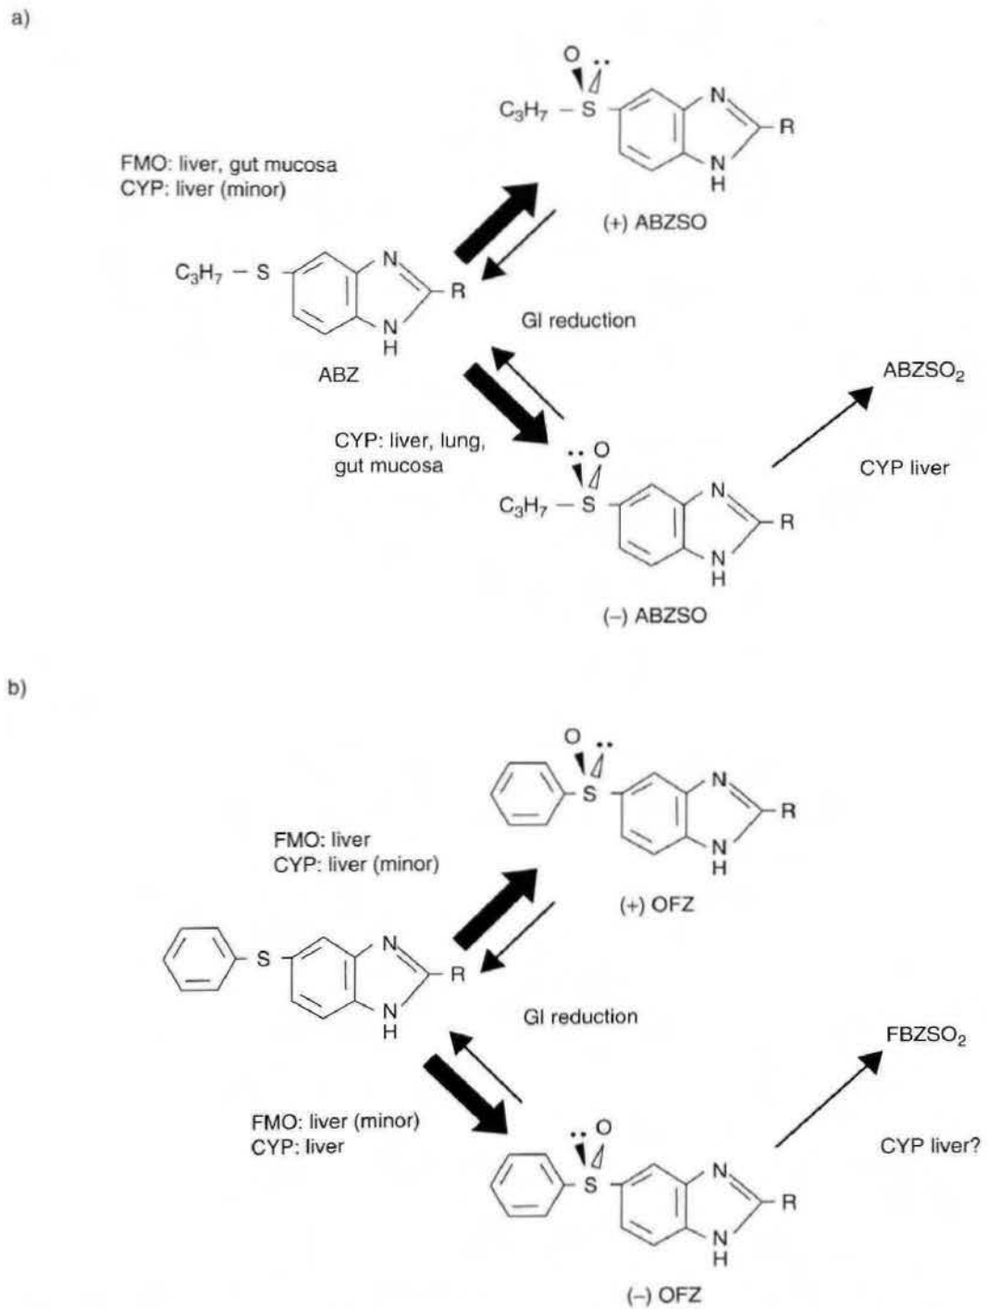

FIG. 40.3 Proposed metabolic pathways for the enantioselective sulphoxidation and sulphonation of a) albendazole (ABZ) and b) fenbendazole (FBZ). The gastrointestinal (GI) sulphoreduction of both sulphoxide enantiomers (ruminants) to form the parent thioethers (ABZ, FBZ) is also shown. The width of the arrows represents the proportional magnitude of each metabolic pathway (see the text). Data from Delatour et al. 1991; Benoit et al. 1992; Redondo et al. 1999; Virkel et al. 2002, 2004.

FMO: flavin monooxygenase; CYP: cytochrome P-450; ABZSO (ABZ sulphoxide); OFZ (oxfendazole, FBZ sulphoxide); $ABZSO_2$ (ABZ sulphone); $FBZSO_2$ (FBZ sulphone).

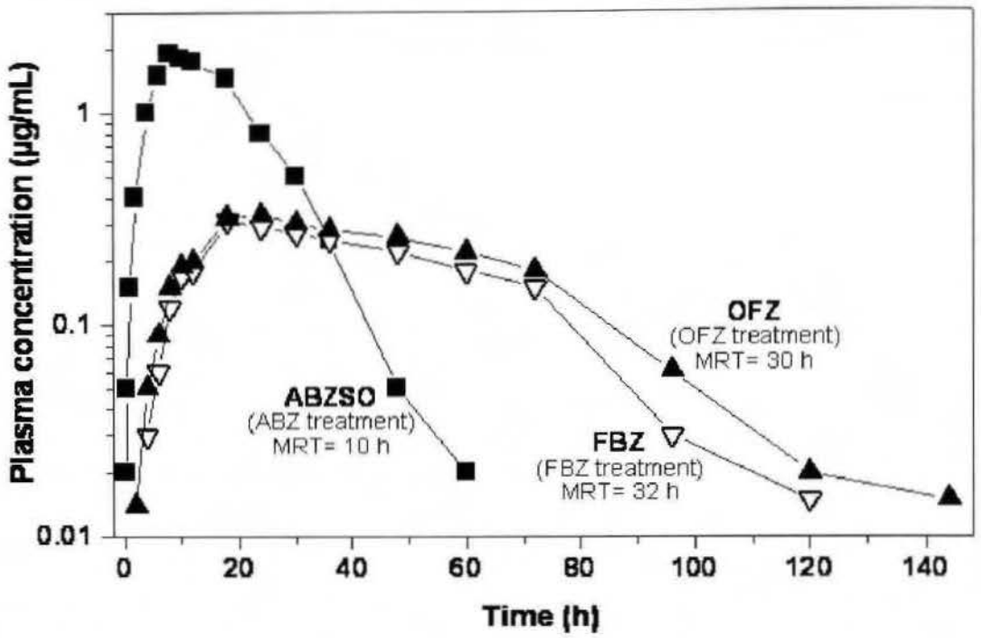

FIG. 40.4 Comparative mean (n = 5) plasma concentrations of the benzimidazole sulphoxide metabolites: albendazole sulphoxide (ABZSO) and oxfendazole (OFZ) obtained after oral administration of albendazole (ABZ), fenbendazole (FBZ), and OFZ (5 mg/kg) to adult sheep (see text for further explanation). Adapted from Lanusse et al. 1995.

MRT: mean plasma residence time (h) for each molecule.

metabolic products occurs when chiral metabolites are generated differentially (in qualitative or quantitative terms) from a single achiral substrate. Thus, two different Km values for the production of each ABZSO enantiomer have been reported after ABZ (prochiral molecule) incubation with liver microsomes obtained from rats (Moroni et al. 1995) and calves (Virkel et al. 2004). These observations are consistent with the involvement of two different enantioselective enzymatic pathways on the liver sulphoxidation of ABZ. Indeed, FMO and CYP are known to be oppositely enantioselective (Cashman 1998). FMO activity accounted for 94% (cattle) and 81% (sheep) of (+)ABZSO production in liver microsomes (Virkel et al. 2004). In both species, the enantioselectivity of the hepatic FMO system toward (+)ABZSO production was close to 100%. On the other hand, FMO-mediated sulphoxidation of FBZ generated both (+) and (−) OFZ enantiomers. FBZ oxidation was enantioselective toward the production of (+)OFZ in both sheep (65%) and cattle (79%). In conclusion, the sulphoxide metabolite recovered in plasma and target tissues after either ABZ or FBZ administration does exist as two different chemical entities: the (+) and (−) enantiomeric forms (see Figures 40.4 and 40.5).

Biotransformation takes place predominantly in the liver, although metabolic activity is apparent in extrahepatic tissues such as lung parenchyma and small intestine mucosa. Large quantities of ABZ parent drug were recovered from tissues of parasite location in both sheep and cattle. Similarly, FBZ has been recovered from tissues of parasite location following oral administration of OFZ to cattle. Altogether, these findings support the need for studying the biotransformation of BZD anthelmintics in extrahepatic tissues such as lung parenchyma and small intestinal mucosa. In fact, the relative involvement of FMO (~49–60%) and CYP (~40–51%) systems on the sulphoxidation of ABZ by gut epithelium was studied in rats (Redondo et al. 1999). The sulphoxidation of ABZ and FBZ by small intestine (cattle) and lung (sheep and cattle) microsomes was shown to be enantioselective (Virkel et al. 2004). Although the liver is the main site of ABZ and FBZ biotransformation, sulphoxidation in the intestinal mucosa and lung tissue (see Fig. 40.4) may contribute to the presystemic metabolism of both anthelmintic drugs and should not be underestimated.

The administration of TBZ results in a rapid conversion of a parent compound into a 5-hidroxy TBZ metabolite,

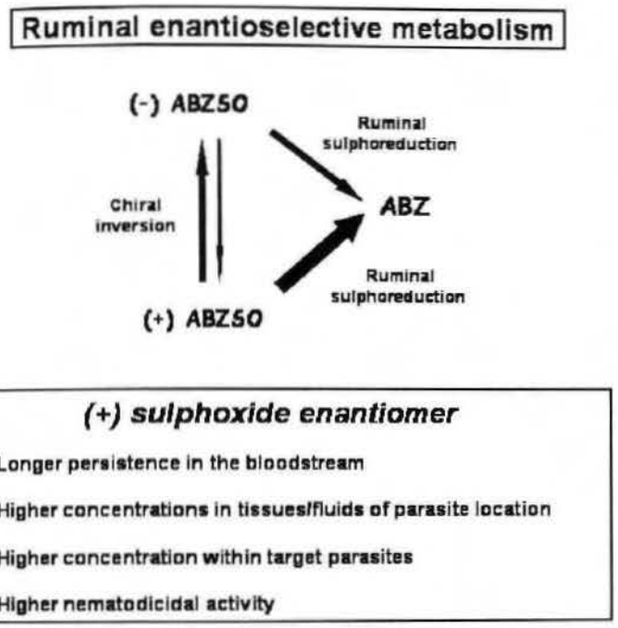

FIG. 40.5 Schematic representation of the ruminal biotransformation of albendazole sulphoxide (ABZSO) enantiomers. The width of the arrows indicates the magnitude of the metabolic reactions. The main pharmacological features of the (+) sulphoxide enantiomer, compared to the (−) isoform, are listed in the bottom box. The enantioselective ruminal sulphoreduction of the (+) isoform is the most relevant metabolic reaction for the formation of the parent thioether (ABZ). The same pattern is applicable to the sulphoreduction of oxfendazole (OFZ) enantiomers into fenbendazole (FBZ) (see the text for detailed explanation). Adapted from Virkel et al. 2004.

formed by aromatic ring hydroxylation. Although this metabolite is sufficiently polar for a rapid urinary excretion, both its unconjugated and sulphate or glucuronide conjugated forms have been found in urine of TBZ-treated animals (Tocco et al. 1965; Gottschall et al. 1990). MBZ is absorbed, metabolized by the liver, and excreted in bile. Following intravenous administration of [C^{14}]MBZ in bile ducts–cannulated rats, 84.3% of the total recovered radioactivity was present in the bile, whereas only 15.7% appeared in urine (Allan and Watson 1983).

After the administration of MBZ to sheep, the parent drug is rapidly absorbed and metabolized into two main metabolites, which are identified in sheep plasma after MBZ treatment (Behm et al. 1983). The main MBZ metabolite results from carbonyl reduction to the secondary alcohol, which was also identified as its glucuronide or sulphate conjugates. Although the specific enzymatic system responsible for MBZ reduction is unknown, several cytosolic ketone reductases are involved in the formation of hydrosoluble metabolites from carbonyl-containing molecules. On the other hand, combination of carbonyl reduction and carbamate hydrolysis produces the hydrolyzed metabolite of TBZ. Hydrolysis of the carbamate group eliminates both, the anthelmintic activity of the compound and its toxicity. MBZ over its metabolites appears to be the active anthelmintic molecule.

Unlike aromatic substituted methylcarbamates, 5-aliphatic substitutes such as ABZ and PBZ, when oxidized, are sufficiently polar to be largely excreted in urine rather than undergo further conjugation and secretion in bile (Hennessy et al. 1989). For instance, following ABZ treatment to sheep only 8% of the total dose was recovered in bile as unconjugated ABZSO and OH-ABZSO metabolites, and 6.3% as conjugated glucuronide and sulphate esters mainly of 2OH-ABZSO and 2OH-$ABZSO_2$ (Hennessy et al. 1989); 59% of the dose was recovered in urine of ABZ-treated cattle (Gyurik et al. 1981). On the other hand, the percentage of FBZ dose recovered in urine (2.5%) in cattle was markedly lower than that recovered from feces (42%), the latter being mainly the unchanged FBZ parent compound (Short et al. 1987).

The parent flubendazole (FLBZ) compound and its reduced (R-FLBZ) and hydrolyzed (H-FLBZ) metabolites have been identified in tissues of treated pigs, poultry, and sheep. FLBZ disposition kinetics has been recently studied in sheep (Moreno et al. 2004). After its i.v. administration, the parent drug was rapidly depleted from the bloodstream, being detectable up to 36 hours posttreatment. The metabolites R-FLBZ and H-FLBZ were rapidly detected in the bloodstream, which indicates a fast biotransformation of FLBZ to form both metabolic products. R-FLBZ was the main analyte measured in plasma for up 60 hours after the i.v. treatment. In vitro incubations with sheep liver microsomes indicate that FLBZ is biotransformed by the mixed-function oxidase system (Moreno et al. 2004). However, sheep liver microsomes failed to hydrolyze the methylcarbamate group in position -2 of the BZD ring to produce the $-NH_2$ derivative of FLBZ (H-FLBZ). The low levels of hydrolytic enzymes in the microsomal fraction may account for the lack of FLBZ conversion into H-FLBZ.

Reductive Metabolism in the Gastrointestinal Tract. In comparison to the liver where oxidative metabolism predominates, the GI microflora is very active in reductive reactions of foreign compounds, particularly

those containing -nitro and -sulphoxide (Renwick et al. 1986; Rowland 1986) groups. Drug GI metabolism may be modified by the type of diet and many other factors affecting the GI bacterial reductive capacity. Orally administered compounds that are poorly absorbed from the GI tract will stand the greatest chance of undergoing metabolism by the microflora, although a large number of drug/metabolites gain entry to the gut via biliary secretion or plasma-GI distribution exchange and will also be exposed to microbial activity. Drug metabolic processes taking place in the rumen are particularly important in ruminant therapeutics.

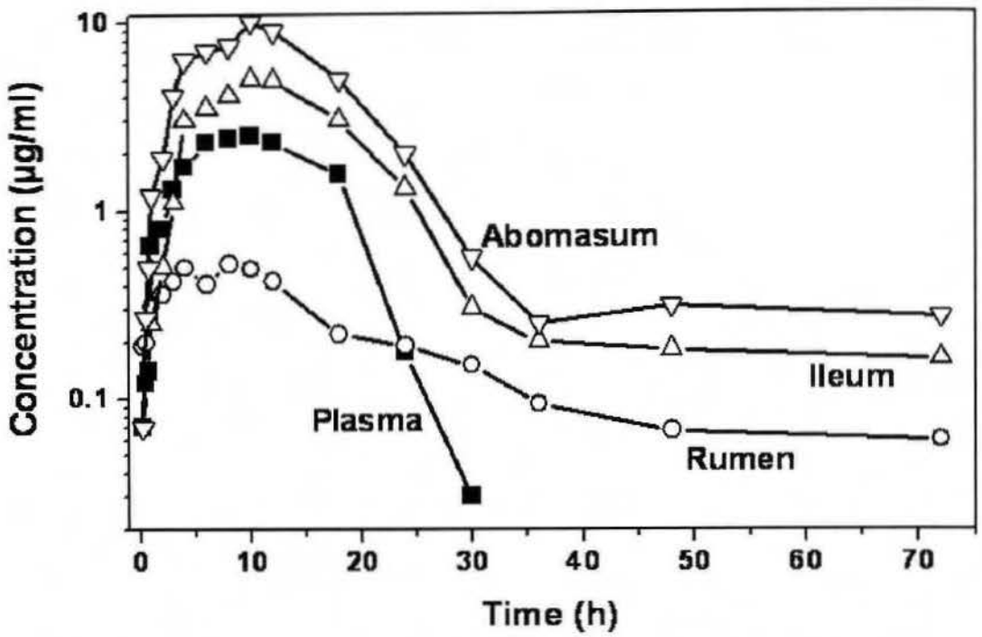
The sequential oxidation of BZD thioether (ABZ, FBZ) compounds in the liver and extrahepatic tissues leads to the production of more polar and less anthelmintically effective sulphoxide and sulphone metabolites. However, the importance of the biotransformation of BZD and pro-BZD compounds in the lumen of the GI tract should not be underestimated. Taking into consideration the extent of the exchange surface between plasma and digestive tract in ruminants and the large volume of the forestomach, any potential bioconversion of these compounds taking place in the gut lumen could have a significant impact on both the pharmacokinetic behavior and the availability of anthelmintically active metabolites at the sites where GI and tissue-dwelling parasites are located. The metabolic sulphoreduction of the BZD sulphoxide metabolites (ABZSO and OFZ) to form the parent thioethers (ABZ and FBZ, respectively) has been shown to occur in ruminal and intestinal fluid contents from sheep and cattle (Lanusse et al. 1992b). A plasma-GI pH gradient (Lanusse et al. 1993a) and/or an active gastric secretion process (Alí and Hennessy 1995) account for the distribution of BZD metabolites from plasma to the digestive tract lumen. Therefore, ABZSO and OFZ can be reduced back to their respective thioethers by ruminal and intestinal microflora and may act as a source of ABZ and FBZ, respectively, in the GI tract. This GI metabolic reduction may be of primary importance for the antiparasitic efficacy of BZD thioethers. Since the thioethers have a greater affinity for parasite tubulin than the sulphoxides (Lacey 1990; Lubega and Prichard 1991), this bacteria-mediated reduction may have significant importance for the efficacy against GI parasites. Thus, the high efficacy of ABZSO and OFZ against GI parasites may depend on this bacterial reduction of the sulphoxide to the more pharmacologically active thioethers. The in vivo nematodicidal efficacy of ABZSO and OFZ is similar to that of ABZ or FBZ.

Undoubtedly, the plasma/GI tract distribution of the active sulphoxide metabolites is of major relevance for the efficacy of BZD anthelmintics against GI parasites. It has also been demonstrated that (+)ABZSO is the main enantiomeric form recovered in tissues of parasite location following ABZ treatment in sheep (Alvarez et al. 2000) and racemic ABZSO administration to cattle (Cristofol et al. 2001), which agrees with the lower systemic availability and faster depletion of the (−)enantiomer observed in both species. The relative contribution of the FMO and CYP-dependent oxygenases to ABZ hepatic sulphoxidation accounts for such differences in the availability of each enantiomeric form in plasma and tissues. Moreover, it has been shown that (−)ABZSO rather than its (+) antipode, would be the main substrate for the CYP-mediated formation of the inactive sulphone ($ABZSO_2$) metabolite (Delatour et al. 1991; Benoit et al. 1992). Altogether, these findings would indicate that (+)ABZSO, being predominant in the bloodstream, may be the main enantiomeric form available in the GI tract. In fact, higher availabilities of the (+)antipode, compared to that of the (−)enantiomer, were observed in plasma and GI tract after the administration of both racemic ABZSO and OFZ to cattle (Cristofol et al. 2001). Since ABZ and FBZ are formed in rumen from ABZSO and OFZ, respectively, in a bacteria-mediated sulphoreduction, the (+)enantiomers would be the main source for the parent sulphide formation (see Fig. 40.5). This is consistent with the faster depletion of the (+)ABZSO antipode incubated with ruminal fluid under anaerobic in vitro conditions (Virkel et al. 2002). The binding of BZD anthelmintics to parasite tubulin produces the subsequent disruption of the tubulin-microtubule dynamic equilibrium. It is well established that ABZ has a greater affinity for parasite tubulin than ABZSO. Although both enantiomeric forms are substrates for the formation of ABZ, the most efficient (enantioselective) sulphoreduction of (+)ABZSO to form a more pharmacologically potent product (ABZ) (Virkel at al. 2002), may greatly contribute to the pattern of efficacy of these anthelmintics against GI parasites. Indeed, these observations may suggest a lower contribution of the (−) antipode to the overall efficacy of ABZ/FBZ and related anthelmintics (see Fig. 40.5). Chiral inversion is the metabolic process by which one enantiomer is transformed into its antipode. The chiral inversions of (+) into (−) but also from (−) into (+) enantiomeric forms were observed when both enantiomers were incubated separately (as pure substrates) with ruminal fluid obtained from both sheep and

cattle (Virkel et al. 2002) (Fig. 40.5). Thus, the reported data suggests that chiral inversion of RBZ and OFZ enantiomers is likely to be bidirectional and may depend on either the metabolic transformation of one enantiomer into its antipode or through the formation of parent thioether (ABZ or FBZ) as an intermediate metabolic product. Overall, the work published by Virkel et al. (2002) demonstrates that the ruminal sulphoreduction of both ABZSO and OFZ is enantioselective, with the (+) antipode being the main substrate to form the more active parent sulphide in the rumen.

Distribution to Parasite Location Tissues. Release from dosage form and absorption precede entry of any anthelmintic molecule into the bloodstream, which serves as the tissue in which drug and metabolite molecules are conducted to various parts of the body. Within the bloodstream, a fraction of most drugs binds reversibly to plasma proteins, and the remainder undergoes simultaneous distribution, metabolism and excretion. The access of BZD molecules to intracellular sites depends upon their ability to penetrate the capillary endothelium and to cross the cell membrane. Most anthelmintics are weak organic acids or bases and exist in solution, at physiological pH, as both nonionized and ionized forms; while the poor lipophilicity of the ionized molecules excludes them from passive diffusion, the lipid-soluble nonionized moieties passively diffuse across biological membranes until equilibrium is established. Once the BZD molecule has been absorbed from the GI tract, it is rapidly distributed by the circulatory system throughout the entire body. During this time, the metabolic processes necessary to facilitate its elimination commence. Extensive tissue distribution of ABZ and its metabolites in sheep (Alvarez et al. 1999) and cattle (Sánchez et al. 1997) have been reported. However, differential distribution patterns among BZD sulphides (FBZ, ABZ), sulphoxide (OFZ, ABZSO), and sulphone ($FBZSO_2$, $ABZSO_2$) metabolites, based on their differential lipophilicities, may be expected. The distribution rate, which is indicated by the apparent volume of distribution, depends on molecular weight, lipid solubility, and plasma protein binding of each drug/metabolite. The majority of BZD compounds show a binding of less than 50% to plasma protein, relatively high volume of distribution, and a relatively fast elimination rate in ruminant species.

The rate of absorption, metabolism, and excretion of BZD anthelmintics varies from drug to drug, with slower absorption and prolonged recycling between enteral and parenteral tissues being relevant to enhance efficacy. Worms attached to the lining of the gut may be more exposed to this recycling drug than to that actually passing down the GI tract in food which is being digested. Moreover, the absorbed BZD drug may be more important than unabsorbed drug passing down the gastrointestinal tract, even against gastrointestinal nematodes (Hennessy and Prichard 1981). OFZ given intravenously to sheep (5 mg/kg) has been proven to be equally or more effective than oral OFZ against BZD-resistant *Haemonchus contortus* in the abomasum and *Trichostrongylus colubriformis* in the small intestine. FBZ, OFZ, and ABZ are less water soluble than earlier members of the group and, therefore, their dissolution rate, passage along the GI tract, and absorption into the systemic circulation are markedly slower compared to TBZ. These more lipophilic substituted BZD methylcarbamate compounds remain in the bloodstream for a longer time and, since it is assumed that an equilibrium exists between plasma and GI tract, the period of exposure of GI nematodes to effective drug/metabolites concentrations is extended. In NTB treated cattle, peak concentrations of ABZSO and $ABZSO_2$ are reached at 7–10 hours (ABZSO) and at 15–22 hours ($ABZSO_2$) posttreatment followed by a well-defined decline in concentration in both plasma and GI compartments. However, whereas plasma concentration fell to undetectable levels (30–36 hours posttreatment), the profile of these metabolites in the rumen, abomasum, and ileum showed an "extra" slow elimination phase that extended to 72 hours posttreatment (see Fig. 40.6). This pharmacokinetic behavior is particularly clear for the ABZSO and $ABZSO_2$ metabolites, whose elimination half-lives in both the abomasum and ileum were significantly longer compared to plasma. This metabolite-distribution process, also described for FBZ metabolites in cattle, may be driven by a plasma/GI tract pH gradient. The ratio of nonionized to ionized forms depends upon the pKa of the drug and the pH of the fluid in which the drug is dissolved, and the pH gradient between plasma and different tissues dictates the concentrations of drug/metabolite at either side of the separating cell membranes; at equilibrium, there will be a higher total concentration of the drug on the side of the membrane where the degree of ionization is greater. For instance, the pKa for the ABZSO metabolite is 7.8, and at plasma pH, there will be an important proportion of this molecule under the nonionic form, which will facilitate its passive diffusion from plasma to parasite location tissues. A greater plasma/abomasum pH gradient compared with that of the rumen and ileum would produce a strong ionic trapping effect,



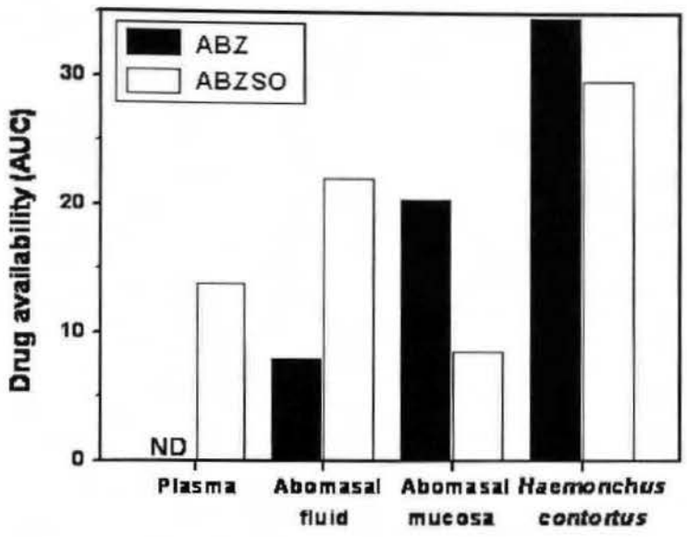


FIG. 40.6 Comparative albendazole sulphoxide (ABZSO) concentration profiles measured in the bloodstream and in different gastrointestinal compartments after the oral administration of netobimin prodrug (20 mg/kg) to cattle.

The results show the slow elimination phase observed in digestive compartments (compared to plasma), which is critical for efficacy against gastrointestinal nematodes (see the text for further explanation). ABZSO elimination half-life values were 2.29 h (plasma), 16 h (rumen), 34 h (abomasum), and 67 h (ileum). Adapted from Lanusse et al. 1993.

which would account for the significantly higher concentrations of ABZ metabolites found in the abomasum in comparison with plasma and other GI compartments. In addition, although ABZ (the most potent anthelmintic molecule) is not detected in the bloodstream, it has been recovered in different GI compartments, with particularly high concentration profiles recovered in the abomasal mucosa as well as from *Haemonchus contortus* recovered from treated sheep (see Fig. 40.7) The extensive distribution of BZD methylcarbamates from the bloodstream to the GI tract and other tissues may contribute to anthelmintic efficacy against parasites localized in body tissues, including GI mucosa and lumen, lungs, and bile ducts (Alvarez et al. 1999, 2000). The recovery of both ABZ and FBZ parent compounds from GI mucosa and lung tissue after intravenous administration of their sulphoxide derivatives to cattle (as described in the section on GI metabolism), is further evidence of the complex relationship among drug distribution, metabolism, and efficacy of BZD anthelmintics in ruminants.

Comparative studies have revealed considerable differences between ruminant species regarding the pharmacokinetics of anthelmintic drugs. Higher concentrations of TBZ have been reported in plasma of sheep compared to goats and cattle. The higher proportion of TBZ over its main metabolite 5-OH-TBZ excreted in the urine of TBZ treated sheep, compared to cattle, may be a consequence of reduced oxidative capacity of sheep liver microsomes compared to that observed for cattle and goats. The lower anthelmintic activity observed for TBZ against lung nematodes and inhibited larval stages of *Ostertagia ostertagi* in cattle, compared to that observed against lung nematodes and inhibited larval stages of *Ostertagia circumcincta* in sheep, may be related to the limited TBZ systemic availability achieved in cattle and by the fact that its main metabolite is anthelmintically inactive. On the other hand, the OFZ AUC after OFZ administration to goats was 39% smaller than that observed in sheep (Hennessy et al. 1993a). It is suggested that goats possess a faster hepatic metabolism than sheep resulting in more rapid elimination of OFZ. This lower availability may account for the poor efficacy reported for OFZ given to goats at the dose recommended for sheep. These observations suggest that extrapolated data can be

- ABZSO was the main active molecule measured in plasma after ABZ treatment in sheep
- High concentrations of ABZ and ABZSO were recovered from H. contortus
- ABZ total availability was greater in H. contortus compared to abomasal tissue/fluid

FIG. 40.7 Comparative albendazole (ABZ) and albendazole sulphoxide (ABZSO) availabilities (expressed as area under the concentration versus time curve, AUC) obtained in plasma, abomasal fluid, abomasal mucosa, and *Hemonchus contortus* recovered from infected sheep treated with ABZ (intraruminal at 7.5 mg/kg) (see the text for further explanation). misleading in predicting adequate dosages and withdrawal times.

PHARMACOKINETICS IN NONRUMINANT SPECIES. The oral administration of BZD (FBZ, OFZ) compounds in horses demonstrated that reduced bioavailability and shorter residence times are obtained in comparison to those observed in ruminants. Following oral administration of either FBZ or OFZ (10 mg/kg) to horses, the inactive $FBZSO_2$ metabolite is the predominant analyte measured in plasma, with AUC ratios OFZ/FBZ/$FBZSO_2$ of approximately 3/1/9 (OFZ treatment) and 1/4/7 (FBZ treatment) (McKellar et al. 2002). In both cases, the time to reach the peak plasma concentration of the active OFZ metabolite was approximately 9 hours, which is earlier compared to that observed in ruminants and agrees with the reduced systemic availability observed in horses.

As described for ruminant species, ABZ is not detected in plasma after its oral administration to pigs (Alvarez et al. 1995). ABZSO and $ABZSO_2$ are the main metabolites recovered from plasma up to 48 hours posttreatment. The pattern of plasma metabolites is similar to that reported after the administration to ruminant species and there appear to be no major differences between the metabolic patterns of ABZ observed in pigs and sheep. However, marked differences in the metabolism of ABZ between cattle and pigs have been described, with predominance of the sulphoxide metabolite over $ABZSO_2$ in pig plasma, while the inverse is observed in cattle after ABZ treatment. Similar to the observations in ruminants, the time of residence of the ABZ suspension at the acidic pH of the stomach in the pig affects its dissolution rate and the subsequent absorption of the drug from the gut. Any factor that influences gastric emptying rate may have a profound effect on the rate and extent of BZD absorption in

monogastric animals. After oral FBZ administration to pigs, OFZ (the main metabolite recovered) and $FBZSO_2$ are rapidly detected in plasma up to 48 hours posttreatment. OFZ reaches a Cmax value (0.7 µg/ml) at 12.5 hours posttreatment (Petersen and Friis 2000). The bioavailability of FBZ in pigs after its oral administration was estimated at about 30%. This low value is a consequence of the low water solubility of FBZ and its poor GI absorption plus the significant liver first-pass effect suffered by the drug.

The gut transit time influences the dissolution and absorption of poor water-soluble drugs such as the BZD anthelmintics. The drugs that do not dissolve in GI contents pass down and are excreted in the feces without exerting their action. The GI physiology and the digesta transit time are markedly different between monogastric species and ruminants. This is relevant for dogs and cats, whose GI transit times are significantly shorter compared to ruminant species; this has a marked effect on the absorption, kinetic behavior, and efficacy of BZD anthelmintics in companion animals. ABZ, FBZ, FBT, or MBZ formulated as tablets or suspensions for oral administration in dogs and cats must dissolve at low pH (stomach), and it has been demonstrated that the dissolution rate may be altered depending on the size of the formulation particle (Hennessy 1993). Several studies suggest that only limited rates of dissolution and absorption of BZD anthelmintics are achieved in cats, dogs, and man. Consequently, these compounds may need to be given at a higher dose or as multiple administrations in order to maintain therapeutic concentrations and, therefore, to achieve acceptable anthelmintic efficacy (Roberson and Burke 1982; Edwards and Breckenridge 1988).

MBZ is poorly absorbed after oral administration and only low concentrations (representing 10% or less of the total administered dose) of MBZ parent drug and its inactive metabolite, OH-MBZ, were recovered in plasma of humans and dogs after oral treatment (Witassek et al. 1981; Edwards and Breckenridge 1988). This observation could explain the lack of efficacy of MBZ against lung parasites in humans and dogs and the need for the design of multiple dose treatments. The pharmacokinetics of FBZ parent drug and its metabolites in dogs has been characterized (McKellar et al. 1990). FBZ parent drug, its active sulphoxide (OFZ), and inactive sulphone ($FBZSO_2$) metabolites were recovered in plasma for 48 hours after administration of a single oral dose of 20 mg/kg. Interestingly, plasma concentrations for both active molecules (FBZ and OFZ) are depleted in parallel from the body, giving an AUC ratio (FBZ:OFZ) of approximately 0.82. This may result in exposure of target parasites to the FBZ moiety (which has greater potency than OFZ), which would account for some advantageous activity against the tissue arrested larvae and other immature parasite stages (McKellar et al. 1990). When ABZ was given as a single dose in tablet form, ABZSO and $ABZSO_2$ were the main metabolites detected in plasma for up to 16 hours posttreatment (Sánchez et al. 2000a). Compared to ruminants, where the rumen acts as drug reservoir, effective treatment in dogs of monogastrics requires more prolonged, multidose regimes of at least 3 to 5 days depending on the dose used. There are conclusive pharmacokinetic results to support the concept that higher efficacy could be expected in dogs and cats by increasing the number of treatments rather than increasing the dose. In fact, the AUC of FBZ in dogs was similar after single administration of FBZ at different dose levels over a range between 2.5 and 100 mg/kg (McKellar et al. 1993). Lower FBZ plasma concentrations were achieved in dogs when FBZ was given on an empty stomach, compared with its administration in food. However, fat content in the diet does not affect the absorption of FBZ after its oral administration to dogs (McKellar et al. 1993).

After the oral administration of FBZ to chickens, the parent drug, OFZ, and $FBZSO_2$ are detected in plasma, with $FBZSO_2$, the main metabolite, recovered up to 96 hours posttreatment (Taylor et al. 1993). ABZ parent drug is absorbed slowly and detected from 1–6 hours posttreatment in chickens, with ABZSO being the main metabolite detected with a peak concentration of 0.83 µg/ml obtained at 1 hour posttreatment (Csiko et al. 1996) and low $ABZSO_2$ concentrations measured between 2.5–30 hours after ABZ administration. Data provided for chickens indicated that ABZ and FBZ are metabolized in avian species via the same metabolic pathway as in mammals (McKellar and Scott 1990). The metabolism of FBZ to its sulphoxide and sulphone metabolites appears to be much more rapid than in ruminant species. As it can be expected for dogs, cats, and man, the GI reductive metabolism of the BZD sulphoxide into the parent sulphides is markedly less relevant in poultry compared to ruminant species. FLBZ is widely used as an anthelmintic in poultry and its main metabolites, H-FLBZ and R-FLBZ, have been identified in tissues of FLBZ medicated turkeys.

MECHANISMS OF DRUG TRANSFER INTO TARGET PARASITES. Understanding the role of the cuticular/tegumental structure on the process of drug uptake by helminth parasites is a scientific area of major interest. It has been shown in ex vivo and in vivo studies that transcuticular diffusion is the predominant pathway for the entry of anthelmintic drugs into nematodes (Cross et al. 1998; Alvarez et al. 2001). Although there are relevant structural differences between the external surface of nematodes (cuticle) and cestodes/trematodes (tegument), the mechanism of drug entry to both types of helminths seems to be equally dependent on lipophilicity as a major physicochemical determinant of drug capability to reach therapeutic concentrations within the target parasite. A high correlation between the octanol-water partition coefficients for different BZD anthelmintics and their capacity to diffuse through the tegument of *Moniezia expansa* has been shown (Mottier et al. 2003). The most lipophilic BZD compounds (FBZ, ABZ, MBZ) (partition coefficients >3.7) were measured at higher concentrations within the tapeworm compared to those with the lowest lipid-water partition values (OFZ, ABZSO, TBZ, etc.). A lower diffusion of ABZ and ABZSO into *Ascaris suum* compared to *Moniezia* spp. and *Fasciola hepatica* has been demonstrated (Alvarez et al. 2001). Nematodes maintain a strongly buffered environment in the aqueous spaces of the cuticle structure, with a pH value of this compartment around 5.0 (accumulation of organic acids as products of carbohydrate metabolism). The lipid-containing region of the cuticle represents the rate-determining barrier for passive transport: the molecular size, restriction by pores, intrinsic lipid-water partition coefficient, and pH/pK_a relationship, are among the rate determining factors (Ho et al. 1992). BZD molecules are weak bases that may largely exist under their ionized form at the acidic environment of the nematode surface, which may limit their diffusion across the cuticle. This ionization-mediated impairment of drug diffusion and the complex structure of the nematode cuticle compared to the cestode/trematode tegument, may explain the drug penetration differences observed between nematode and other helminths (Alvarez et al. 2001). In fact, this work demonstrated that the diffusion of BZD molecules into *F. hepatica* and *Moniezia* spp. is markedly greater than that observed in the nematode *A. suum* maintained under the same ex vivo conditions (see Fig. 40.8).

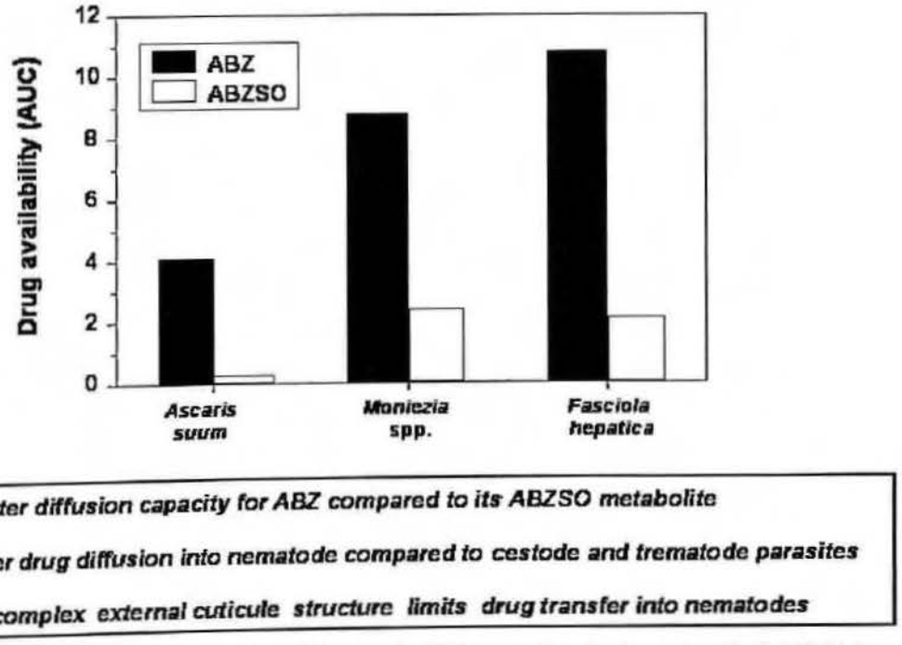

FIG. 40.8 Comparative assessment of the ex vivo transfer of albendazole (ABZ) and albendazole sulphoxide (ABZSO) into *Ascaris suum* (nematode), *Moniezia* spp. (cestode), and *Fasciola hepatica* (trematode). Values represent drug availability in the parasite tissue, expressed as area under the concentration versus time curve (AUC) (see the text for further explanation). Adapted from Alvarez et al. 2001.

AUC values expressed in µg.h/g.

The identification of the capability of different helminth parasites to biotransform anthelmintic drugs is considered as another crucial step to the overall interpretation of their pharmacological activity. It has been shown that both cytosolic and microsomal fractions obtained from different helminths are able to oxidize ABZ into its sulphoxide derivative. While this oxidative pathway is predominant in *F. hepatica*, the sulphoreduction of ABZSO into its parent sulphide compound is the main metabolic activity identified in tapeworms (Solana et al. 2001). As described above, the liver microsomal oxidation of ABZ and FBZ in sheep and cattle is enantioselective toward the (+) enantiomeric form. However, the oxidation of ABZ by helminth microsomal fractions produced equivalent proportions of both ABZSO enantiomers. Although further investigation is required to establish the pharmacological relevance of drug biotransformation in target parasites, particularly regarding its potential impact on the development of resistance, these findings are complementary to the studies addressed to understand the mechanisms of drug penetration in helminths.

Higher ABZSO and OFZ compared to ABZ and FBZ, concentrations have been reported in GI fluids of different ruminant species. However, the high lipophilicity of the parent thioethers (ABZ, FBZ) assures their penetration through the external parasite. The higher anthelmintic potency of ABZ and FBZ and their greater capability to diffuse into the parasite, suggest that the parent drug may be the main molecule responsible for the activity against GI parasites. However, a complementary effect of the sulphoxide metabolites, measured at higher concentrations in most of the parasite location tissues, may contribute to the overall anthelmintic activity of these BZD methylcarbamates. Thus, the pharmacological activity of ABZ against helminth parasites may depend on the irreversible impairment of essential microtubule-dependent cellular functions induced by an additive effect of both molecules. A similar pattern could be expected for FBZ, where the high OFZ concentration profiles recovered in tissues of the parasite location and its bacteria-mediated GI sulphoreduction into the more active FBZ parent drug could markedly contribute to its overall anthelmintic efficacy. The recovery of anthelmintically relevant concentrations of both ABZ and FBZ parent molecules in critical parasite location tissues (i.e., GI mucosa, lungs, etc.) after treating cattle with ABZSO and OFZ, respectively, strongly support the argument stated above on the relative role of the parent drug and sulphoxide metabolites on anthelmintic activity.

ANTHELMINTIC SPECTRUM. BZDs and pro-BZDs were introduced into the animal health market primarily for the control of GI nematodes, not only for use in livestock animals (cattle, sheep, goats, swine, and poultry), but also for horses, dogs, and cats. The use of BZD and pro-BZD compounds quickly became widespread because they offered major advantages over previous available drugs in terms of spectrum, efficacy against immature stages, and safety for the host animal. Additionally, BZD anthelmintics have ovicidal activity. With the exception of the halogenated BZD thiol, triclabendazole, which has only flukicidal activity against all stages of *Fasciola hepatica* (see Chapter 41), all BZDs and pro-BZDs can be classified as broad-spectrum anthelmintics. However, the substituted sulfur-containing methylcarbamates (ABZ, FBZ, etc.) and pro-BZDs (FBT, NTB) have an extended spectrum of activity compared to the earlier BZD thiazolyls (i.e., TBZ). It has been demonstrated that the greater potency and spectrum of activity of the newer BZDs are largely a function of their pharmacokinetic behavior rather than entirely due to their intrinsic differences in activity (see Fig. 40.2). Overall, the BZD methylcarbamates are broad-spectrum anthelmintics active against a variety of GI and lung nematodes, tapeworms, and trematodes (ABZ derivatives). As a consequence of their pharmacokinetic behavior in monogastric species (particularly in dogs and cats), the BZDs are more effective when they are administered for several days, over single-dose treatments. The available commercial formulations and indications for use (route of administration, dosage and target animal species), may vary among different countries. Readers interested in any specific issue on the spectrum of activity for BZD compounds are referred to the previous edition of this textbook (see Reinemeyer and Courtney 2001). Some general considerations on the spectrum of activity for the most widely used BZD and pro-BZD compounds are summarized in the following sections.

Thiabendazole. TBZ is indicated for the treatment and control of GI roundworms in horses, cattle, sheep, and goats, and the control of lungworms in sheep. TBZ is administered orally at the dose range 66 to 110 mg/kg. It is also used as a fungicide for crop protection. In horses, TBZ is used as a single oral dose administered as a drench or by stomach tube, or as an oral paste. It is usually associated with piperazine to increase the efficacy against ascarids and immature *Oxyurus* spp. TBZ is ineffective against cestodes or trematodes. In cattle, at the recommended dose

rates, it is effective against adult and developing stages of *Ostertagi ostertagi* but not against EL_4. Thus, TBZ is not useful to prevent Type II ostertagiasis. In pigs, TBZ has little efficacy against *Ascaris suum* and *Trichuris suis*.

Netobimin. The pro-BZD NTB is formulated as a suspension for oral administration in cattle and sheep. It is indicated (7.5 mg/kg) for the removal and control of tapeworms (heads and segments) (*Moniezia expansa, M. benedeni*), adults and larval stages of abomasal worms (*Haemonchus contortus, H. placei, Trichostrongylus axei, Ostertagia ostertagi, Teladorsagia circumcincta, Marshallagia marshalli*), intestinal worms (*Trichostrongylus colubriformis, Chabertia ovina, Nematodirus spathiger, N. filicollis, N. helvetianus, Cooperia oncophora, C. punctata, Bunostomun phlebotomum, Oesophagostomun radiatum*), and lungworms (*Dictyocaulus filaria, D. viviparus*). Higher doses (20 mg/kg) are required for control of adult liver flukes (>14 weeks old) (*Fasciola hepatica, Fascioloides magna*) and *Thysanosoma actinioides*, and Type II ostertagiasis (cattle).

Albendazole. ABZ is formulated as a suspension for oral administration (as a drench) in cattle and sheep at the recommended dose of 7.5 and 5 mg/kg, respectively. It is indicated for the removal and control of a broad spectrum of helminth parasites, including: tapeworms (heads and segments), abomasal and intestinal nematodes (adults and 4th-stage larvae) and lungworms (adults and larval stages). Additionally, at 10 (cattle) and 7.5 mg/kg (sheep), ABZ is active against adult liver flukes (>14 weeks old). ABZ also demonstrates ovicidal activity at 8 hours posttreatment. ABZ a potential antigiardial drug to be used in farm animals (Xiao et al. 1996), appeared to be effective in suppressing cyst excretion by *Giardia*-infected calves, at the oral dose of 20 mg/kg once daily for 3 days. Similar results were observed in *Giardia*-infected dogs after its oral administration (25 mg/kg) twice a day for 2 days (Barr et al. 1993).

Ricobendazole. RBZ is the sulphoxide metabolite of ABZ and it is also available as suspension for oral administration in cattle (10 mg/kg) and sheep (7.5 mg/kg). The spectrum of activity is equivalent to that described for ABZ, including the ovicidal effect. A novel RBZ injectable solution (15%) for subcutaneous administration to cattle is available in different countries. It is successfully used to control abomasal and intestinal nematodes and lungworms. A 5 mg/kg dose rate is recommended to control the larval 4th stage of *O. ostertagi*. The formulation is not recommended for control of liver flukes or tapeworms. In Europe, RBZ is also approved for use in pheasants by feed administration (17 mg/kg during 3 days) and is mainly indicated for the control of ascarids and capillarid infections.

Febantel. FBT, a pro-BZD compound, is used in ruminants, horses, dogs, cats, and pigs. It is formulated as a paste, suspension, or tablets for oral administration. It is used at a dose of 10 (ruminants), 6 (horses), 10 (dogs and cats), and 20 (pigs) mg/kg. Dogs and cats required a 3-day period of treatment. Since FBT has no anthelmintic activity, its spectrum depends on its main active metabolites FBZ and OFZ. Consequently, its spectrum is similar to those compounds.

Fenbendazole. FBZ is formulated as a suspension for oral administration in cattle, sheep, and goats at the recommended dose of 10 (cattle) and 5 mg/kg (sheep, goats). FBZ is indicated for the removal and control of tapeworms (heads and segments), abomasal and intestinal nematodes (adults and 4th-stage larvae), and lungworms (adults and larval stages). FBZ also presents ovicidal activity. FBZ is effective for the treatment of *Giardia* infections in calves at an oral dose of 10 mg/kg administered once, or 5 mg/kg given every 24 hours for a 3-day period (O'Handley et al. 1997). FBZ is administered orally to horses at 5 mg/kg for control of large strongyles (*Strongylus vulgaris, S. edentatus, S. equinus*), small strongyles (cyathostomes), and pinworms (*Oxyuris equi*). Higher doses (10 mg/kg) are required for control of ascarids (*Parascaris equorum*). At 10 mg/kg for 5 consecutive days, FBZ is indicated for control of arteritis caused by the 4th-stage larvae of *S. vulgaris*, encysted mucosal cyathostomes larvae including early (hypobiotic), and late 3rd-stages larvae. In pigs, FBZ is used as a powder (3 mg/kg per day for 3 consecutive days), being 99% effective against *Ascaris suum* larvae migrating through the liver and lungs, and most GI nematodes (mature and immature) (*Metastrongylus apri, Oesophagostomun dentatum, O. quadrispinulatum, Hyostrongylus rubidus, Trichuris suis, Stephanurus dentatus*). FBZ is used at 50 mg/kg daily for 3 consecutive days in dogs for removal of hookworms (*Ancylostoma caninum*), ascarids (*Toxocara canis, Toxascaris leonina*), whipworms (*Trichuris vulpis*), and tapeworms (*Taenia*). However, it is not recommended for control of the cestode *Echinoccocus granulosus* or *Echinococcus multilocularis*. At a 50 mg/kg

dose for 3 days, FBZ reaches good therapeutic effect against *Giardia* in dogs (Barr et al. 1993). The use of FBZ (granules) in zoo and wildlife animals has been approved by the FDA. It is used at 10 mg/kg during 3 days, orally administered with food, and is indicated for the control of nematodes (ascarids, hookworms, and tapeworms) of *Felinae* (lion, tiger, puma, cheetah, leopard) and *Ursidae* (black bear, polar bear).

Oxfendazole. OFZ is administered orally to cattle (4.5 mg/kg), sheep (5 mg/kg), and horses (10 mg/kg). Additionally, it has been used in goats, dogs, and pigs. In all cases it is recommended for the control of the same parasites as is its sulphide parent compound (FBZ). To avoid the ruminal bypass, an OFZ suspension has been approved for intraruminal administration in cattle. As described for ABZ and FBZ, OFZ can be used for the prevention and control of both Type I and Type II ostertagiasis in cattle. However, variable efficacy against EL_4 has been reported. A probable explanation for the observed variability in efficacy is the metabolic activity associated with the larval stage, where the highest efficacy could be expected during induction of inhibition and emergence of inhibited larvae and the lowest efficacy during the quiescent period. In horses, OFZ has a similar efficacy against GI nematodes to the parent FBZ.

Oxibendazole. OBZ is used in the treatment of adult and larval stages of GI nematodes of pigs, cattle, sheep, and horses. It is used orally in suspension or paste at a dosage of 10 mg/kg (sheep and cattle) or 15 mg/kg (horses). A 10 mg/kg dose in horses is sufficient for removal and control of large strongyles, small strongyles, large roundworms, and pinworms.

Mebendazole. MBZ is administered orally to horses (8.8 mg/kg), sheep, and goats (15 mg/kg). It is also used in game birds, pigs, deer, dogs, and poultry as different types of formulations: premixes for medicated feed, pastes, tablets, granules, and drenches—all for oral administration. It is indicated for the control of large strongyles, small strongyles, large roundworms, and mature and immature larval stages of pinworms in horses. Doses of 22 mg/kg for 3 consecutive days are recommended for use in dogs for the treatment of roundworms, hookworms, whipworms, and tapeworms.

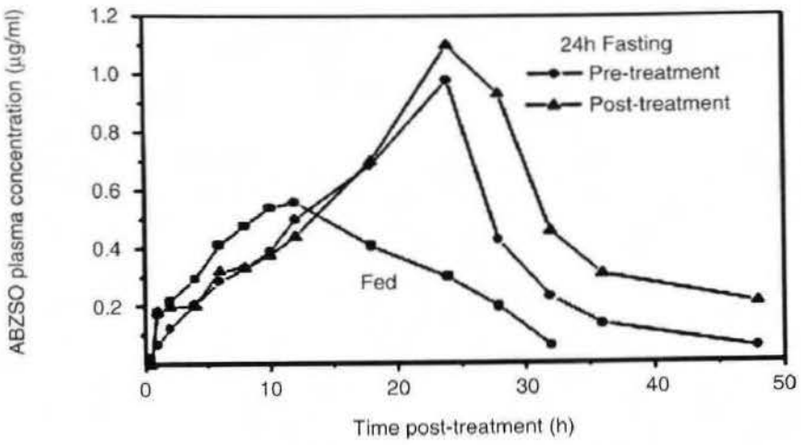
Flubendazole. FLBZ is available as tablets, pastes, pellets, and premixes for oral administration in pigs, chickens, turkeys, and game birds. It is used at 5 mg/kg (single oral administration) and at 30 mg/kg in feed for 10 days in pigs, being active against lungworms, roundworms, nodular worms, and whipworms. A 10-day feed period is required for control of heavy *Trichuris suis* infestations. Oral treatment at 22 mg/kg for 3 consecutive days is recommended in dogs and cats for removal of common GI parasites and tapeworms. FLBZ is used in poultry at 60 mg/kg in feed for 7 days (equivalent to 5 mg/kg/day for broilers and 3.6 mg/kg/day for laying hens). FLBZ has ovicidal activity, and recent work done in sheep demonstrates that FLBZ has a volume of distribution higher than those reported for ABZ and OFZ (Moreno et al. 2004), which may offer a new attractive alternative for use of the drug against tissue-dwelling parasites in sheep, where the presence of high drug concentrations for an extended period of time is usually crucial to achieve optimal clinical efficacy.

ROUTES OF ADMINISTRATION AND DRUG FORMULATIONS. As expressed earlier in this chapter, BZD anthelmintic compounds are virtually insoluble in water, which limits most of the formulations to suspension, paste, granule, tablets, blocks, powder, and pellets for oral or intraruminal administration, or for administration in feed. Drench formulations are most frequently used in ruminant species, pastes are often preferred for horses, tablets for dogs and cats, and powder in feed administration for swine and poultry. BZDs are generally administered to ruminants in the form of a single oral dose. This single-dose treatment has traditionally been done by oral drench or by intraruminal injection; this latter approach is based on the design of a special syringe (intraruminal injector) that ejects the drug directly into the rumen cavity. This device is commercially available for the administration of a concentrated suspension of OFZ to cattle and was mainly designed to overcome the potential problems of the esophageal groove closure after oral treatment (see below). To reduce the cost associated with treating a large number of animals and with growing evidence that divided anthelmintic doses and prolonged administration increase anthelmintic efficacy, several methods for drug delivery have been used in the past. The incorporation of drug into feed blocks, for ingestion of small amounts over a

prolonged grazing period, and the inclusion of drugs in drinking water have been used for therapeutic and prophylactic parasite control. Convenience and labor saving are obvious for these group medication systems, but at the same time no direct control is possible over the drug intake rate of individual animals.

The most versatile technology in anthelmintic drug delivery has been the development of ruminal devices that, when given to individual animals, can deliver drugs for an extended period of time. These controlled-release devices or boluses more readily provide the conditions for increased anthelmintic efficacy, such as prolonged exposure of parasites to sustained concentrations of active parent drugs or their metabolites. However, since the high selection pressure, this sustained exposure may facilitate the development of drug-resistant parasite populations. After oral administration, the boluses remain in the rumen-reticulum and release the drug over a long period of time, either in a sustained or pulsatile manner. Different controlled-release systems have been developed for the delivery of BZD anthelmintics. The OFZ pulse-release bolus (Rowlands et al. 1988) is based on the principle of releasing a series of individual therapeutic doses of OFZ at predetermined intervals (20–21 days), which approximately coincide with the prepatent period of the major redundant nematodes of cattle, and for about 4 months. This is achieved by the continuous galvanic corrosion of a magnesium alloy rod that periodically exposes an annular OFZ tablet to the ruminal fluid (Campbell 1990). An intraruminal slow-release capsule that delivers a low daily dose of ABZ for approximately 3 months has been designed. The device is a hollow cylinder of nonbiodegradable plastic that contains tablets of 3.85 g (sheep) and 18.46 g (cattle) of ABZ and two external wings. After the administration, the wings spread out while the ruminal fluid starts to dissolve the first tablet, which releases the drug slowly in the rumen; a metal spring pushes six tablets toward the pen end of the capsule. Following the administration of this device, ABZ metabolites were found in plasma for 90 days (cattle) and 105 days (sheep) postcapsule administration (Delatour et al. 1990b). ABZ is also available in controlled release capsules, which contain 2.1 and 3.85 g of ABZ/capsule for use in weaner and adult sheep, respectively, showing a sustained anthelmintic action for 90 to 100 days postadministration. Additionally, an ivermectin/ABZ capsule has been developed to assure protection against GI parasites susceptible to either compound.

Combining drugs has been used to increase anthelmintic spectrum. Furthermore, since extensive parasite resistance to different anthelmintic compounds has been reported, the use of drug combinations may be a practical approach to delay the development of resistance. Currently, there are a large number of combined anthelmintic drenches available for use in sheep. These drenches include, within the same commercial formulation, a combination of two, three, or four molecules with different mechanisms of action and spectrum. Combined preparations containing either ABZ and levamisole; FBZ and levamisole; ABZ and ivermectin or ABZ; ivermectin and levamisole; or ABZ, abamectin, levamisole, and closantel are now available in countries where anthelmintic resistance in sheep and goat nematodes is a serious problem.



FACTORS AFFECTING THE DISPOSITION KINETICS AND EFFICACY OF BENZIMIDAZOLE ANTHELMINTICS. Several *host-related factors* may affect the kinetic behavior and resultant clinical efficacy of BZD compounds. Dissolution, absorption, and biotransformation are three of the most important processes affected by a series of host-related factors. Manipulation of the pharmacokinetic and metabolic patterns and the comprehension of different factors modulating them seem to be excellent alternatives to improve the use of BZD in ruminants:

1. *Effect of ruminant esophageal groove closure:* The rumino-reticulum is usually the first enteric chamber encountered by an orally administered drug. However, ingested fluids may partially bypass the rumino-reticulum to enter the abomasum via the omasum following closure of the reticular groove, a reflex especially developed in the nursing ruminant but inconsistently active in the adult. Thus, variable portions of a drug solution or suspension administered orally may became divided between the rumino-reticulum and abomasum, resulting in a complex absorption process that may then contribute to unpredictable drug efficacy. Occasionally, reduced systemic availability and efficacy of BZD methylcarbamates have been found after oral in comparison with intraruminal administration (Prichard and Hennessy 1981). A portion of the orally administered anthelmintic may bypass the rumen and rapidly enter the abomasum by closure of the esophageal groove. As a consequence, a portion of

the dose directly enters the abomasum with resultant poor absorption due to insufficient time for dissolution of the BZD suspension's particles, which results in reduced plasma bioavailability of active BZD metabolites. Such an effect may indicate that the so called "reservoir" and "slow-delivery" effects of the rumen would be lost; although lag times between treatment and plasma detection of active metabolites could be shorter, the overall bioavailability of active BZD metabolites and their resultant efficacy are significantly reduced. In spite of conflicting results and difficulties in assessing its practical implications, it is clear that upon spontaneous closure of the esophageal groove a portion of an oral drench dose may bypass the rumen, which consequently affects the kinetic behavior and clinical efficacy. It is also likely that this phenomenon is more relevant for 1) compounds that are activated in the rumen such as netobimin prodrug, or 2) those BZD anthelmintics with a low solubility in abomasal fluid such as FBZ or ABZ. Thus, an important portion of the dose of orally administered FBZ would directly reach the abomasum, whereby FBZ insolubility and the short residence time of the digesta in this organ may account for both an inefficient and/or erratic absorption and a significant portion of the dose passing down the GI tract to be eliminated in feces.

2. *Effect of reduced GI transit time:* Modified feeding management has been recommended to restore the anthelmintic action of those BZD compounds whose potency has been compromised by resistance (Alí and Hennessy 1995). An enhanced plasma availability of OFZ induced by temporary feed restriction in sheep, accounted for increased efficacy of the drug against BZD-resistant nematode strains (Alí and Hennessy 1995). Fasting the animals prior to intraruminal treatment resulted in pronounced modifications to the absorption and disposition kinetics of ABZ metabolites in cattle, in which the administered drug appeared to be absorbed to a greater extent than in fed animals (Sánchez et al. 2000b). Starvation decreases digesta flow rates. A delayed GI transit time that decreased the rate of passage of the anthelmintic drug down the GI tract may have accounted for the enhanced ABZ absorption observed in fasted compared to fed animals (see Fig. 40.9). The fasting-induced changes to the kinetic behavior and quantitative tissue distribution of BZD methylcarbamates may have particular relevance to design strategies to increase activity against susceptible parasites and to delay the development of resistant strains. The increased concentration profiles of active drug (both parent ABZ and its sulphoxide metabolite) measured in tissues where target parasites are located (i.e., GI mucosa, lung tissue, etc.) is a strong scientific argument to recommend the "fasting approach" to improve parasite control in cattle, which is now recommended worldwide.
3. *Effect of the type of diet:* The type of feed also influences the rate of passage of digesta and that of orally administered BZD drugs in ruminants and pigs, which may in turn affect drug absorption. The binding of different BZD compounds to dietary fiber substantially modified the duration of the so-called "rumen reservoir" effect (Hennessy 1993), altering the overall bioavailability of BZDs and their metabolites in the bloodstream. Various reports using widely differing type of diets, according to local feeding conditions, have demonstrated the impact of feeding on the systemic availability of ABZ, FBZ, and OFZ in different ruminant species and pigs. The delayed GI transit time and lower abomasal pH in calves fed on a concentrate-based diet, compared to those grazing on pasture, facilitated the dissolution and absorption of ABZ administered intraruminally as a drug suspension in cattle (Sánchez et al. 1999). As a consequence, significantly higher Cmax and AUC values were obtained in calves fed on the concentrate diet compared to those grazed on pasture. Furthermore, enhanced abomasal fluid levels of ABZ and ABZSO were observed in concentrate-fed calves. Additionally, different types of diets have been shown to affect ruminal pH and to modify the microflora-mediated metabolic sulphoreduction of BZD derivatives (Virkel et al. 1997), which further impacts the disposition kinetics of these compounds in ruminants.
4. *Effect of nutritional status and parasite infection:* Because of its central position in the biotransformation and metabolic activities of the animal, the liver is vulnerable not only to damage by various foreign chemicals, microorganisms, and parasites, but also to dietary-induced metabolic disorders that may induce important changes on the pharmacokinetic behavior, side effects, and expected efficacy of the chosen anthelmintic for therapy. The results reported by Sánchez et al. (1996) showed that the poor nutritional status of feed-restricted animals induced marked modifications to the pattern of ABZ biotransformation and to its resultant disposition kinetics in cattle, which was likely produced by interference of the nutritionally induced biochemical changes on

a)

b)

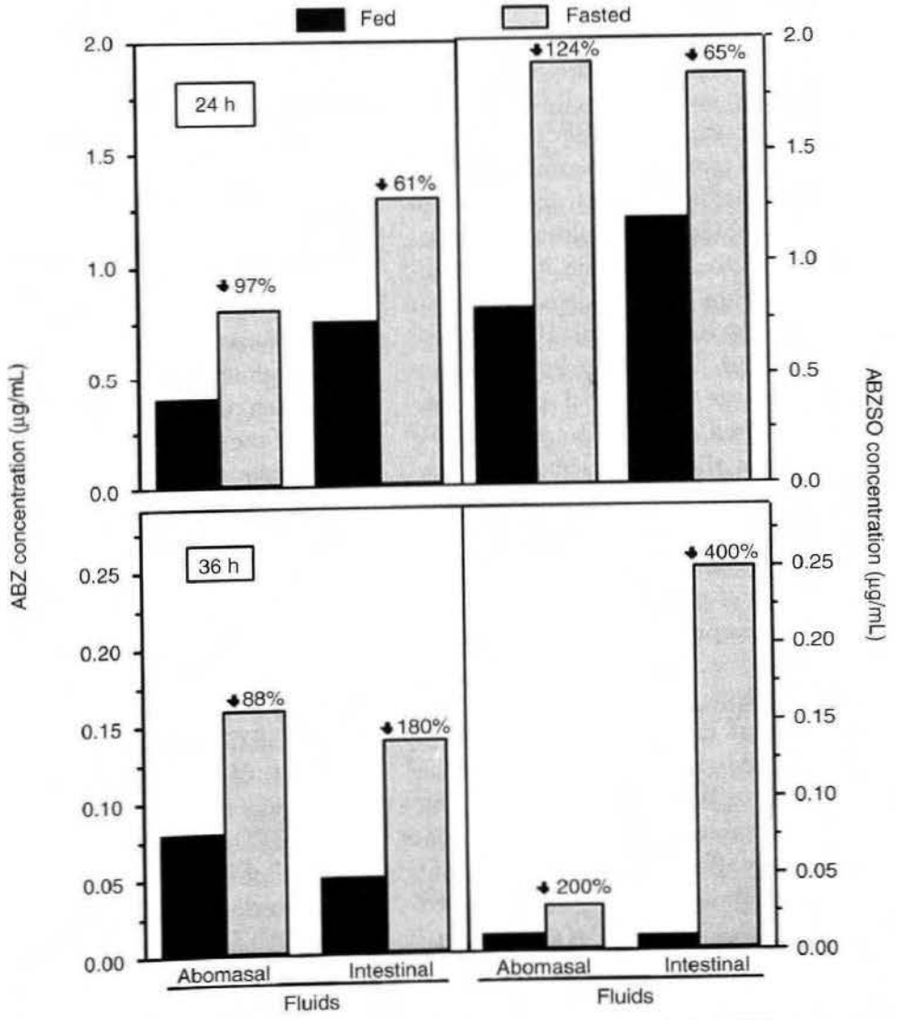


FIG. 40.9 Influence of fasting on the kinetics of albendazole in cattle. a) Mean albendazole sulphoxide (ABZSO) plasma concentrations obtained after the intraruminal administration of albendazole (ABZ) (10 mg/kg) to calves either fed ad libitum (control) or fasted during 24 h prior to or after the treatment. The systemic availability of ABZSO increased between 96% (fasting pretreatment) and 118% (fasting posttreatment) in fasted compared to calves fed ad libitum. b) Mean concentrations of ABZ (left panel) and ABZSO (right panel) obtained in abomasal and intestinal fluids at 24 and 36 h after the intraruminal administration of ABZ (10 mg/kg) to calves either fed ad libitum or fasted for 24 h pretreatment. The figures on the top of each bar represent the enhancement (percentage) on drug concentrations in the different digestive fluids observed in fasted compared to animals fed ad libitum. Adapted from Sánchez et al. 2000.

ABZ liver biotransformation. During both starvation and underfeeding in cattle, the hepatic concentrations of NADPH and ATP have been shown to decrease to about 60 and 40%, respectively, of their normal values in animals fed ad libitum. It is likely that both the decreased energy (ATP) production and the reduced NADPH availability in the liver cell may have contributed to the decreased rate of ABZ biotransformation and delayed elimination of ABZ and its metabolites observed in calves subjected to undernutrition.

The presence of the parasite itself could induce important changes to the pharmacokinetics, side effects, and expected efficacy of the chosen BZD anthelmintic for therapy. Liver disease and parasite-mediated liver damage with alteration of liver enzyme pattern could affect biotransformation and the resultant bioavailability of anthelmintically active BZD metabolites. A reduced enzymatic activity of different liver microsomal oxidases has been reported in *Fasciola hepatica*–infected sheep (Galtier et al. 1986b), which could lead to altered patterns of drug/xenobiotic metabolism and clearance. A significant decrease in the rate of both ABZ sulphonation and $ABZSO_2$ elimination has been demonstrated in sheep infected with *F. hepatica* (Galtier et al. 1991). These findings are well correlated with a 58% decrease in the rate of ABZ sulphonation by liver microsomal preparations obtained from 8-weeks–infected sheep; these authors have postulated that a decrease in the liver microsomal cytochrome P450–dependent monooxygenase activity, induced by the presence of the immature liver flukes on the hepatocyte parenchyma, could likely be the cause of such a metabolic change.

Parasite-mediated inflammatory reactions with changes in mucosal permeability and in abomasal/intestinal pHs could have an impact both on absorption and ionic-trap–mediated distribution of different BZD molecules. Elevation in abomasal pH and increased permeability of the mucosa to macromolecules has been demonstrated during abomasal parasitism. The pathophysiological changes occurring during GI parasitism may affect the absorption of BZD compounds due to modifications in the GI transit time and to the atrophy of intestinal villi. Some studies on the influence of GI parasitism on the plasma kinetics of different anthelmintic drugs have been reported. Following artificial infection with abomasal nematodes (*Ostertagia circumcincta*, *Haemonchus contortus*), the patterns of absorption and systemic availability of FBZ (Marriner et al. 1985), OFZ (Hennessy et al. 1993b), and FBT (Debackere et al. 1993) in sheep have been shown to be altered. On the other hand, the presence of moderate nematode infections was sufficient to identify important changes to the plasma and abomasal disposition kinetics of ABZ in both artificial and naturally infected sheep (Alvarez et al. 1997). The main modification observed in infected sheep was the elevation of the abomasal pH. The increased abomasal pH induced by the presence of the parasite, decreased the plasma/abomasum pH gradient and reduced the ionic-trapping of BZD molecules in the abomasum, which may have a relevant impact on anthelmintic efficacy.

Factors Related to Pharmaceutical Formulation. The relevance of water solubility and rates of dissolution of drug particles in the GI tract lumen on the absorption and resultant pharmacokinetic behavior of BZD compounds has been extensively demonstrated. Further evidence was obtained by altering the crystalline nature of the OFZ molecule. The production of an amorphous form of OFZ by acidic treatment has resulted in a marked change in water solubility from 4 μg/ml (crystalline form) to 11.3 μg/ml (amorphous form) at a pH of 7.6. The oral administration of amorphous OFZ resulted in a more rapid and complete absorption compared with the crystalline form. It was shown that half the dose of the amorphous OFZ produced equivalent efficacy to that of the normal crystalline OFZ. Erratic absorption and variable systemic availability can be expected after administration of low quality BZD suspensions, where large drug particle size and poor pharmacotechnical elaboration may affect the rate of dissolution and resultant absorption in the GI tract.

Different pharmaceutical strategies have been investigated to overcome the limited GI dissolution and absorption of BZD anthelmintics. An injectable formulation (solution) of ABZSO (RBZ) has been developed for use in cattle, exploiting its greater hydrosolubility compared to other BZD methylcarbamates (Lanusse et al. 1998). Development of more water-soluble prodrugs, ABZ loaded nanoparticles (Rodrigues et al. 1995), aqueous formulation of ABZ with cyclodextrins (Evrard et al. 2002), and surfactant-based ABZ suspensions (Virkel et al. 2003) are among other strategies used to enhance the GI absorption of BZD compounds. A marked enhancement in the systemic availability of ABZ metabolites has been reported after administration of an ABZ suspension

prepared with sodium lauryl sulphate to cattle (Virkel et al. 2003).

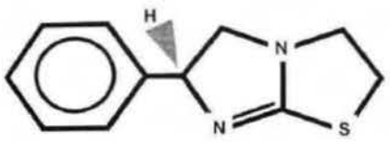
WITHDRAWAL TIMES, SAFETY, AND TOXICITY. Because of tissue and milk residues of BZD compounds, slaughter clearance times are required after treatment with substituted BZD and it is recommended that milk of treated animals not be used for human consumption. Withdrawal times of 3 days (meat) and 4 days (milk) are required after TBZ treatment in cattle. When TBZ is used as a single oral dose in sheep or goats, 30 days of withdrawal time prior to slaughter is recommended. Withdrawal times are required after ABZ treatment in beef cattle (27 days) and sheep (7–10 days). For FBZ given as a suspension, a period of 8 days (cattle) and 6 days (goats) of withdrawal time is needed. However, since numerous commercial products containing BZD compounds are available around the world, it is critical to check label instructions of each formulation concerning withdrawal times before its use. BZDs are not indicated in horses to be slaughtered for food purposes. FLBZ is widely used as an anthelmintic in poultry. Its main metabolites, H-FLBZ and R-FLBZ, have been identified in tissues of FLBZ-medicated turkeys (De Ruyck et al. 2001). Concentrations of FLBZ/metabolites in eggs collected from laying hens feed with 10 and 30 mg/kg of FLBZ reached a plateau level after 10 days. The residues of FLBZ and metabolites were detected mainly in the yolk, where the metabolites, accounting for almost 60–65% of the total residue, were H-FLBZ, the main metabolite recovered (Kan et al. 1998). A 7-day withdrawal time is required for FLBZ in broiler chickens. Pigs may be slaughtered for human consumption a minimum of 7 days after FLBZ treatment.

BZDs are probably some of the least toxic of the available anthelmintics. The remarkable overall safety of BZD compounds has been a major factor in their successful worldwide use. All BZDs are extremely well tolerated by domestic animals and man, and they are usually free of side effects at therapeutic doses even when administered to young, sick, or debilitated animals. For instance, OFZ does not cause detectable toxic effects at 10 times the recommended dose or after eight successive administrations of 3 times the therapeutic dose at 4-day intervals in ruminants and horses. The high safety margins, particularly for the most potent substituted BZDs, are thought to be correlated with their low solubility in the GI fluids; this account for a low absorption rate and for insufficient drug reaching the bloodstream to induce toxic effect. Some members of the group—such as parbendazole, cambendazole, OFZ, FBT, and ABZ—have been reported to be teratogenic at approximately 4 times their recommended doses; this limits their use in the early stages of pregnancy, and sheep seem to be especially sensitive compared to other animal species (McKellar and Scott 1990). The administration of OFZ or ABZ in pregnant cows caused no increase in the incidence of congenital abnormalities in the offspring. Similar results have been reported in pigs and horses. Teratogenic effects may occur at dosages much lower than those associated with acute toxicity in target species. The observed species' differences in the sensitivity to the teratogenic activity may be related to differences in the pharmacokinetics and metabolism of BZDs among species. The main malformations observed following treatment at day 20 of pregnancy have been deformities of the limbs and overflexion of the carpal joints. In ewes treated with NTB at the 17th day of pregnancy, congenital malformations (skeletal and renal) and abortions were observed (Navarro et al. 1998). The types of malformations induced by FLBZ in rats after its oral administration (160 mg/kg/day for 7 consecutive days between days 8 through 15 of pregnancy) are similar to that described for parbendazole and cambendazole, and include encephalocele, meningocele, hydrocephaly, short tail, absent tail, fusion or agenesis of vertebrae and fused ribs. The mechanism of BZD teratogenicity seems to be related to their effects on the disruption of the tubulin-microtubules equilibrium dynamics in mammalian cells and subsequent alteration of cell division. Since the main toxic effects involve their teratogenic effect, some substituted BZD molecules are contraindicated for use in early pregnancy. ABZ is not indicated for use during the early pregnancy in cows (45 days) and ewes (30 days). The administration of FBT as tablets in dogs and cats is not recommended in pregnant animals. However, FBZ and MBZ do not appear to exert a teratogenic effect in sheep when administered in early pregnancy.

Large doses of TBZ (a more soluble BZD compound) administered for a long period has been associated with anemia in dogs. In feed, FLBZ treatment in poultry does not affect egg production, fertility, or hatchability. In spite of the antimicrotubular effect of BZD molecules, different experiments involving FBZ, ABZ, and OFZ in bulls, rams, and stallions could not demonstrate adverse effects on

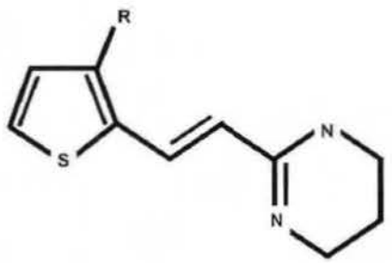
reproductive function, including spermatogenesis, testicular weight, and testosterone production (McKellar and Scott 1990).

IMIDAZOTHIAZOLES



CHEMISTRY. The first imidazothiazole anthelmintic introduced into the veterinary market (1967) was *tetramisole*. It is a racemic mixture of two optical isomers in equal amounts: S(−)tetramisole (*l*-tetramisole or levamisole) and R(+)tetramisole (*d*-tetramisole). Following approval and marketing of the racemic mixture, pharmaceutical scientists were able to separate *dl*-tetramisole into its two isomers. Further studies discovered that the anthelmintic activity of the racemic mixture was attributable almost solely to the *l*-isomer. Thus, by using the *l*-isomer alone, the dosage could be reduced by half. This also increased the safety margin since both components of tetramisole are similarly toxic but differ in anthelmintic efficacy. Currently, *levamisole* is the worldwide imidazothiazole compound available for use in veterinary medicine. However, in some countries, tetramisole formulations are still available. The information described below is based on the pharmacological properties of levamisole, the most extensively used drug in this chemical class. Another compound within the group, *butamisole hydrochloride*, used as an injectable anthelmintic to control whipworm (*Trichuris vulpis*) and hookworm (*Ancylostoma caninum*) infections in dogs, is no longer marketed. Interested readers are referred to earlier editions of this text (Courtney and Roberson 1995) for additional information on this molecule.

Levamisole is the *l*-isomer of tetramisole. The chemical name of levamisole is (−2,3,5,6-tetrahydro-6-phenylimidazo[2,1-*b*] thiazole) (see Fig. 40.10). Levamisole is an antinematodal drug with a broad range of activity in several host species. It is approved and marketed worldwide for use in cattle, sheep, swine, poultry, and dogs. Levamisole is a nematodicidal compound effective against lung and GI tract nematodes but not against cestode and trematode parasites. A major advantage is its formulation flexibility allowing for alternative routes of administration (oral, parenteral, topical). Depending upon formulation, the drug is marketed as levamisole hydrochloride or phosphate salts (oral drenches, feed premixes, and injectable preparations) and as levamisole base (pour-on). Levamisole hydrochloride, a white to pale cream crystalline powder, is highly soluble in water (1 g in 2 ml of water). This solubility facilitates the formulation of an injectable solution and a stable drench.



MODE OF ACTION. Levamisole acts selectively as a cholinergic agonist at the synaptic and extrasynaptic nicotinic acetylcholine receptors on nematode muscle cells. This causes a spastic paralysis of susceptible nematodes by selectively gating acetylcholine receptor ion-channels on nerve and muscle (Robertson and Martin 1993). Its uptake in helminth parasites is considered to be mainly by a transcuticular mechanism. In vitro studies have shown that levamisole (10 μM) passive transcuticular diffusion in *Trichostrongylus colubriformis* produced a plateau level after 90 minutes of incubation. Detailed information on the mechanism of anthelmintic action and resistance for levamisole can be obtained from Martin (1997), Sangster et al. (1988), and Martin and Robertson (2000).

PHARMACOKINETICS. The rate of levamisole absorption differs with the route of administration. The drug is most rapidly absorbed following intramuscular or subcutaneous injection in cattle, and the highest plasma levels (>1 μg/ml) are observed at 0.5–2 hours. Several oral formulations gave similar absorption rates (Tmax = 3 hours) and slower absorption was observed after dermal application (Bogan et al. 1982). Bioavailability differs depending on the route of administration. In sheep, the highest mean plasma concentrations were achieved after the subcutaneous (3.1 μg/ml), compared to oral (0.7 μg/ml) and intraruminal (0.8 μg/ml), administration at a dose rate of 7.5 mg/kg (Bogan et al. 1982). Following pour-on administration in cattle, plasma and GI concentrations of levamisole were lower than those measured following parenteral and oral treatments (Forsyth et al. 1983), which agrees with the limited anthelmintic efficacy reported for the topical preparation. An oral bioavailability of 44% has been demonstrated in dogs, which increased to 64% when animals were fasted for a total period of 24 hours (Watson et al. 1988). Absorption and systemic bioavailability are important since, given the mode of anthelmintic action of levamisole, the level of concentration is more important than the time of parasite exposure to drug (Lanusse and Prichard 1993b).

Once it is systemically available, levamisole is widely distributed in the organism, being recovered in tissues

S(-) LEVAMISOLE

PYRANTEL: R = H
MORANTEL: R = CH_3

Nicotinic receptor agonism	MODE OF ACTION	Nicotinic receptor agonism
Lung and GI nematodes (mainly adult stages)	ANTHELMINTIC SPECTRUM	GI nematodes (narrow, adult stages) Equine tapeworms (pyrantel)
Side-resistance with pyrantel and morantel	ANTHELMINTIC RESISTANCE	Side-resistance with levamisole
Rapid absorption (injectable) Limited absorption (oral, topical) Fast elimination	PHARMACOKINETICS	Poor GI absorption (ruminants) Good GI absorption (dog, pig)
Subcutaneous, Oral, Topical	ROUTES OF ADMINISTRATION	Oral (all species) Slow release bolus (cattle)
Hydrochloride, phosphate	FORMULATIONS	Pamoate, tartrate
Narrow safety margin (do not use in horses)	TOXICITY	Good safety margin

GI: gastrointestinal.

such as muscle, fat, kidney, and particularly liver, at 2 hours postadministration of an oral or subcutaneous dose. In cattle, the highest milk concentrations are achieved at 1 hour postadministration. Levamisole plasma concentrations decline over a period of 6 to 8 hours, with 90% of the total dosage being excreted in 24 hours. Levamisole is rapidly and extensively metabolized to a large number of metabolites in the liver. The main metabolizing pathways appear to be oxidation, hydrolysis, and hydroxylation. Oxidation of the imidazothiazole ring is followed by oxidation to a carbonyl and hydrolysis to a thiohydantoic acid. Excretion of both levamisole and metabolites (glucuronyl or S-cysteinyl-glycine conjugates) is mainly in the urine (about 60%) and feces (about 30%). Unchanged levamisole accounted for 5–10% of the dose in urine and feces in cattle, sheep, and swine (Nielsen and Rasmussen

1982; IPS INCHEM 2003). The reported elimination half-life values are: 4–6 hours (cattle), 1.8–4 hours (dogs), and 3.5–6.8 hours (pigs). Levamisole is fast depleted from the animal body and tissue residues of the drug are not appreciable. Approximately 0.9% of the initial dose is found in tissues (liver and kidney) at 12–24 hours after dosing. By 7 days after dosing, levamisole is not detectable in muscle, liver, kidney, fat, blood, or urine of rats or other animals tested. Unchanged levamisole accounts only for 3% of the total tissue residues measured over a 14-day period.

ANTHELMINTIC SPECTRUM. The compound has a broad spectrum of activity against mature stages of the major GI nematodes and against both mature and larval stages of lungworms. However, levamisole shows little action against arrested larval stages. Depending on the product licensed, levamisole is indicated for nematodes in cattle, sheep, goats, swine, poultry, dogs, and cats. In ruminants, levamisole has a relatively good activity against abomasal nematodes, small intestinal nematodes (not particularly good against *Strongyloides* spp.), large intestinal nematodes (except *Trichuris* spp.), and lungworms. Adult stages of the nematode that are usually covered by levamisole, include *Haemonchus* spp., *Ostertagia* spp., *Cooperia* spp., *Nematodirus* spp., *Bunostomum* spp., *Oesophagostomum* spp., *Chabertia* spp., and *Dictyocaulus vivaparus*. Levamisole is less effective against the immature forms of these parasites and is generally ineffective in cattle against arrested larval forms. In swine, levamisole is indicated for the treatment of *Ascaris suum*, *Oesophagostomum* spp., *Strongyloides ransomi, Stephanurus dentatus*, and *Metastrongylus* spp. Levamisole has been used in dogs against GI nematodes and as a microfilaricide to treat *Dirofilaria immitis* infection at a dosage of 5.5 mg/kg twice daily (12 hours interval) for 6 days (or up to 15 days for persistent microfilaremias). Because of its narrow safety margin and limited efficacy against many equine parasites, levamisole is not generally used in horses.

FORMULATIONS, DOSAGES, AND ROUTES OF ADMINISTRATION. Levamisole is administered as tablet, solution, oral drench, feed additive, subcutaneous injectable solution, or topical pour-on. In cattle, sheep, goats, and pigs, a dose of 8 mg/kg levamisole is recommended in a single oral or subcutaneous administration and 10 mg/kg as a pour-on for cattle. The bioavailability of levamisole in sheep was significantly lower after oral (42%) and intraruminal (45%) administration compared to the injectable treatment (Bogan et al. 1982). Administration of levamisole in drinking water is used routinely only for swine and poultry. For poultry, the medicated drinking water is prepared by calculating the total amount of drug needed to provide a dose of 40 mg/kg. As the peak concentration rather than the duration of exposure is important for the anthelmintic effect of levamisole, medicated feed should be consumed fairly rapidly; otherwise, efficacy may be reduced.

Injectable levamisole is preferred for use in cattle. The original, aqueous solution of levamisole hydrochloride was administered by intramuscular or subcutaneous injection. The hydrochloride, however, proved to be irritating to tissues, and intramuscular injection resulted in moderate to severe reactions at the injection site. The monobasic phosphoric acid salt of levamisole was found to be less irritating to tissues. Pour-on formulation for cattle contains 10–20% levamisole as base, which is absorbed through the skin following application to the midline of the back.

Levamisole is approved for use in dogs and cats in some countries. Tablets and oral solutions are used in dogs and cats at dose rates between 5 and 10 mg/kg. Oral treatment with 10 mg tetramisole/ kg/day for 2 days removed more than 95% of ascarids (*Toxocara*, *Toxascaris*) and hookworms (*Ancylostoma*, *Uncinaria*). Levamisole is not effective against canine whipworms (*Trichuris vulpis*). Overall, levamisole remains a useful nematodicidal compound as a result of an acceptable margin of safety and spectrum of activity coupled with very low cost.

IMMUNOMODULATORY EFFECTS. In addition to its anthelmintic activity, levamisole also may enhance immune responsiveness. This characteristic has caused considerable excitement in both veterinary and human medicine. Levamisole has been proven to act as an immunomodulator in experimental models and in a number of selected human and animal immunodeficiencies with related pathology. This property has been extensively reviewed (Koller 1982; Blecha 1988). The studies on its application in veterinary practice, mainly in bovine practice, have been also reviewed (Desplenter 1983). Levamisole modulates the immune function at 2–3 mg/kg of body weight, in contrast to the greater anthelmintic doses.

When administered at higher doses, levamisole may even suppress immune function. Intermittent treatment is more efficient than continuous treatment in restoring the immune responsiveness. In vitro and in vivo, levamisole is able to restore to normal the major functions of effector cells of the cell-mediated immune response. This restoration is most pronounced and consistent in compromised hosts, whose T-lymphocytes or phagocyte functions are below normal. Usually an adequate immune response is not increased. The B-lymphocyte activity is not directly stimulated: the proliferative response to mitogens is not increased and there is no direct effect on antibody production. However, it should be kept in mind that the responses to levamisole are not always predictable, even if it is used in appropriate conditions. The results are fluctuating between highly favorable and no effect. In cattle, for example, protective effects have been obtained in the prevention or reduction of complications associated with shipping fever (Desplenter 1983).

SAFETY AND TOXICITY. The pharmacodynamic actions of levamisole (or tetramisole) in the host suggest that the drug exerts both muscarinic and nicotinic effects. Signs of levamisole intoxication (salivation, defecation, and respiratory distress from smooth muscle contraction) are like those observed during organophosphate poisoning. Indeed, evidence suggests that some of the toxicity of this drug may be related to cholinesterase inhibition, leading to manifestations of the muscarinic action of acetylcholine (ACh) (i.e., constriction of pupils and respiratory bronchioles, acceleration of GI motility, slowing of the heart rate, and other autonomic actions).

Tetramisole itself has a safety margin estimated to be two to six times the therapeutic dose of 15 mg/kg. Tetramisole is lethal to sheep at a dose of 90 mg/kg. At a dose of 45 mg/kg signs of toxicity occur. Side effects or death are more likely to occur when tetramisole is administered parenterally. The safety factor of levamisole is about twice that of the parent tetramisole compound. Levamisole is considered to be more dangerous when administered parenterally than after the oral or topical treatments. Intravenous administration is particularly hazardous and is never recommended. Cattle appear to be somewhat more tolerant of parenteral administration than sheep. A twofold overdose of injectable levamisole phosphate may cause about two-thirds of treated cattle to lick their lips and to develop temporary foaming of the muzzle. The pour-on formulation has been tested on several thousand cattle with only occasional dermal irritation. When given to pigs at three times the recommended dosage, levamisole causes only occasional vomiting. In such cases, reaction is due to expulsion of the worms and should terminate in several hours. The LD_{50} of subcutaneously injected levamisole in pigs is 40 mg/kg. Simultaneous administration of pyrantel tartrate (a nicotinelike drug) enhances toxicity by lowering the levamisole LD_{50} value to 27.5 mg/kg.

Chickens tolerate tetramisole and levamisole very well. The LD_{50} for chickens is quite high (2.75 g tetramisole/kg), and minimum toxic levels of the drug in chickens exceed 640 mg/kg. In geese, however, a dosage of 300 mg/kg is known to be toxic. In chickens, therapeutic doses of levamisole (36–40 mg/kg) cause no undesirable side effects, and egg production, fertility, and hatchability are not affected adversely. Dogs and cats are much more tolerant to oral than parenteral administration of tetramisole. When given orally to dogs, doses of 20 mg/kg are well tolerated, and even 40 and 80 mg/kg are not fatal, although vomiting occurs. Subcutaneous tetramisole at 40 mg/kg is fatal to dogs in 10–15 minutes; even at 20 mg/kg, the drug causes severe reactions in dogs, although they persist for only about 20 minutes. On the basis of these findings, the oral route of administration is recommended for dogs and cats. Imidazothiazole compounds have a narrow margin of safety in horses and they are not approved for use in this species.

Levamisole should be administered within specified time periods before slaughtering swine, cattle, or sheep. A 2- to 11-day slaughter clearance time is mandated, depending on the formulation used and animal species. The identified levamisole metabolites are much less toxic than the parent compound, so the parent drug is sought in analysis of tissue samples. Since no withdrawal time is established for dairy cows, this drug should not be administered to lactating cattle producing milk for human consumption. There are no specific contraindications in administration of levamisole with other drugs. However, other nicotinelike (e.g., pyrantel, morantel) or cholinesterase-inhibitor drugs (e.g., organophosphate, neostigmine) could theoretically enhance the toxic effects of levamisole.

TETRAHYDROPYRIMIDINES

PYRANTEL. Introduced in 1966, pyrantel was the first compound within the tetrahydropyrimidine family. It was

initially used as a broad-spectrum anthelmintic against GI nematodes in sheep and thereafter, developed for use in cattle, swine, horses, dogs, and cats. Subsequently, its methyl ester analogue, *morantel,* was also introduced as a nematodicidal compound in the veterinary market (see Fig. 40.10). The newest drug in this chemical family is *oxantel,* an m-oxyphenol derivative of pyrantel. However, due to its cost, it is not used in veterinary medicine.

CHEMISTRY. Pyrantel is *E*-1,4,5,6-tetrahydro-1-methyl-2 [2-(2-thienyl)vynil]-pyrimidin (Fig. 40.10). It is formulated as tartrate, citrate, or pamoate (also known as *embonate*) salts. Pyrantel pamoate is practically insoluble in water and alcohol, while the tartrate salt is more water soluble. Each gram of pyrantel pamoate is approximately equivalent to 347 mg (34.7%) of the base. Pyrantel citrate is equivalent to 410 mg (41%) of the base. Pyrantel salts are relatively stable in the solid phase. Aqueous solutions are subject to photoisomerization upon exposure to light, with loss of potency. Morantel (1,4,5,6- tetrahydro-1-methyl-2-[2-(3methyl-2-thienyl)ethenyl]pyrimidine) is mainly formulated as a tartrate salt (see Fig. 40.10). Each gram of the tartrate salt is equivalent to 59.5% of base activity. Oxantel is 1-methyl-2-(3-hydroxyphenyl-ethenyl) 1,4,5,6-tetrahydropyrimidine.

MODE OF ACTION. Tetrahydropyrimidine compounds act selectively as agonists at synaptic and extrasynaptic nicotinic acetylcholine receptors on nematode muscle cells and produce contraction and spastic paralysis. Pyrantel and morantel are 100 times more potent than acetylcholine, although slower in initiating contraction. Pharmacologic effects of pyrantel and morantel on the host are similar to the effects of levamisole. These anthelmintics share biologic properties with acetylcholine and act essentially by mimicking the paralytic effects of excessive amounts of this natural neurotransmitter. Pyrantel, morantel, levamisole, and diethylcarbamazine mimic this paralytic action, which is similar to the paralytic effect caused by nicotine; thus the action of these anthelmintics is referred to as *nicotinelike effect.* Although the chemical structures of oxantel and pyrantel are similar, oxantel offers some advantages in efficacy against *Trichuris* spp., which may be due to a difference in the cholinergic subtype selectivity between both molecules as well as to a difference in the dominant cholinergic receptor subtype present in *Trichuris* spp. compared to other intestinal nematodes (Martin et al. 2004).

PHARMACOKINETICS. The pyrantel pamoate salt is poorly absorbed from the GI tract and high concentrations of the unabsorbed drug reach the lower digestive tract in dogs, cats, and horses. Pyrantel tartrate is absorbed more readily than the pamoate salt. The tartrate salt is better absorbed in pigs and dogs compared to ruminants, with peak plasma levels occurring 3–6 hours after its oral administration. Peak plasma levels occur at highly variable times in ruminants. Absorbed drug is rapidly metabolized and excreted into the feces. Pyrantel is extensively metabolized in dogs, rats, sheep, and cattle by oxidation of the thiophene ring, oxidation of the tetrapyrimidine ring, and mercapturic acid conjugation. From the in vivo radiolabeled studies, it was shown that the thiophene ring underwent extensive degradation leading to acidic metabolites that are highly polar, eliminated mainly by urine. Urinary excretion of pyrantel accounts for about 40% of the dose in the dog and 34% in the pig, about 80% of which is excreted as metabolites. The dog is the only species excreting a larger proportion of the drug/metabolites in urine compared to feces. In ruminants, urinary excretion accounts for about 25% of the original dose, much of the remainder passing unchanged in feces. In rats, urinary excretion of the drug is minor; bile is the major route of excretion of metabolites of the absorbed drug.

Morantel is negligibly absorbed in ruminants. The drug is undetectable in the bloodstream in cattle after oral treatment. Morantel is largely excreted as the unmetabolized parent compound in the feces. In a pharmacokinetic and GI compartmental distribution study in calves treated with a morantel tartrate slow-release bolus (Lanusse et al. 1992a), it was shown that the morantel peak concentration is reached at 24 hours postadministration in all GI compartments and in feces. A steady-state concentration was reached at 7–10 days posttreatment and maintained over 84–91 days in feces and in ruminal fluid, and over 98 days in abomasal and ileal fluids. These morantel concentrations in the GI tract of cattle may account for removal of established worms with the initial high peak concentration, and prevention of establishment of incoming larvae with a plateau steady-state concentration that is desirable to minimize selection for drug resistance.

FORMULATIONS, DOSAGES, AND ROUTES OF ADMINISTRATION. Both the tartrate and pamoate salts of pyrantel are used for parasite control in horses. Pyrantel tartrate is formulated for continuous, daily administration over prolonged periods of parasite exposure. Pyrantel pamoate can be administered in suspension or paste formulations, as well as by mixing it with feed. Regardless of the method of administration, a dose of 6.6 mg pyrantel base/kg should be used. A powdered premix formulation containing 10.6% pyrantel tartrate is available for treating parasitic infections of swine via medicated feed. Overnight fasting is advised. Water should be available ad libitum during the fasting and treatment periods.

Formulations of pyrantel pamoate for dogs include suspension and tablet forms. Pyrantel pamoate is also combined with febantel and praziquantel in a tablet form for dogs. Each of the above formulations is given to dogs as a single dose. A higher dose of pyrantel pamoate (20 mg/kg) is combined with praziquantel (5 mg/kg) for cats. Administration with food delays passage through the digestive tract, prolongs contact time of the drug with parasites, and thereby increases efficacy. Mackenstedt et al. (1993) proved that preadult stages of *Toxocara canis* continuously absorbed the drug through the whole body surface and that duration of exposure to pyrantel is more important in efficacy than variations in dosage. Another formulation for dogs is a beef-based chewable form that combines ivermectin (6–12 μg/kg) for control of heartworms and pyrantel pamoate (5–10 mg/kg) for control of hookworms and ascarids. This form is administered once a month.

A sustained-release bolus of morantel tartrate for both dairy and beef cattle is widely used in Europe and has been approved in many places in America. The drug (11.8 g morantel base) is packaged in a cylindrical trilaminate cartridge, which is administered orally by a special delivery device and is retained in the rumen/reticulum. This device is known as the MSRT (morantel slow-release trilaminate bolus). The permeable wall allows continuous release of morantel tartrate (approximately 150 mg/day) into the rumen/reticulum fluid for at least 90 days (Lanusse et al. 1992a). Administration of the MSRT bolus is recommended as preventative for larvae establishing as well as to control existing adult nematode burdens in cattle. The ultimate effect is marked reduction in pasture contamination for a prolonged period, e.g., 90 days of drug release and benefits that extend for another 90 days. Inhibited *Ostertagia* larvae are not killed by this method of treatment, but lowered pasture contamination helps prevent development of type II ostertagiasis.

Dosages for pyrantel tartrate are a single therapeutic dose of 12.5 mg/kg (horses), 22 mg/kg (swine), or 25 mg/kg (sheep, cattle, goats). Dosages for pyrantel pamoate are 6.6 mg base/kg (horses), suspension and chewable form at 5 mg base/kg (dogs); tablets at 5 mg/kg for dogs over 2.2 kg, but 10–15 mg/kg for dogs less than 2.2 kg body weight. Morantel tartrate is recommended for oral treatment at 8.8–9.6 mg/kg (cattle) and at 10 mg/kg (sheep).

ANTHELMINTIC SPECTRUM. In general, activity of pyrantel on GI helminths in horses is independent of the method of administration or the salt, i.e., tartrate or pamoate. Activity of each of the two salts is characterized by consistently high efficacies. A more limited efficacy has been observed against *Strongylus edentatus*, small strongyles, and mature and immature *Oxyuris equi*. Pyrantel is >95% effective against the ileocecal tapeworm (*Anoplocephala perfoliata*) at double the regular therapeutic dosage (i.e., 13.2 mg/kg) (Reinemeyer et al. 2006).

Pyrantel is indicated for the removal or prevention of the large roundworms (*Ascaris suum*) and *Oesophagostomum* spp. in swine. It also has activity against the swine stomach worm (*Hyostrongylus rubidus*). The citrate salt of pyrantel has similar efficacy to that of pyrantel tartrate in swine. Pyrantel is used to control the following parasites in dogs: ascarids (*Toxocara cani, Toxascaris leonina*), hookworms (*Ancylostoma caninum, Uncinaria stenocephala*), and stomach worm (*Physalopter*). It is useful for similar parasites in cats and is considered to be safe to use, even in kittens.

Pyrantel tartrate is an effective nematodicidal in ruminants. It is effective in sheep, cattle, and goats against GI nematodes such as *Ostertagia* spp., *Haemonchus* spp., *Trichostrongylus* spp., *Nematodirus* spp., *Chabertia* spp., *Cooperia* spp., and *Oesophagostomum* spp. The drug is highly effective against mature worms and any immature stages that dwell in the lumen. Morantel is an effective nematodicidal drug for use in sheep and cattle. The salts of morantel have greater anthelmintic activity than the parent compound, pyrantel. Efficacy of morantel tartrate is quite good against adult and immature stages of *Haemonchus* spp., *Ostertagia* spp., *Trichostrongylus* spp., *Cooperia* spp., and *Nematodirus* spp. The MSRT (morantel bolus) has been designed for removal of established worms

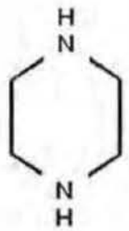
(initial peak concentration) and prevention of establishment of incoming larvae (plateau steady-state concentrations).

SAFETY AND TOXICITY. The salts of pyrantel are free of toxic effects in all animal hosts at doses up to approximately 7 times the therapeutic dose. The oral LD_{50} of pyrantel tartrate is 175 mg/kg in mice and 170 mg/kg in rats. In dogs, the acute oral LD_{50} for pyrantel pamoate is greater than 690 mg/kg (138 times the therapeutic dose). In chronic toxicity studies, dogs showed ill effects when administered pyrantel tartrate at 50 or more mg/kg/day for 3 months but no adverse effects when the dosage was reduced to 20 mg/kg/day for the same period. Pyrantel is safe for horses and ponies of all ages, including sucklings, weanlings, pregnant mares, and stallions. At 20 times the recommended dose in horses, ponies, and foals, pyrantel pamoate shows no adverse clinical effects or changes in blood cell values or serum chemistry parameters. Pyrantel tartrate is slightly less tolerated in horses than the pamoate salt. The tartrate salt (100 mg/kg) produced death in one of three horses. Toxic signs preceding death included a marked increase in respiration rate, profuse sweating, and incoordination. No signs of toxicosis occurred following administration of 75 mg/kg. Ataxia is seen in some cattle treated with a high dose of pyrantel tartrate (200 mg/kg). The toxic dose of the drug in pigs is not known. Pyrantel is not recommended for use in severely debilitated animals, presumably because its pharmacologic action (cholinergic) may be more pronounced in these hosts.

Withdrawal periods exist for swine and ruminants designated for slaughter. Because of lack of metabolism data in horses, the drug should not be used in horses intended for human consumption. Despite its cholinergic properties, there is no clinical evidence that simultaneous use of organophosphates increases toxicity. Thus labeling for pyrantel products indicates safety for simultaneous use with insecticides, tranquilizers, muscle relaxants, and central nervous system depressants. Pyrantel is recommended not to be used concurrently with other cholinergic agonist anthelmintics (morantel or levamisole). Piperazine and pyrantel/morantel have antagonistic mechanisms of action and their combined use should be avoided.

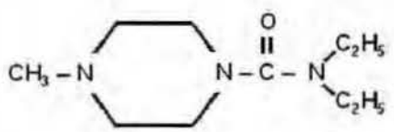
Morantel tartrate is a safer drug than pyrantel tartrate. The oral LD_{50} of pyrantel for mice is only 170 mg/kg while that of morantel is 5 g/kg. Chronic toxicity studies indicate that doses up to four times the therapeutic dose for sheep for 60 days and two and one-half times that for cattle for 20 days produce no toxic signs. Following a single therapeutic dose (10 mg/kg) via medicated feed, the drug is barely detectable (≤0.05 mg/ml) in plasma or milk of lactating cattle and goats. Negligible levels of morantel tartrate in plasma and milk following single or sustained administration allow its use in dairy animals without a milk withdrawal restriction.

ORGANOPHOSPHATE COMPOUNDS



Organophosphate compounds had their origins as pesticides and only subsequently found use as narrow spectrum anthelmintics. Among the organosphosphates used as anthelmintics in domestic animals are dichlorvos, trichlorfon, haloxon, coumaphos, naphthalophos, and crufomate. The first two were used primarily in horses, and the latter four in ruminants. Organophosphate compounds generally remove the principal parasites of horses, pigs, and dogs but are somewhat deficient in their activity against nematodes of ruminants. Dichlorvos remains useful to control nematode parasites in monogastrics, and its spectrum includes bot flies (*Gasterophilus* spp.) in horses. Overall, the organophosphates have satisfactory efficacy for nematode parasites of the abomasum (especially *Haemonchus*) and small intestine but lack satisfactory efficacy for nematodes of the large intestine (*Oesophagostomum, Chabertia*). However nowadays, other more efficacious and safer antiparasitic drugs have replaced them. Interested readers are referred to the previous edition of this text (Reinemeyer and Courtney 2001) for additional specific information regarding the anthelmintic spectrum, mode of action and toxicity of the organosphosphate compounds. Additional information on the pharmacological properties of the organophosphate compounds can be obtained in Chapter 44.

HETEROCYCLIC COMPOUNDS



PHENOTHIAZINE. Phenothiazine was perhaps the first anthelmintic to demonstrate a fairly wide range of activity against GI nematodes. Phenothiazine was used extensively to control nematodes in sheep, cattle, goats, horses and chickens since 1938. Toxicity limited its use in swine and precluded its use in dogs, cats and humans. As stated by Reinemeyer and Courtney (2001), the emergence of phenothiazine-resistant strains of ruminant and equine

nematodes in the 1960s and competition from other broad-spectrum drugs markedly reduced the utility of this compound in subsequent years. It is no longer used as an anthelmintic compound. However, readers interested in specific information on phenothiazine are referred to the previous editions of this textbook, including the 8th edition (Reinemeyer and Courtney 2001).

PIPERAZINE (DIETHYLENEDIAMINE). Discovered around 1900, piperazine was recognized as an anthelmintic moiety in 1954. It has good efficacy profiles against ascarid and nodular worm infections of all species of domestic animals, moderate for pinworm infections, and zero to variable for other veterinary helminths. Its low cost and wide safety margin in all domestic animals have been determinant for its extensive worldwide use in antiparasitic therapy. Piperazine (MW 86.14 Kda) has a relatively simple chemical structure (see Fig. 40.11). It is a strong base soluble in water (1:18), glycerol and glycols, but only sparingly soluble in alcohol and totally insoluble in ether (Pharmaceutical Codex 1979). Piperazine is relatively unstable as the free base, and to improve its stability is usually formulated as different salts such as adipate, citrate, phosphate, hexahydrate, and sulphate. Anthelmintic activity is directly related to the proportion of free base, and this varies according to the salt form (e.g., adipate, 37% free base; chloride, 48%; citrate, 35%; dihydrochloride, 50–53%; hexahydrate, 44%; phosphate, 42%; sulphate,46%) (Courtney and Roberson 1995). FIG. 40.11 Chemical structures and some comparative pharmacological properties of piperazine and diethylcarbamazine.

piperazine salts are white crystalline powders that are readily soluble in water. Exceptions are adipate, which dissolves to only a maximum concentration of 5% in water, and phosphate, which is insoluble.

Piperazine is classified as a narrow spectrum antinematodal drug since its efficacy has been demonstrated only against some specific nematodes in horses, pigs, dogs, cats, and chicken. In ruminants, this moiety is seldom used because of its low efficacy against the commonest sheep abomasal parasites (*Teladorsagia circumcinta*) and other parasites located in the ruminants' small intestine. Piperazine's mode of action was initially thought to involve antagonism of cholinergic receptors located on the neuromuscular membrane. However, it is now clear that piperazine blocks transmission by hyperpolarizing nerve membranes at the neuromuscular junction leading to parasite immobilization by flaccid paralysis and consequent removal from predilection site and death. The most recent studies (Martin 1997; Harder 2000) demonstrate that piperazine is a selective agonist of gamma-amino butyric acid (GABA) receptors, resulting in the opening of chloride channels and hyperpolarization of the membrane of the muscle cells of the nematode parasites. Mature worms are more susceptible to the action of piperazine than younger stages. Immature adults and lumen-dwelling larvae are sufficiently susceptible to be at least partially eliminated. Larval stages in host tissues, however, are relatively insusceptible. Because of subsequent larval development, repeated treatments are generally indicated within 2 weeks for carnivores and within 4 weeks for swine and horses.

Piperazine is readily absorbed through the GI tract and then extensively metabolized (60–70%). The remaining parent molecule is eliminated in urine over the 24-hour period following dosing. Piperazine base is detectable in urine as early as 30 minutes after the drug is administered. The therapeutic dose recommended for dogs and cats is 45–65 mg/kg of piperazine free base, given as a single oral administration. Efficacy has been demonstrated against *Toxocara* and *Toxoascaris*, although piperazine is ineffective against *Trichuris vulpis* (Jacobs 1987). Treatment of nursing pups with piperazine at 2, 4, 6, and 8 weeks of age is highly effective (over 90%) in removing prenatally acquired *Toxocara canis* infections.

The dose recommended in horses, swine, and ruminants is 110 mg/kg. In horses, different piperazine salts are highly effective against ascarids, cyathostomes, and mature pinworms (*Oxyuris equi*). In foals, treatment at 8-week intervals is recommended for prevention of patent *Parascaris equorum* populations. Retreatment within 3–4 weeks is recommended in *O. equi* infections since piperazine has not demonstrated efficacy against immature pinworms. Single doses of piperazine are also effective (approximately 100%) against ascarids and nodular worms in swine. Retreatment 1–2 months later may be desirable for optimizing the efficacy against migrating larvae from tissues after the first treatment. The drug is also recommended (2 doses of 32 mg/kg every 24 h) in two successive feedings (adipate of citrate) or drinking water (hexahydrate) as a highly effective treatment against *Ascaridia galli* in poultry. However, this treatment is apparently not effective against *Heterakis gallinarum*.

Experience over many years has confirmed the safety of piperazine; it is almost nontoxic under ordinary circumstances showing a large safety margin. However, large oral doses of piperazine produce emesis, diarrhea, incoordination, and head pressing in cats and dogs. In cats, piperazine was the anthelmintic for which toxicity (confirmed or suspected) was most frequently recorded by the Illinois Animal Poison Information Center (IAPIC) between January 1986 and August 1988 (Lovell 1990), although this may reflect its widespread use as much as its toxic potential. Symptoms of neurotoxicity in dogs and cats manifest as muscle tremors, ataxia, and alteration of the patient behavior within 24 hours after a daily dose of 100 mg/kg. No toxic effects have been reported in foals and horses after they were given six or seven times the therapeutic dose. However, four times the therapeutic dose may provoke digestive discomforts such us transitory diarrhea and excessive rumen gas accumulation in cattle. The therapeutic index of piperazine has been established as 3 (cats) to 6 (horses) (EMEA 2001). Overall, piperazine remains useful as a result of its low cost, safety, and high efficacy against ascarids in different animal species.

DIETHYLCARBAMAZINE CITRATE (DEC). DEC (MW 391.4) (see Fig. 40.11) is a derivative of piperazine, which is highly soluble in water, alcohol, and chloroform, but insoluble in organic solvents (Pharmaceutical Codex 1979); it is stable in the environment. In veterinary medicine, DEC is formulated as tablets or chewables that are sold as a preventive for heartworm disease (*Dirofilaria*

immitis) in dogs. DEC should be administered daily throughout the mosquito vector season and continued for 2 months following. It is also used in combined commercial formulations that also contain oxibendazole, ivermectin, or milbemycin oxime. DEC has also been previously used for the treatment of lungworm infection in ruminants.

DEC appears to have a different mode of action compared with other antiparasitic molecules, since its microfilarial activity is absent in vitro but extensive in vivo. It has been shown that DEC inhibits cyclic peroxide generation from arachidonic acid (AA) breakdown, specifically through its effects on the enzymes leukotriene A4 synthetase (LTA4), prostacyclin (PGI) 2 synthetase, and prostaglandin (PG)E2 synthetase. However, DEC has no apparent inhibitory effect on thromboxane synthetase and, therefore, cannot be classified as an inhibitor of cyclooxygenase (Martin 1997). The microfilaria produces PGI2 and PGE2 within endothelial cells of blood vessels of infested patients. Since DEC can alter AA metabolism in both parasite and host, it is possible that vasoconstriction combined with amplified endothelial adhesion may be responsible for the immobilization of the microfilaria with a complementary cytotoxic action provided by host platelets and granulocytes (Martin 1997).

After oral administration, DEC is readily absorbed by the GI tract, achieving maximum plasma concentration (Cmax) at 3 hours postadministration, with a subsequent plasma detection period of approximately 48 hours. The drug is widely distributed in tissues and is metabolized in the liver by N-dealkylation and N-oxidation into four metabolites. DEC is excreted in the urine either unchanged or as the N-oxide metabolite. Urinary excretion and, consequently, plasma half-life are dependent on urinary pH (Martindale 1993). Studies with activated charcoal demonstrated that the latter significantly decreased the absorption and elimination of DEC by adsorption in the GI tract (Orisakwe et al. 2000). DEC was shown to have generally low toxicity at the therapeutic dose of 6.6 mg/kg given as oral tablets, or 2.5 mg/kg orally given in powder form once a month, although gastric irritation was observed as a side effect in a few dogs. DEC is contraindicated in dogs parasitized with adult filaria since a hypovolemic shock-type reaction may occur in a small percentage (0.3–5%) of such dogs after DEC administration, which may lead to death within in a few hours (Courtney and Roberson 1995).

HEARTWORM ADULTICIDES: ORGANIC ARSENICALS

THIACETARSAMIDE SODIUM. This compound is a disodium salt of *S,S*-diester of *p*-carbamoydithiobenearsonous acid with mercaptoacetic acid. It is recommended to evaluate the liver and kidney function before dosing since this arsenical compound has shown to be toxic. The plasma pharmacokinetics of thiacetarsamide has been reported in dogs after intravenous injection (2.2 mg/kg), displaying a two-compartment open model curve. High variation given by wide range in kinetic values, were obtained for elimination half-life (20.5 to 83.5 min) and clearance rate (80.0 to 350 ml/kg/min). The mode of action is still unclear, presumably due to the action of the arsenic on cell glycolysis. Treatments of heartworm (*Dirofilaria immitis)* is its main therapeutic use, although a potential use on chronic fatigue syndrome associated with *Staphylococcus* spp. bacteremia has recently been described (Tarello 2001). The compound has no efficacy against circulating microfilariae. Adult worms die within a week after treatment. A dose of 3.7 mg/kg daily for 3 days produced serious side effects in one-third of the dogs tested. Side effects at the standard dose increase with the clinical severity of the heartworm disease. Toxicity is revealed by vomiting, icterus, and orange-colored urine. Dimercaprol (8.8 mg/kg/day in four divided doses) is the recommended antidote when toxic signs are manifested. Cats have demonstrated sensitivity to thiacetarsamide, and its use is not recommended in this species.

MELARSOMINE. Melarsomine is a trivalent arsenical of the melanonyl thioarsenite family with activity against adult and 4-month-old heartworms (*Dirofilaria immitis*) in dogs. Melarsomine is available as a powder for mixing with sterile water before use. The FDA approved this molecule for use in dogs under a hospital setting. Its mode of action is unknown. It is rapidly absorbed after intramuscular injection (2.5 mg/kg) in dogs, achieving the Cmax at only 8 minutes postinjection. It has also been reported that melarsomine and its metabolites are free in plasma, unlike thiacetarsamide, which binds to red blood cells. Arsenic plasma levels are higher and measured for a longer time after treatment with melarsomine compared to those achieved after thiacetarsamide administration.

Melarsomine is active against immature (>4-month-old) and adult heartworms in dogs. Heartworm disease is preventable using the daily or monthly heartworm-prevention medications. It is preferred over the use of thiacetarsamide since it can be used more safely in dogs with severe heartworm disease. The side effects provoked after injection are described as pain, swelling, and tenderness at the injection site. Coughing, gagging, depression, lethargy, lack of appetite, fever, lung congestion, and vomiting may also appear as side effects. Melarsomine has a low margin of safety and it is recommended to have an accurate weight before treating. Dimercaprol can be used as a possible antidote for reversing the toxicity within 3 hours.

RESISTANCE TO ANTHELMINTIC COMPOUNDS: MOLECULAR BASIS

Perhaps it is the simplicity of treating infections with very effective drugs on a routine basis and the proven cost-effective gains in short-term productivity that has led to the predominance of chemotherapy (Zajac et al. 2000). Consequently, resistance to anthelmintic drugs has become a major problem in veterinary medicine and threatens both livestock income and animal welfare.

Resistance is present when there is a greater frequency of individuals within a population able to tolerate doses of a compound than in a normal susceptible population of the same species. The most important feature of anthelmintic resistance is that it is inherited. It is a population of worms, and not of individuals, that become resistant. Selection contributes to produce resistant populations. Once resistance is present in a population, reversion or loss of resistance has never been observed (Sangster and Dobson 2002). For each chemical class of anthelmintics, resistance to one member usually confers resistance to the other members. Genetic modifications conferring resistance are translated into different biochemical modifications that determine a reduced drug effect in the resistant cell. These molecular changes represent the pharmacological basis of the resistance phenomena. Parasites have a number of strategies to become resistant, including 1) molecular changes affecting the capacity of the drug to accumulate at intracellular site of action (reduced uptake, enhanced active efflux and metabolism); 2) modified activity of parasite enzymatic systems; 3) changes on the number, structure, and/or affinity of cellular drug receptors; and 4) amplification of target genes to overcome the effect of the anthelmintic drug. The mechanism of action determines the time of appearance of the antiparasitic effect and the potential risk for the development of resistance to a given drug chemical class. The appearance of resistance to all the major families of broad-spectrum anthelmintics—benzimidazoles, imidazothiazoles (levamisole), tetrahydropirimidines (pyrantel, morantel), and macrocyclic lactones (avermectins and milbemicyns)—has strongly motivated the development of pharmacodynamic studies in order to understand the mechanisms of drug action and resistance.

As described in this chapter, the nematodicidal action of the benzimidazole (BZD) anthelmintics is based on their selective binding to β-tubulin, which produces subsequent disruption of the tubulin-microtubule dynamic equilibrium. BZD resistance in *Haemonchus contortus* has been associated with the loss of high-affinity binding receptors and an alteration of the β-tubulin isoform pattern (Lubega and Prichard 1991) based on a well-conserved mutation at amino acids 200 or 167 (phenylalanine to tyrosine) in both β-tubulin isotypes 1 and 2 (Kwa et al. 1994; Prichard 2001).

Levamisole (LVM) acts selectively as agonist at the synaptic and extrasynaptic nicotinic acetylcholine receptors on nematode muscle cells, inducing spastic paralysis. Resistance to cholinergic agonists is produced by changes on the properties of the nicotinic receptor populations (Robertson et al. 1999) and through an alteration of the drug binding to the nicotinic receptors in the nematode muscle cells. Strains of *H. contortus, Caenorhabditis elegans,* and *Oesophagostomun dentatum* resistant to LVM presented a lower number of active receptors. Martin and Robertson (2000) reported that the normal function of the LVM receptor is modified in resistant nematodes. The active channels stay opened for a shorter amount of time, and a lower depolarization and consequently lower muscle contraction occur. In the low affinity binding site of the receptor, the resistant parasites present lower drug affinity and more binding sites (Moreno-Guzmán et al. 1998; Sangster and Gill 1999). *C. elegans*–resistant strains have a mutation at a single amino acid, replacing glutamic acid in the ion pore of the receptor with a positively charged lysine. This modification is believed to be sufficient to change the ion channel from an excitatory channel to an inhibitory one. On the hand, it has been reported that the presence of the amino acid leucine in the pore of the ion-channel is expected to produce increased desensitization and reduced affinity for the drug, rendering LVM less potent as a nicotinic agonist (Martin 1997). However, the molecular basis

for the pharmacological differences between LVM-sensitive and LVM-resistant worms remains obscure (Wolstenholme et al. 2004). It is important to note that nematodes resistant to LVM are also resistant to the tetrahydropirimidine compounds (morantel, pyrantel). Although chemically different, morantel and pyrantel share the same mode of action with LVM (see Fig. 40.11) and, therefore, side resistance among them has been demonstrated and described elsewhere.

Resistance to the avermectin and milbemycin macrocyclic lactones had been related to selection of genes related to the expression of some subunits of the glutamate-gated chloride channels (GluCl) and to the drug transport P-glycoprotein (P-gp) (see Chapter 42 for detailed information). Additionally genes related to a GABA-gated chloride channel subunit and β-tubulin seem to be also associated with resistance to the macrocyclic lactone compounds (Eng and Prichard 2005). In spite of the involvement of different genes on the resistance to these molecules, not all of them may contribute to the same extent in different nematode resistant strains.

P-gp is a member of the ATP-binding cassette (ABC) group of transporters that function as an ATP-dependent efflux mechanism, enabling drugs to be expelled from cells. P-gp overexpression is a common pattern on the multidrug-resistant (MDR) phenotype in different cancer cells. Overexpression of P-gp has also been implicated in the resistance of nematodes to ivermectin and moxidectin (Pouliot et al. 1997), closantel, and BZDs, although the exact nature of the role has yet to be established. P-gp genes have been identified in *C. elegans* (at least 14 genes) (Lincke et al. 1992), in *H. contortus* (7 genes) (Sangster et al. 1999), and *Onchocerca volvulus* (2 genes) (Kwa et al. 1998). In trematodes, genes encoding ABC proteins have been identified in *Schistosoma mansoni* (Bosch et al. 1994) and *Fasciola hepatica* (Reed et al. 1998). The macrocyclic lactones interact with P-gp and ivermectin has been used as an MDR-reversing agent. It has been shown that *H. contortus* resistant to ivermectin possess an increased level of P-gp expression (Xu et al. 1998) and coadministration with verapamil (an MDR-reversing agent) increase the efficacy of ivermectin and moxidectin against resistant *H. contortus* (Molento and Prichard 1999).

Anthelmintic resistance is a worldwide problem, which mainly involves nematode parasites from sheep, goats, and horses. However, there are already cattle nematodes resistant to multiple anthelmintic classes in New Zealand and South America (Fiel et al. 2000; Mejía et al. 2003; Loveridge et al. 2003) and this will probably become more widespread. The rate at which anthelmintic resistance develops and spreads within a population is determined by the amount of parasites that survive the anthelmintic treatment and contribute their resistance genes to the next generations. This contribution is mainly influenced by parasite genetic factors, fecundity of adult parasites (generation time, offspring per generation, breeding patterns), parasites in refugia, drug features (frequency and timing of treatments, drug persistence in the host, drug dose, and efficacy), rate of consumed larvae, grazing management strategy, and climatic conditions. Refugia are subpopulations of parasites that are not selected by drug treatment. Organisms in the environment (larvae on pastures) which are not exposed to drugs are in refugia. They are important because the higher the proportion of the population in refugia, the slower the selection for resistance (Sangster 2001).

Due to the great effort that goes into the development of new anthelmintic molecules, to optimize the use of the existing ones is a high priority. Increasing drug bioavailability is a pharmacological tool that contributes to the optimization of the treatment, delaying the development of anthelmintic resistance. Any pharmacological tool that allows the enhancement of drug systemic bioavailability will facilitate higher drug concentrations reaching the sites of parasite location for sufficient time to induce the antiparasitic effect, especially on those carrying the resistant genes. This is applicable to those resistance mechanisms that depend on drug concentration. A number of strategies for optimizing the use of available anthelmintics and to delay the development of resistance are under investigation: 1) use of different pharmacotechnically based approaches to enhance drug absorption, 2) enhancement of drug systemic availability by feed management (fasting before/after treatment), 3) pharmacological interference to diminish drug efflux from resistant parasites, 4) interference on drug metabolism/elimination, etc.

The use of a drug class that has been shown to be effective, or a combination of drugs with different modes of action, combined with rotation among chemical groups and the use of as few drug treatments as possible, are the most practical and viable recommendations now to delay the development of resistance. A major challenge is to define strategies to preserve susceptibility. Monitoring parasite populations and treating the animals when numbers reach a threshold are practical options suggested to slow

down the spread of resistance (Sangster 2001). Early detection of resistance and provision of information to farmers and their advisors are essential features of parasite control strategies aimed at preserving drug efficacy. In conclusion, integrated pharmaco-parasitological research is required to minimize the impact of resistance and to obtain a complete understanding of the basic biology of the parasites and the strategies they develop for becoming resistant. Such an approach may help identify solutions for delaying the development of resistance to the currently available anthelmintics.

MISCELLANEOUS AND NOVEL ANTHELMINTIC DRUGS

The development of resistance to the existing chemical classes of broad-spectrum anthelmintics is a primary challenge for discovering new drugs to assure the long-term viability of the animal health industry (Hennessy 1997). This situation highlights the need for developing new antiparasitic compounds with unique modes of action.

Nitazoxanide is a salycilanilide derivative of nithrotiazole. Nitazoxanide is effective against a broad spectrum of parasites and bacteria infecting animals and humans, including nematodes, cestodes, trematodes, coccidian, and ciliate and flagellate protozoa. Its antiparasitic activity in domestic animals was reported a long time ago (Euzeby et al. 1980) but the efficacy patterns are too low to be attractive to be marketed in veterinary medicine. The mode of action for killing worms, protozoa, and some bacteria is unknown but its comprehension may offer an opportunity to discover analogs with improved potency and efficacy (Geary et al. 1999a).

The cost of developing a new class of broad-spectrum anthelmintics for use in food-producing animals is rapidly becoming prohibitive (Hennessy 1997). However, in the last decade numerous pharmacological studies have been carried out to generate new promising molecules with potent and unique pharmacological activity: *diketopiperazines, cyclic octadepsipetides,* and *neuropeptides.* The diketopiperazines (*marcfortine* and *paraherquamide A*), cyclic octadepsipetides (*PF1022, emodepside*), and neuropeptides *(FaRP)* are among the most important novel antiparasitics. Although there is some information on the specific site of action for these novel molecules, the exact mechanism of action is not yet fully understood.

Paraherquamide (PHQ) has excellent activity against almost all the major parasites of sheep (Shoop et al. 1990). Furthermore, oxindole alkaloids in the PHQ/marcfortine family exhibit broad-spectrum anthelmintic activity including drug-resistant nematode strains (Zinser et al. 2002). PHQ and related anthelmintics act as antagonists of neuronal nicotinic cholinergic receptors in both nematodes (flaccid paralysis in vitro) and mammals, and this mechanism appears to underlie both their efficacy and toxicity. 2-Desoxoparaherquamide, known as PNU-141962, is a promising PHQ semisynthetic derivative active against both BZD- and ivermectin-resistant *H. contortus* that shows markedly lower affinity for mammalian receptors than PHQ itself (Geary and Thompson 2003).

PF1022A (Sasaki et al. 1992), the mother compound of the class of the N-methylated 24-membered cyclooctadepsipeptides obtained as a secondary metabolite of the fungus *Mycelia sterilia*, demonstrates exceptional activity against a variety of nematodes in vitro and in vivo (Conder et al. 1995; von Samson-Himmelstjerna et al. 2000). It has been reported that PF1022A paralyzes the worms by acting as GABA agonist (Chen et al. 1996) and cholinergic antagonist simultaneously (Harder et al. 2005). However, difficulties have been reported regarding its delivery to ruminant animals. *Emodepside* is a semisynthetic derivative of PF1022A, which contains a morpholine molecule attached in *para* position at each of both D-phenyllactic acids (see Fig. 40.12). This novel anthelmintic molecule is efficacious against a variety of GI nematodes. Emodepside acts presynaptically on a latrophilinlike receptor (depsiphilin, a putative G protein–coupled receptor), located in the pharynx and body wall muscle of nematodes, which induces activation of a signal transduction cascade via Gq-alfa-protein and phospolipase-C-beta causing an increase in intracellular calcium and diacylglycerol (DAG) levels. DAG activates some protein paying a relevant role in presynaptic vesicles-functioning, which leads to the release of an inhibitory neuropeptide that acts postsynaptically inducing flaccid paralysis in both pharyngeal and somatic body wall muscles of the nematode (Harder et al. 2005). Emodepside has a novel mode of anthelmintic action being fully effective against benzimidazole-, levamisole-, or ivermectin-resistant nematodes of sheep and cattle (Harder et al. 2005). Emodepside is efficacious in cats against nematodes, either following its administration alone or in combination with praziquantel, which has no nematodicidal activity. At 3.0 mg/kg emodepside (spot-on formula-

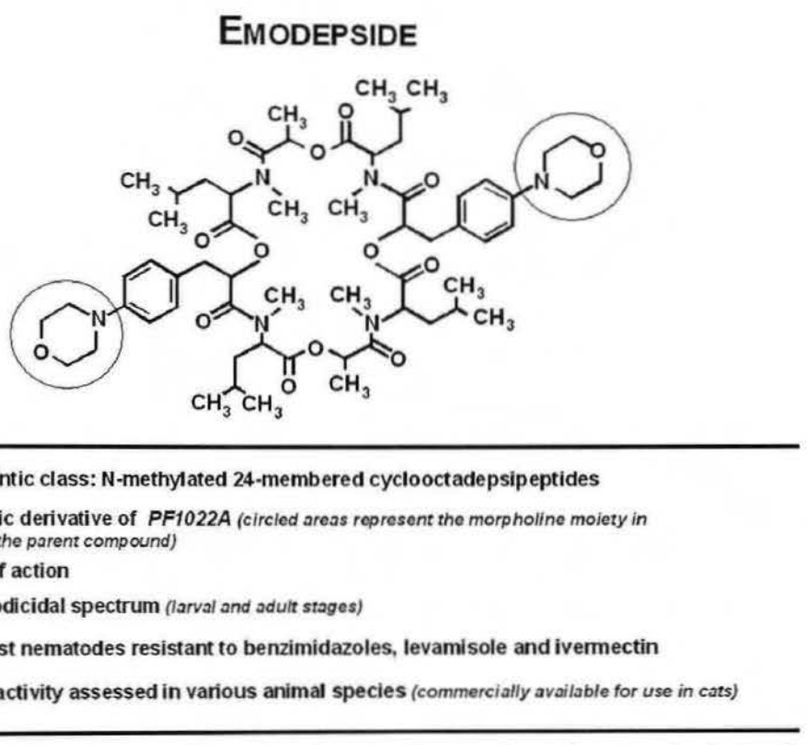

FIG. 40.12 Chemical structure and main pharmacological properties of emodepside, a novel anthelmintic molecule. *Emodepside* in combination with the cestodicide praziquantel is commercially available for use in cats (*Profender R Spot-on*, Bayer Health Care, Animal Health).

tion) has excellent activity against *Toxacara cati* (mature and immature adults), *Toxascaris leonina* and *Ancylostoma tubaeforme* (Altreuther et al. 2005).

The discovery of neuropeptides known as *FMRFamide-related peptides (FaRPs)*, with motor-modulatory activities in both arthropods and helminths, coupled with recent progress in the characterization of invertebrate neuropeptide receptors, has demonstrated that neuropeptide signaling may be a sound approach to identify novel endectocide molecules (Mousley et al. 2004a). FaRPs play a key role in motor coordination, which has been evidenced in arthropod, flatworm, and nematode nervous systems (Geary et al. 1999b). FaRPs are the most potent peptides, supporting their selection as the strongest candidates for chemotherapy intervention (Mousley et al. 2004b). As per their marked structural diversity, FaRPs within each phylum display either myoexcitatory (flatworms) or a variety of myomodulatory effects (arthropods and nematodes) that are dependent upon peptide structure (Mousley et al. 2004a). FaRP receptors (G-protein coupled receptors) may present a suitable target for new anthelmintics (Geary et al. 1999b). FaRP receptors (or the tissues that express them) in arthropods, flatworms, and nematodes are "promiscuous" with respect to the interactive peptide ligands. In fact, an individual peptide from a nematode or arthropod source can activate receptors involved in motor function within the three phyla. The interphyla activity data support the concept of a single drug being able to interfere with FaRP signalling across the phyla that encompass metazoan parasites of importance (Mousley et al. 2004a).

The molecules described here represent encouraging classes of novel antiparasitics due to their particular mechanisms of action. They may constitute a solution to control parasites resistant to the available drugs. However, a series of difficulties (toxicity, formulation, etc.) must be overcome before most of them can reach commercial development. For instance, emodepside has been recently introduced in combination with praziquantel as a broad-spectrum anthelmintic for cats, but its use in other animal species requires further work.

CONCLUDING REMARKS

To maximize the efficacy of anthelmintic compounds against parasites difficult to control in human and veterinary medicine, while preserving an adequate margin of safety, a complete understanding of their pharmacokinetic, and metabolic patterns in the host, is necessary. The complex connections among route of administration, formulation, drug physicochemical properties, and resultant kinetic behavior need to be understood to optimize the efficacy of the existing anthelmintics. Understanding the mechanisms of drug diffusion and metabolism in target parasites is now a key issue to predict drug activity. Additionally, knowledge about the differential drug pharmacologic behavior among animal species and identification of different factors affecting drug activity is relevant for achieving optimal parasite control and avoiding selection for drug resistance. The technical information summarized in the current chapter is useful to illustrate the complexity of the pharmacology of antinematodal compounds in the different animal species. Integrated evaluation of the available knowledge regarding the pharmacological features is required to optimize their anthelmintic activity and to achieve rationale use. Considering the increasing concern for the development of resistance, the use of pharmacology-based information is critical to design successful strategies for the future of parasite control.

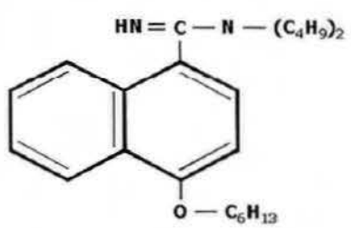
Diamphenethide	**1113**

ANTICESTODAL DRUGS

INTRODUCTION



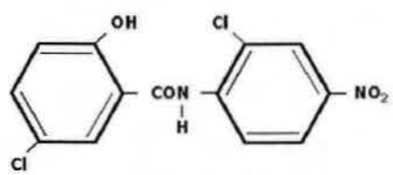
Anticestodal drugs used to treat tapeworm infections may act as either taeniafuges or taeniacides. The former compounds facilitate tapeworm expulsion from the host; while the latter cause the death of the tapeworm in situ. Because the cestode's scolex is capable of regenerating an entire organism, drugs that merely remove the proglottids or the whole tapeworm body but leave the scolex intact are unsatisfactory. Insufficient drug diffusion into the scolex and consecutive two or three proglottides, due to the inflammatory reaction of the intestinal mucosa, may account for such a limited cestocidal activity. The usual interval from destrobilization to patency is approximately 3 weeks, so the recommended interval for evaluating tapeworm therapy is 3 weeks after initial drug treatment. Tapeworm infection in farm animals may be a minor problem and usually does not require treatment with a specific cestocidal drug. Some of the broad-spectrum benzimidazole compounds used to control nematode infections (see Chapter 40) are also effective against tapeworms. However, special attention is given to the treatment of *Anoplocephala perfoliata* infections, the commonest tapeworm parasite in horses. This tapeworm causes erosions around the ileocecal valve and intussusception, particularly in horses chronically infected with large numbers of worms (Gasser et al. 2005). It has been shown that oral administration of a pyrantel pamoate (see Chapter 40) paste at 13.2 mg/kg resulted in effective (96%) control of this tapeworm in naturally infected horses (Reinemeyer et al. 2006). Treatment of tapeworm infections is also highly necessary in companion animals. Of greatest importance is the fact that dogs and cats are definitive hosts of tapeworms whose larval stages cause zoonosis. For example, effective treatment of *Echinococcus*

granulosus in dogs is extremely important since the larval stage of this tapeworm may cause hydatidosis in the intermediate hosts, mainly sheep and humans. Environmental control of intermediate hosts is also essential to prevent reinfection after treatment. The control of fleas and lice that vector *Dipylidium caninum*, and restricted access of carnivores to mammalian intermediate hosts to preclude *Taenia* infections are essential (Reinemeyer and Courtney 2001).

Taeniafuge compounds interfere with the ability of tapeworms to maintain their site of location in the gut. They paralyze tapeworms at least temporarily, but if tapeworms recover prior to expulsion, reattachment to the gut may occur. Thus, treatment with taeniafuges has been routinely accompanied by purgation. *Arecoline,* a muscarinic agonist, induces the parasite's spastic paralysis and enhances host gut motility, which facilitates tapeworm expulsion. The search for enhanced efficacy motivated the development of synthetic taeniacidal drugs that are now widely used. Many of the older antitapeworm drugs are natural organic compounds (taeniafuges). Readers interested in specific information on those older drugs are referred to a previous edition of this textbook (Roberson and Courtney 1995).

BUNAMIDINE

Bunamidine (N,N-dibutyl-4-(hexyloxy)-1-naphthamidine) (Fig. 41.1) is a taeniacidal drug that disrupts the tapeworm's tegument and reduces glucose uptake. Consequently, subtegumental tissues are exposed and destroyed by the host's digestive enzymes. It is formulated as tablets (hydrochloride salt) or suspension (hydroxynaftoate salt) for oral administration in companion animals and ruminants, respectively. The hydrochloride salt is widely used for treatment of cestode infections in dogs and cats. Bunamidine hydrochloride exhibits >90% efficacy against *Taenia* spp., *Dipylidium* spp., *Mesocestoides* spp., and *Diphyllobothrium* spp. (oral treatment at 25–50 mg/kg). However, efficacy against *D. caninum* may be erratic. Effectiveness ranging from 85.9 to 98.8% (immature stages) and 100% (mature stages) of *E. granulosus* have been reported (Andersen et al. 1975). Bunamidine prepared as a hydroxynaftoate salt is effective against *Moniezia* spp. infections in small ruminants.



Bunamidine

FIG. 41.1 Bunamidine chemical structure.

Dissolution of tablets in fasted animals is improved and, therefore, subsequent contact of the drug with the parasite in the gut is enhanced resulting in advantageous efficacy. The drug is safe because is not extensively absorbed in the duodenum and low amounts of the absorbed compound are inactivated in the liver. Administration of dissolved tablets enhances drug absorption and, consequently, the risk of systemic adverse effects such as liver damage and ventricular fibrillation. Death as consequence of cardiac failure has been sporadically reported within 24 hours posttreatment. Emesis and diarrhea are the most frequent adverse effects following bunamidine administration. More efficacious cestodicidal drugs have displaced bunamidine, which is no longer available in the U.S. market.

NICLOSAMIDE

This salicyanilide compound (5-chloro-*N*-(2-chloro-4-nitrophenyl)-2-hydroxybenzamide (Fig. 41.2) was widely used for treatment of cestode infections in dogs and cats from the 1960s to the 1980s. Niclosamide is highly effective against most of the tapeworm species in companion animals. However, it has poor efficacy against *Dipylidium* spp. and *E. granulosus*. This drug is also effective for the treatment of common tapeworms in ruminants such as *Moniezia* spp. and *Thysanosoma* spp. In horses it may be used for the treatment of *Anoplocephala* spp. Niclosamide's action involves interference with glucose absorption and

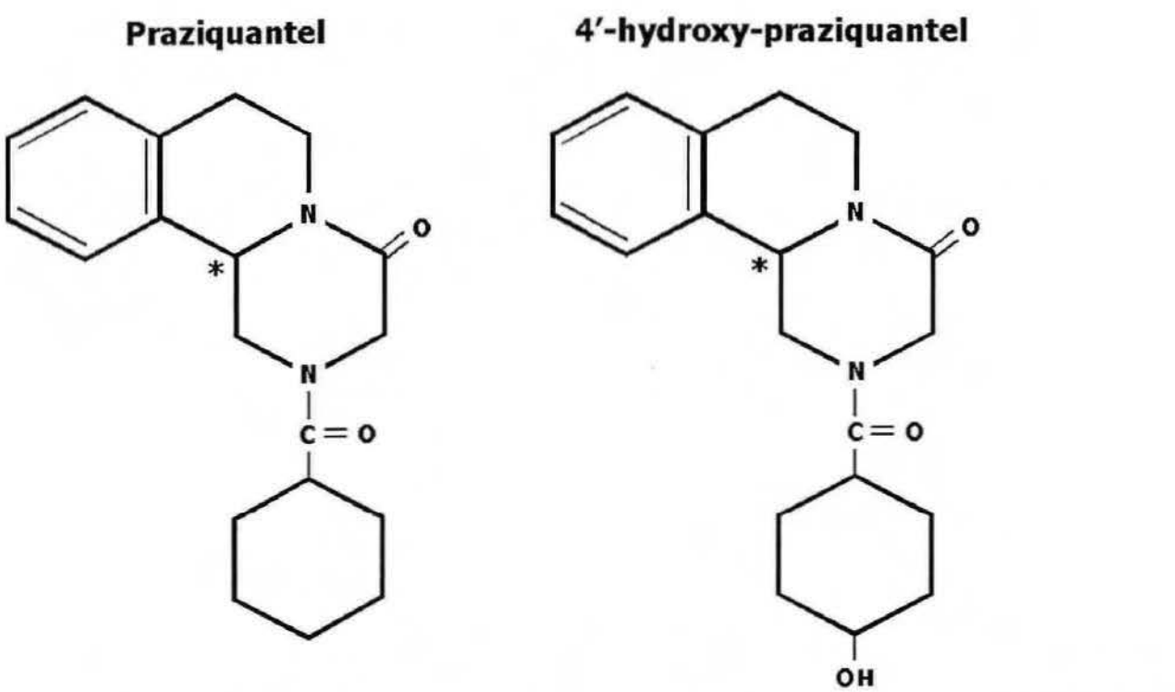
Niclosamide

FIG. 41.2 Chemical structure of the salicylanilide drug niclosamide.

oxidative phosphorylation, mechanisms that lead to the death of the parasite and its subsequent digestion within the gut. It may be administered either as suspension by oral or intraruminal routes in ruminants or as tablets for oral treatment in companion animals. Niclosamide administration in fasted animals increases its efficacy. Its oral administration at doses of 100–157 mg/kg, produced only low plasma concentrations which correlates with low GI absorption and the well-known safety of the drug. The absorbed drug is rapidly inactivated in the liver into aminoniclosamide. Similarly to bunamidine, niclosamide has been replaced in small animal practice by modern cestocides. Interested readers are referred to a previous edition of this text (Roberson and Courtney 1995) for a thorough discussion of the therapeutic properties of niclosamide.

PRAZIQUANTEL

Praziquantel is a synthetic isoquinolinepyrazine derivative: 2-(cyclohexykcarbonyl)-1,2,3,6,7,11b-hexahydro-4*H*-pyrazino[2,1-a] isoquinolin-4-one (Fig. 41.3). Praziquantel is highly efficacious against a variety of cestode and trematode parasites and it is widely used in both veterinary and human medicine. It has extremely high activity against adult stages of all species of tapeworms in farm and companion animals (Thomas and Gonnert 1978). It also has good activity against larval forms of cestodes. Administration of praziquantel at 5 mg/kg in cats and dogs is completely effective against all stages of *Taenia hydatigena*, *T. pisiformis*, *T. ovis*, *T.taeniaeformis*, *D. caninum*, *Mesocestoides corti*, *E. multilocularis*, and *E. granulosus* (Thomas and Gonnert 1978). This dose is generally recommended for elimination of the common cestode species of dogs and cats, except *Spirometra mansonoides* and *Diphyllobothrium erinacea*, which require 25 mg/kg on each of 2 consecutive days. A 10 mg/kg dosage is required to achieve good efficacy against the juvenile forms of these parasites. The drug ensures 100% elimination of *E. granulosus* in dogs and is the unique drug recommended for the treatment of this tapeworm. A combined formulation of febantel and praziquantel is available on the veterinary market for use in the treatment of GI nematodes and cestodes. This formulation must be administered on three consecutive days, at doses of 10–15 mg/kg (febantel) and 1–1.5 mg/kg (pra-



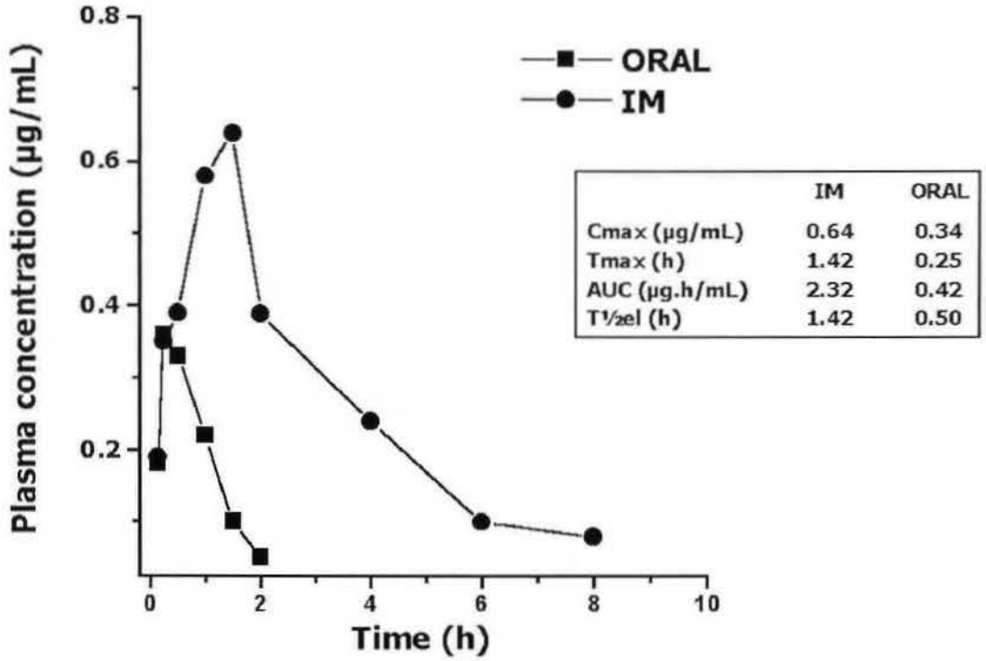


FIG. 41.3 Chemical structures of praziquantel and its active metabolite (4'hydroxy-praziquantel). The asterisk (*) indicates the asymmetric (chiral) center in both molecules.

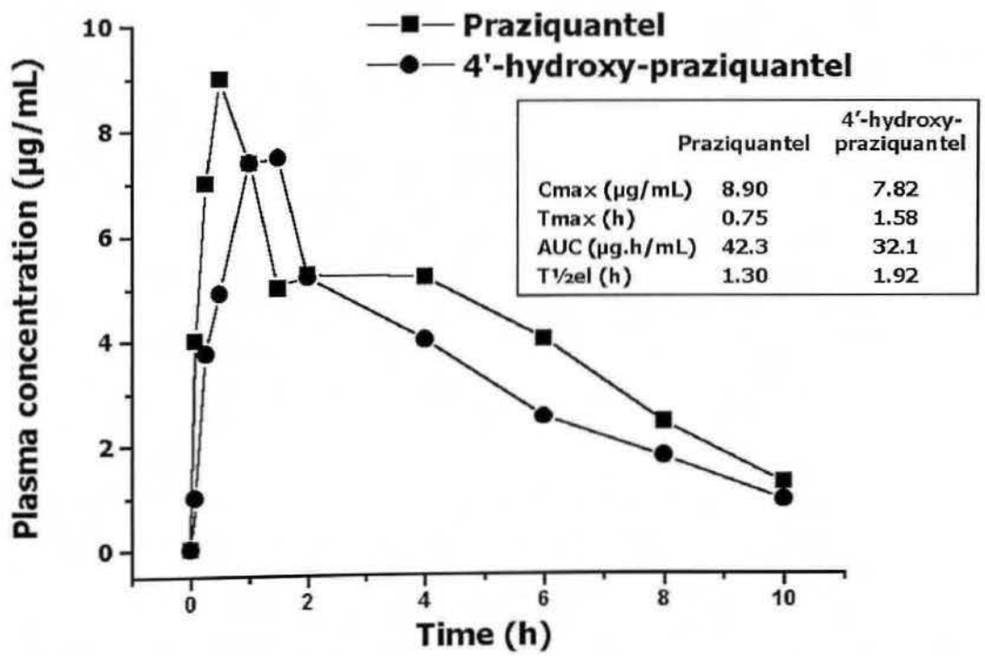
ziquantel) for adult and young dogs. A triple combination of praziquantel, pyrantel, and oxantel is also marketed as a broad-spectrum dewormer for dogs and cats. Other commercial combinations used in companion animals include praziquantel plus oxibendazole, mebendazole, or fenbendazole. Recently, a combined preparation of praziquantel and emodepside (a novel nematodicidal drug) has been introduced into the market as a broad-spectrum anthelmintic for cats (see Chapter 40).

Praziquantel is also highly effective against cestodes of ruminants. All species of *Moniezia, Stilesia,* and *Avitellina* of sheep and/or goats are eliminated by a single dose of 10–15 mg/kg. Praziquantel has been approved for tapeworm treatment in horses in different countries. It has been successfully used for the treatment of the cestode *A. perfoliata* in this species (Lyons et al. 1998). Combined formulations (gel, paste) containing ivermectin plus praziquantel are marketed for use in the treatment of GI nematode and cestode infection in horses.



Most studies concerning praziquantel's mode of action have been done using the human trematode *Schistosoma mansoni* as a model parasite (Day et al. 1992). Praziquantel induces a rapid and sustained paralytic muscle contraction of the parasite and tegumental disruption. The contraction of parasite musculature is the primary effect, which is followed by a rapid vacuolization of the syncytial tegument. Muscular contraction and tegumental disruption are followed by exposure of parasite antigens, binding, and penetration of host immune cells into the parasite (Martin 1997). Metabolic changes include decrease in glucose uptake, glycogen storage, ATP content, and lactate release. All these effects are attributed either directly or indirectly to an alteration of intracellular Ca^{2+} homeostasis. Praziquantel effects are thought to be mediated by the release of intracellular stored Ca^{2+}, in addition to the increase of Ca^{2+} influx across the schistosome tegument (Day et al. 1992). Exposure and release of parasite antigens, as well as metabolic changes, are attributable to the primary effect on the tegument. The exact molecular target, as well as its location within parasite tissues remains to be completely understood. Recently, several investigations have been focused on voltage-gated Ca^{2+} channels as targets of praziquantel action (Greenberg 2005). These channels are critical sites of extracellular Ca^{2+} influx and also play an important role in regulation of intracellular Ca^{2+} homeostasis. The chiral nature of praziquantel is another feature related to its pharmacological effects on the parasite. The drug has an asymmetric center in position 11b (see Fig. 41.3) and, consequently, two enantiomeric forms: R(–) and S(+) praziquantel. Only the R(–) enantiomeric form has antiparasitic activity as shown by in vitro and in vivo experiments (Staudt et al. 1992; Cioli and Mattoccia 2003).

Praziquantel can be formulated as a tablet, paste, or suspension for oral administration, and as a solution for SC or IM injections. Commercial formulations are racemates composed of equal parts of both praziquantel enantiomers. The pharmacokinetic behavior and metabolic fate of praziquantel has been investigated in sheep and dogs (Giorgi et al. 2001, 2003). These authors used a higher oral dose (30 mg/kg) than those recommended in these species in order to generate sufficiently high plasma concentrations for analysis. In sheep, praziquantel Cmax and AUC values administered by the IM route at 15 mg/kg were sixfold higher compared to those values observed following oral treatment at 30 mg/kg (Fig. 41.4). It has been shown that praziquantel is completely absorbed in the GI tract in almost all species studied including sheep. Thus, its low oral bioavailability in sheep is not attributed to poor GI absorption but due to an extensive hepatic first-pass effect. Liver oxidative metabolism of praziquantel in sheep resulted in the production of one hydroxylated metabolite, which might be either 11b-hydroxy- or 1-hydroxy-praziquantel (Giorgi et al. 2001). A cytochrome P450 3A isoenzyme was found to be involved in praziquantel hydroxylation in sheep liver. Conversely, the metabolite formed following praziquantel administration to dogs is 4′-hydroxy-praziquantel (Giorgi et al. 2003). This is consistent with previous studies in other species such as rats, monkeys, and humans in which 4′-hydroxy-praziquantel was the main metabolite (Masimirembwa and Hasler 1994). Praziquantel and its 4′-hydroxylated metabolite were depleted in parallel from plasma in dogs, which is supported by an AUC praziquantel/4′-hydroxy-praziquantel ratio equal to 1.3 (Fig. 41.5). Increased levels of the parent drug and its metabolite following administration of liquid or dry grapefruit juice combined with praziquantel to dogs have been observed. It has been shown that grapefruit juice may be an inhibitor of the P-gp transport protein and cytochrome P450-mediated oxidative drug metabolism. Grapefruit juice may interfere with either the P-gp-mediated efflux or cytochrome P450-mediated oxidation of praziquantel. Interestingly, 4′hydroxy-praziquantel has been shown to exert roughly similar pharmacological activity compared to its parent compound (Staudt et al. 1992). Metabolism of praziquantel is also

	IM	ORAL
Cmax (µg/mL)	0.64	0.34
Tmax (h)	1.42	0.25

	Praziquantel	4'-hydroxy-praziquantel
Cmax (µg/mL)	8.90	7.82
Tmax (h)	0.75	1.58
AUC (µg.h/mL)	42.3	32.1
T½el (h)	1.30	1.92

FIG. 41.5 Plasma concentration profiles of praziquantel parent drug and its main hydroxylated metabolite (4'hydroxy-praziquantel) following praziquantel administration to dogs (orally, 30 mg/kg). The inserted table shows the comparative pharmacokinetic parameters for both molecules. Adapted from Giorgi et al. (2003). Cmax: peak plasma concentration; Tmax: time to peak plasma concentration; AUC: area under concentration-time curve; T1/2el: elimination half-life.

stereoselective for the two enantiomers. Thus, two 4′-hydroxy-praziquantel isomers were identified in the plasma of human volunteers (Westhoff and Blaschke 1992). It has been shown that (–)4′-hydroxy-praziquantel is far more abundant in human plasma than its respective (+) isomer. This finding is highly relevant since, in vitro, there is no significant difference in the pharmacological effect of (–) praziquantel and its respective (–) 4′hydroxylated isomer against *S. mansoni* (Staudt et al. 1992). It has been suggested that efficacy of praziquantel in humans is mainly due to the pharmacological activity of its (–) 4′hydroxylated metabolite rather than to (–) praziquantel itself. Renal excretion is the main route of elimination of praziquantel and its metabolites.

Acute and chronic toxicity studies indicate a wide margin of safety for praziquantel. An acute, oral LD_{50} has not been established in dogs because they vomit when dosages exceed 200 mg/kg. The single therapeutic dose is 3.8–12.5 mg/kg in dogs and 4.2–12.7 mg/kg in cats. Overdoses of up to fivefold are tolerated without adverse effect. Studies in pregnant rats and rabbits detected no embryotoxic or teratogenic effects. Similar tests support the use of praziquantel in breeding and pregnant animals without restrictions.

EPSIPRANTEL

This cestocidal compound (2-(cyclohexylcarbonyl)-oxo-1,2,3,4,6,7,8,12b-octahydropyrazino[2,1-a] [2] benzazepine) (Fig. 41.6), is chemically related to praziquantel. Epsiprantel is used specifically for treatment of the common

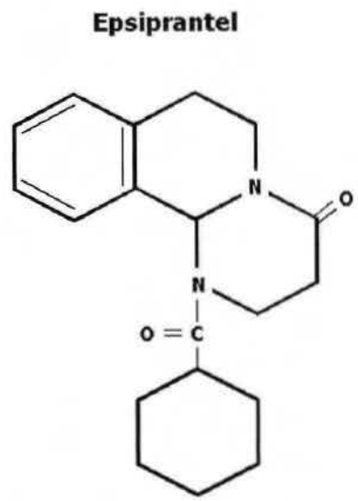

FIG. 41.6 Epsiprantel chemical structure.

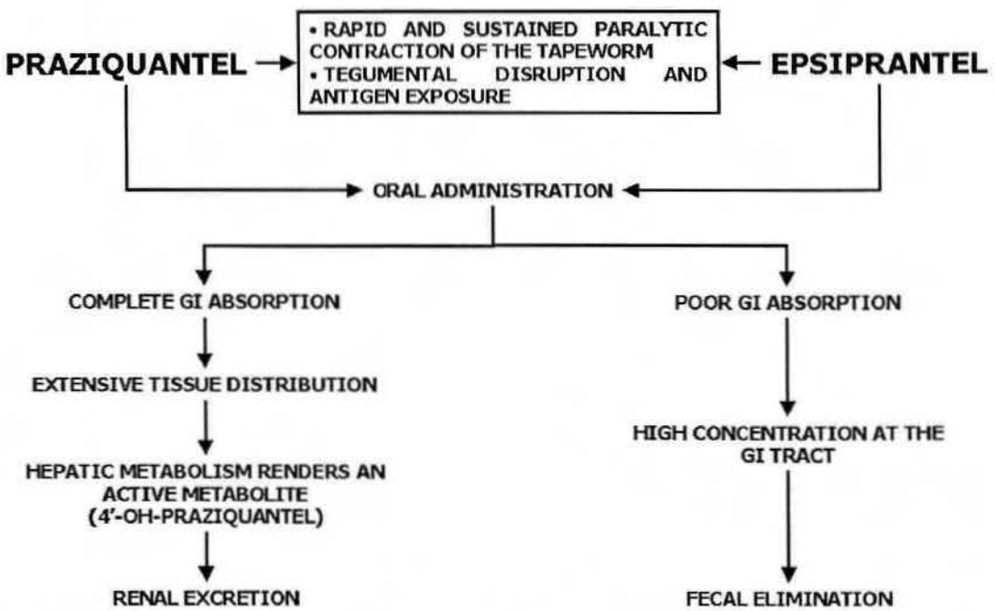

FIG. 41.7 Comparative pharmacodynamic and pharmacokinetic properties of the chemically related anticestodal drugs: praziquantel and epsiprantel. GI: gastrointestinal tract.

tapeworms of dogs (*D.caninum, T.pisiformis*) and cats (*D. caninum, T. taeniaeformis*). Recommended dosages are virtually 100% effective against those cestode parasites. Epsiprantel causes tegumental damage in larval and adult stages of *E. granulosus*. At a dosage of 5 mg/kg in dogs, the drug is 94% effective against immature (7-day-old) worms and more than 99% effective against mature stages (Thompson et al. 1991). At doses of 5.5 mg/kg in dogs and 2.5 mg/kg in cats, the drug was >99% effective against *E. multilocularis*, although residual worms may persist in some animals (Eckert et al. 2001). The recommended dose of 5.5 mg/kg is also 100% effective against *Taenia* spp. and 99.8% against *Dipylidium* (Corwin et al. 1989).

Similar to praziquantel, epsiprantel affects Ca^{2+} homeostasis within the parasite. The drug damages the tegument, making it vulnerable to lysis and digestion within the host's gut. Epsiprantel is only formulated for oral administration in dogs and cats. It is poorly absorbed in the GI tract and is thereby available to act against intestinal cestodes, being eliminated in feces. There are no metabolites and only 0.1 % of the administered drug is eliminated by urine. The comparative pharmacological properties of praziquantel and epsiprantel are summarized in Figure 41.7.

Due to its low GI absorption, epsiprantel is a safe drug. For example, cats tolerate 5 times the therapeutic dose of this cestocide once daily for 3 consecutive days. Emesis has been reported in cats administered 40 times the therapeutic dose daily for 4 days. Beagle puppies (7–10 weeks of age) given 100 mg/kg once (18 times the recommended dosage) exhibited no signs of toxicity. Adult dogs treated once with a 36 times overdose were not adversely affected. Emesis is the most commonly observed side effect of epsiprantel and may occur in prolonged treatments.

ANTITREMATODAL DRUGS

INTRODUCTION

Fasciolosis, caused by the cosmopolitan liver fluke *Fasciola hepatica*, is the most common and economically important disease caused by trematode parasites in domestic animals worldwide. Fasciolosis is an important zoonotic disease, particularly in underdeveloped countries (Mas-Coma 2004). Chemotherapy based on the use of flukicidal compounds is the main tool to control liver flukes. Most of the antitrematodal drugs discussed herein are compounds used for the treatment of fasciolosis. The tropical counterpart of *F. hepatica* is *F. gigantica* and all drugs active against one of the species are equally effective against the other (Boray 1986). Rumen fluke (*Paramphistomum* spp.) infections are common in cattle and sheep throughout the world. Adult flukes attach to the rumen wall and are of little consequence to the health of the animal. Large numbers of the immature stages, however, can be seriously pathogenic as they migrate within the gut lumen from the duodenum to the rumen. Intestinal paramphistomosis generally responds well to treatment with drugs that are effective against liver fluke and/or cestode infections in ruminants. Readers interested in specific issues regarding treatment of infections caused by either rumen flukes (*Paramphistomum* spp.) in sheep and cattle or lung flukes (*Paragonimus* spp.) in dogs and cats are referred to the previous edition of this textbook (see Reinemeyer and Courtney 2001).

The liver fluke's life cycle has several features that should be considered for a better understanding of the pharmacological properties of the antitrematodal drugs. Both immature and mature flukes damage the host liver. After the infective metacercariae are ingested by grazing sheep or cattle, the immature fluke emerges from its cyst, penetrates the wall of the small intestine, traverses the peritoneal cavity, and penetrates the liver capsule within 4 days of infection. During the next several weeks, immature flukes tunnel through liver tissues, feeding and increasing rapidly in size. Acute and subacute fasciolosis are most common in sheep. Both are characterized by the migration of a high number of immature flukes through the liver parenchyma causing severe hepatic hemorrhage, jaundice, and anemia. These stages are often fatal. Clinical signs of acute and subacute fasciolosis are presented within 6–8 weeks postinfection. Antitrematodal drugs used against immature forms must achieve effective concentrations within the liver tissue. The severity of *F. hepatica* infections in sheep may be enhanced by the fluke's potential role in disseminating enteric bacteria (*Clostridium novyi*) in the liver during migration (Reinemeyer and Courtney 2001). During the eighth week of infection, flukes begin to penetrate the main bile ducts, where they attain sexual maturity by ~10–12 weeks after infection. Adult flukes are blood-sucking parasites and penetrate within the bile ducts, causing biliary hyperplasia and progressive occlusion. The infected areas may be surrounded by connective tissue that progressively becomes calcified. Such a tissue reaction is most common in cattle where fasciolosis

is typically more chronic and subclinical in nature. Although adult flukes are most susceptible (or perhaps most accessible) to fasciolicidal drugs at this stage, the affected areas of the liver tissue become progressively less penetrable by therapeutic agents and consequently more difficult to treat (Reinemeyer and Courtney 2001).

Carbohydrate and energy metabolism in helminth parasites differs from that of the mammalian host. Parasites also exhibit a wide variation in their carbohydrate breakdown pathways during their life cycle (Kita et al. 1997). Parasite metabolism uses an aerobic-anaerobic transition. In general, free-living larval stages obtain their energy from aerobic processes, whereas adult forms have mainly an anaerobic metabolism. A transition in the pathways of energy metabolism was observed in both the cytosol and mitochondria of the liver fluke *F. hepatica* (Tielens et al. 1987; Tielens 1994). Overall, energy metabolism in the adult stages is almost completely anaerobic, and aerobic processes remain only in the tegument of the parasite, which is also one of the main absorptive surfaces for drug uptake by the fluke and may be a primary target for anthelmintic action. Recent studies in *F. hepatica* have shown that the transtegumental transfer mechanism is critical to achieve sufficient drug concentration at the site of action to exert its flukicidal action (Mottier et al. 2006). Thus, adult forms in the bile ducts are exposed to anthelmintics or their metabolic products eliminated by bile excretion. Although the tegument represents only 1% of the total volume of the adult parasite, the integrity of the surface plasma membrane and the tegumental syncytium is essential for the viability of the fluke. The disruption of the tegument by different mechanisms (including those involved in energy generation) may have severe consequences for the parasite because the drug would penetrate deeper and disrupt subtegumental tissues as well. The surface damage will be exacerbated by the surfactant action of the bile. In addition, adult blood-sucking stages may uptake the anthelmintic drugs through the alimentary canal. In fact, most of the fasciolicides have high efficacy against adult flukes due to their extended residence in the systemic circulation as a consequence of their strong plasma protein binding (~98–99%).

Since the introduction of carbon tetrachloride for treatment of helminth infections of animals in the 1920s, numerous other compounds have been investigated for efficacy against *F. hepatica*. Carbon tetrachloride and other halogenated hydrocarbons have a narrow therapeutic index and their adverse effects (mainly hepatotoxicity) restrict their use for the treatment of fasciolosis. Based on their chemical structure, the fasciolicidal drugs can be classified into several groups:

1. *Halogenated hydrocarbons* (carbon tetrachloride, hexachloroethane, tetrachlorodifluoroethane, hexachloroparaxylene)
2. *Bisphenolic compounds* (hexachlorophene, bithionol)

TABLE 41.1 Comparative efficacies of the most widely used antitrematodal compounds against different stages of the liver fluke *Fasciola hepatica*

Flukicide Drugs	Fluke's Age (in Weeks)											
	1	2	3	4	5	6	7	8	9	10	11	12
DIAMPHENETIDE	90–100%						50–80%

3. *Nitrophenolic compounds* (nitroxynil, disophenol, niclofolan)
4. *Salicylanilides* (closantel, rafoxanide, oxyclozanide) and *brominated salicylanilides* (bromosalans)
5. *Bencenesulfonamides* (clorsulon)
6. *Benzimidazole* (albendazole, netobimin, luxabendazole) and *halogenated benzimidazole* (triclabendazole)
7. *Phenoxyalkanes* (diamphenethide)

Most of the halogenated hydrocarbons; bisphenolic compounds; the nitrophenolics, disophenol and niclofan; as well as the bromosalans are little used old drugs, which have been extensively reviewed in previous editions of this text (see Roberson and Courtney 1995). This chapter is focused on the description of the pharmacological properties of the most currently used antitrematodal drugs. A schematic representation of the efficacy of different flukicidal drugs against immature and adult stages of *F. hepatica* is shown in Table 41.1.

NITROPHENOLIC COMPOUNDS

NITROXYNIL. Nitroxynil (3-iodo-4-hydroxy-5-nitrobenzonitrile) (Fig. 41.8) was developed in the late 1960s as an injectable fasciolicide for sheep and cattle. It is a trematodicidal compound highly effective against *F. hepatica*, which also holds activity against the abomasal nematode *Haemonchus contortus*. Nitroxynil is highly effective against adult stages of *F. hepatica* (from 8 weeks postinfection) and *F. gigantica*. Activity against earlier stages is rather erratic and it is not effective for the treatment of flukes younger than 6 weeks. Moreover, this anthelmintic is used for the control of ivermectin- and benzimidazole-resistant *H. contortus* in sheep. It is also marketed for the control of *Oesophagostomum* spp. and *Bunostomum* spp. in

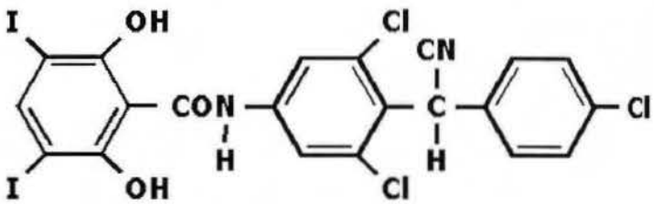
Nitroxynil

FIG. 41.8 Chemical structure of the nitrophenolic compound nitroxynil.

both sheep and cattle and shows good activity against *Parafilaria bovicola* infections in cattle. On the contrary, nitroxynil is not effective for the treatment of paramphistomes in sheep and cattle.

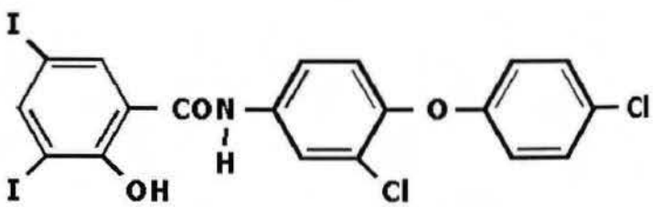
Due to the structural similarity between nitrophenols and 2,4-dinitrophenol, a known uncoupler of oxidative phosphorylation, it was assumed that nitroxynil and related compounds act in a similar way in the fluke. However, there is little direct evidence showing this mechanism of action for these fasciolicides. It has been shown that nitroxynil produced a rapid spastic paralysis (within 3 h) of the fluke in vitro at similar concentrations to those found in the systemic circulation in vivo (Fairweather et al. 1984). This action was not believed to be the consequence of an uncoupling effect on the oxidative phosphorylation (Fairweather and Boray 1999). More recently, it was shown that nitroxynil causes severe disruption of the tegument of *F. hepatica*, both in vitro and in vivo (McKinstry et al. 2003). Liver flukes recovered from rats after 24 hours of nitroxynil treatment showed extensive swelling and blebbing of the tegument in both dorsal and ventral surfaces. These changes became more severe after 48 and 72 hours following nitroxynil administration, and specimens recovered following these posttreatment intervals showed more widespread tegumental loss. Although the intrinsic mechanism of nitroxynil action on the parasite has not been established as yet, it was shown that the tegument is an important target for this flukicidal drug.

Nitroxynil can be administered orally or intraruminally (IR) but is more effective when administered by parenteral routes (SC, IM). A ruminal microflora-mediated nitroreduction may account for its low efficacy after oral or IR treatments. Solutions (25% or 34%) of nitroxynil-N-alkylglucamine are available in the market to be used at 10 mg/kg. SC and IM administrations provide similar efficacy against liver flukes, but the SC route has become the method of choice in practice. Local tolerance at the site of injection is satisfactory, although transitory inflammatory swellings are occasionally observed in cattle. Nitroxynil is well absorbed after its SC administration and binds strongly to plasma proteins (~98%) mainly to albumin (Alvinerie et al. 1991). Plasma concentrations in sheep remain high within 3 days posttreatment and may be detected in the bloodstream for 60 days. Due to its high affinity for plasma proteins, nitroxynil has low tissue distribution and, consequently, the amount of drug reaching the liver parenchyma seems to be insufficient for treatment of immature flukes at the recommended dose rate.



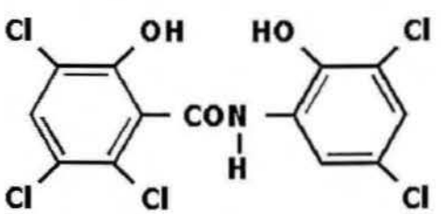
Nitroxynil was shown to be metabolized by hydrolysis of the cyano group to produce 3-iodo-4-hydroxy-5-nitrobenzamide and 3-iodo-4-hydroxy-5-nitrobenzoic acid in rat liver. The enzyme(s) responsible for this hydrolytic reaction was primarily localized in the cytosol (Markus and Kwon 1994). Nitroxynil was also found to be nitroreduced in rat liver into 3-iodo-4-hydroxy-5-aminobenzonitrile (Maffei Facino et al. 1982). Further methylation of this metabolite into 3-iodo-4-methoxy-5-aminobenzonitrile was also shown. However, the inactive metabolites were not detected in the urine nor in the plasma of nitroxynil-treated sheep. Indeed, unchanged drug is likely to be the only source responsible for nitroxynil action. Due to its high plasma protein binding, it was suggested that the blood is the primary source of drug uptake via the fluke's digestive system. In addition, the levels of nitroxynil in bile are far lower than those observed in plasma and so, the uptake of this anthelmintic through the tegument would be limited (McKinstry et al. 2003). The urine is the primary route of nitroxynil elimination, although the drug is also excreted in feces and milk (it is not approved for use in dairy animals). Animals can be slaughtered for human consumption 60 days after nitroxynil treatment. Nitroxynil also stains wool or hair yellow; thus, care must be exercised to avoid spilling. The drug is well tolerated in cattle and sheep at the therapeutic dose of 10 mg/kg. Nitroxynil side effects in these species include hyperthermia and hyperpnea, which were associated with the uncoupling of oxidative phosphorilation in the target species and observed at higher dose levels. Doses above 40 mg/kg may be lethal.

Other nitrophenolic flukicidal compounds such as disophenol and niclofolan were replaced by nitroxynil and many other newer and safer fasciolicidal drugs.



SALICYLANILIDES

This family includes fasciolicidal drugs of similar chemical structure sharing the same mode of action. The most extensively used salicylanilides (closantel, oxyclozanide, and rafoxanide) are described here. For information on the flukicidal activity of the brominated salicylanilides (bromosdalans) readers are referred to a previous edition of this text (Roberson and Courtney 1995).



CLOSANTEL. Closantel (N-[5-chloro-4-[(4-chlorophenyl)cyanomethyl]-2-methylphenyl]-2-hydroxy-3,5-diiodobenzamide) (Fig. 41.9) is highly effective for the treatment of adult flukes and shows good activity against immature specimens aged 6–8 weeks (Table 41.1). It is not effective against earlier stages (Boray 1986). At an oral dosage of 10 mg/kg, its efficacy is more than 92% against 8-week-old and adult *F. hepatica*. It is less active against younger stages of this parasite, i.e., 70–77% efficacy for 6-week-old flukes migrating in the liver. It is also effective (94.6–97.7%) against 8-week-old *Fascioloides magna* in sheep at

Closantel

Rafoxanide

Oxyclozanide

FIG. 41.9 Chemical structures of salicylanilide flukicidal compounds: closantel, oxyclozanide, and rafoxanide.

oral dosages of 15 mg/kg or IM dosages of 7.5 mg/kg. However, closantel is not effective against paramphistome flukes.

Closantel is also highly effective against *H. contortus* in sheep and is used as an alternative drug for the treatment of ivermectin-, benzimidazole-, levamisole- and morantel-resistant strains of this nematode. In addition, it is effective for the treatment of many other adult nematodes such as *Oesophagostomum* spp., *Bunostomum* spp. and *Ostertagia* spp. in both, sheep and cattle. Additionally, closantel is effective against certain ectoparasites such as blood-sucking lice, ticks, mites, and certain grubs of ruminants. It is also used for the treatment of the nasal bot *Oestrus ovis* in sheep. The drug can be used against the adult stage of *Ancylostoma caninum*, but is not effective against the somatic larvae of this hookworm. Closantel also has been used in horses to prevent or reduce infections of *Strongylus vulgaris* and *Gasterophilus* spp.

Closantel and other salicylanilides are uncouplers of the oxidative phosphorylation in the liver fluke. There is stronger evidence supporting this mechanism of action for these compounds than for nitrophenolic flukicides (Martin 1997). ATP production in the mitochondria is coupled to a proton (H^+) gradient across the inner mitochondrial membrane. During the oxidative phosphorylation, electrons coming from NADH or FADH are transported through a series of protein complexes on the inner mithocondrial membrane. During this process, protons (H^+) are pumped out of the mitochondrial matrix into the space between the inner and outer mitochondrial membrane, establishing a proton gradient across the inner membrane. This proton motive force is due to the pH gradient and transmembrane electric potential being critical for ATP synthesis. Salicylanilides possesse a detachable proton (H^+) that could be shuttled across the inner mitochondrial membrane, removing the proton (H^+) gradient and uncoupling oxidative phosphorilation. Metabolic changes consequently to this mechanism include increase in glucose uptake, decrease in glycogen content, changes in respiratory intermediates, and decrease in ATP synthesis (Fairweather and Boray 1999).

In addition, an alternative mechanism of action of closantel has been investigated. A significant decrease in tegumental pH (6.8 to 6.5) was observed after its in vitro incubation with *Schistosoma mansoni* and *F. hepatica* specimens (Pax and Bennett 1989). In fact, this fall occurred within 10 minutes after closantel addition and before any change in the production of ATP by the parasite. This effect was also observed at a lower concentration than that required to produce any reduction in ATP synthesis. It was concluded that the action of closantel is more complex than a conventional uncoupler of the oxidative phosphorylation. Indeed, this anthelmintic is a membrane-active molecule capable of affecting many biochemical and physiological processes within the parasite. Closantel may also shuttle protons (H^+) across the tegumental membrane leading to a disruption of the mechanisms responsible for mantaining pH homeostasis, which are likely to reside in the tegument and excretory system (Fairweather and Boray 1999). Closantel also induces spastic paralysis in *F. hepatica* at concentrations comparable to maximum blood levels attained in vivo. This effect was attributed to an increase in calcium ions in the muscle cells. It has been suggested that this neuromuscular action of closantel may take place before any disruption of energy metabolism. Consequences of the paralysis are cessation of feeding and starvation; the fluke has to draw on its energy reserves to survive, and this may account, at least in part, for some of the biochemical changes observed.

Closantel is a weak acid ($pK_a = 4.28$) molecule of high molecular weight (663 Kda) and extremely lipophilic. It is formulated for oral, IR, or parenteral (SC or IM) administration in ruminants. Closantel is marketed as 3.75 or 5% suspensions or solutions for oral drench or IR administration (solutions also may be used for parenteral administration). The pharmacokinetic behavior of a novel injectable (SC) formulation containing closantel plus ivermectin was recently studied in cattle (Cromie et al. 2006). The plasma availability of both active drugs in the combination was not affected by the presence of the other. Plasma profiles of closantel in the combined product were similar to those observed after administration of a reference product. On the contrary, ivermectin was absorbed and eliminated faster following its administration in the combined formulation compared with a reference product containing only ivermectin.

Closantel is well absorbed after either enteral or parenteral administrations in sheep and cattle. The recommended enteral dose rate in these species is 10 mg/kg; the same efficacy could be attained following its SC or IM administration at 5 mg/kg. Consequently, the oral bioavailability of closantel administered at 10 mg/kg resulted similar to that observed following its parenteral administration at 5 mg/kg (Michiels et al. 1987). It was shown that the bioavailability of closantel administered by the oral route was 50% lower compared to that observed

following its parenteral administration. It has been shown that closantel is not subjected to any significant biodegradation by the ruminal fluid, but more than 80% of the drug was shown to be associated with the particulate phase of the abomasal digesta (Hennessy and Ali 1997). The strong association of closantel with the particulate digesta and the limited time available for the exchange of the drug between the particulate material and the GI fluids prior to absorption may explain its low enteral bioavailability (Hennessy and Ali 1997). In addition, closantel is a weak acid and almost 99.5% of the total drug present in the intestinal lumen may be in the ionized form at the absorption site in the intestine. Altogether these observations may help explain the incomplete GI absorption of closantel after its oral administration in ruminants. Reduction of feed intake, which slows the digesta flow rate and extends the residence of the drug within the GI's lumen, increases the plasma and GI availabilities of closantel in sheep (Hennessy and Ali 1997).

Closantel is extensively bound (>99%) to plasma proteins, mainly albumin, and has a long terminal half-life of 14.3–14.5 days in sheep (Ali and Bogan 1987; Hennessy 1993). It binds specifically to ovine serum albumin at site I, the warfarin/phenylbutazone binding site of albumin and also to invertebrate haemocyanin and haemolymph (Rothwell et al. 2000). As a consequence of its high protein binding, the duration of therapeutic levels of closantel in plasma is prolonged. Thus, a single dose of closantel protects sheep against susceptible *H. contortus* reinfection for up 28 days (Hall et al. 1981). A small apparent volume of distribution (Vd) (<0.15 l/kg) indicates that the distribution of closantel to tissues (including the liver) is limited in ruminant species (Michiels et al. 1987; Swan et al. 1999). Overall, plasma albumin constitutes a reservoir from which this anthelmintic is directly available to haematophagous helminths, such as *F. hepatica* and *H. contortus*. Indeed, the blood is the primary source for the uptake of closantel via the digestive system of the parasites.

Dehalogenation in the liver renders two inactive monoiodo metabolites (3- and 5-monoiodoclosantel), although the metabolism of closantel is poor. Approximately 80–90% of the administered drug is eliminated by biliar/fecal excretion without metabolic changes. Only 10% of the administered drug was eliminated as monoiodo metabolites in sheep. Other minor routes of elimination of closantel are urine (less than 0.5% of the administered dose) and milk. In dairy cattle, approximately 1% of the administered dose was found to be excreted with the milk per day. Residual tissue concentrations are extremely low in sheep: 7 to 21 times lower than the corresponding plasma concentrations. In cattle, closantel concentrations in milk were 45-fold lower than those observed in plasma. In addition, tissue and milk residues decline parallel to plasma levels. Animals may be slaughtered for human consumption 28 days before closantel treatment. However, the use of this anthelmintic in milk production is forbidden.

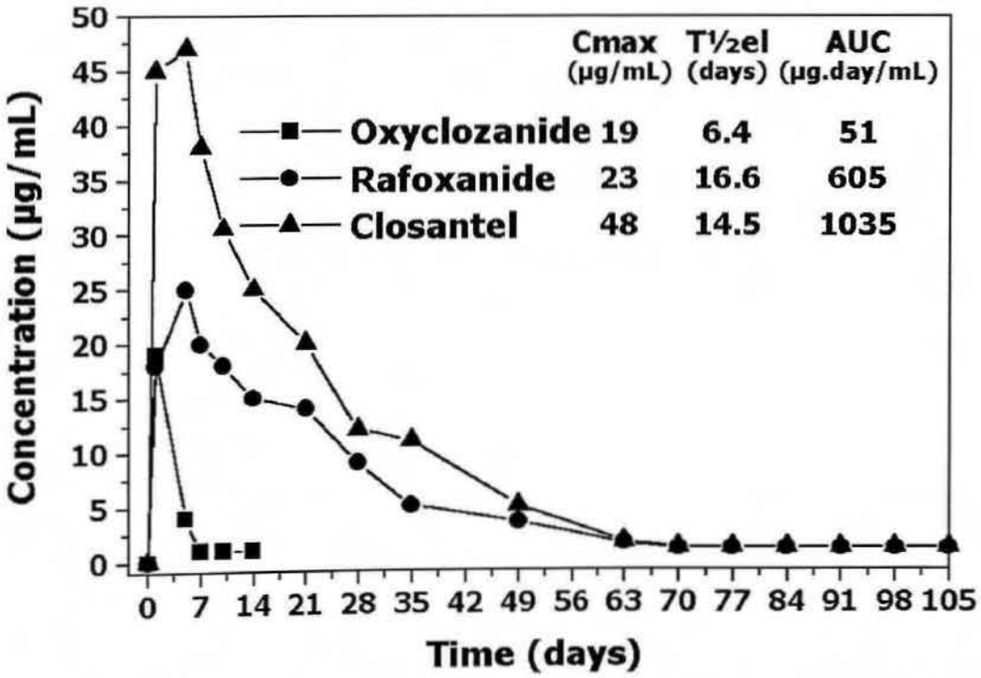
The acute toxicity resulting from single dosing of closantel in rats is characterized by hypotonia, ataxia, diarrhea and dyspnea. Clinical signs of acute toxicity in ruminants are anorexia, labored breathing, general weakness and decreased vision (or blindness) appearing approximately one week after dosing. At the lethal dose (LD_{50} in sheep = >40 mg/kg oral/IM; LD_{50} in cattle = >40 mg/kg oral and >20 mg/kg IM), anorexia, hypotonia, and quadriplegia preceded death. In short-term toxicological studies conducted in rats, male gonads and the liver were the target organs for toxicity. Some fatty deposition was observed in the liver tissue of males but not in females. Extensive reproductive studies in rams, ewes, and bulls indicate that closantel has no risk to reproductive parameters.

RAFOXANIDE. This anthelmintic is a halogenated salicylanilide. Its chemical formula is 3′-chloro-4′-(p-chlorophenoxy)-3,5-diiodosalicylanilide (Fig. 41.9). It is an off-white crystalline powder and is commercially formulated for use as a bolus or as a drenching suspension, which also may be used for IR administration. Rafoxanide was developed in 1969 and subsequently has been used extensively worldwide against fasciolosis and haemonchosis in sheep and cattle. Its principal use is as an adulticide for *F. hepatica* and *F. gigantica*. A single therapeutic dose (7.5 mg/kg) in sheep is nearly 100% effective for 12-week-old flukes of *F. hepatica*, 86–99% for 6-week-old flukes, and 50–98% for 4-week-old specimens of this parasite. At elevated doses (10–15 mg/kg), rafoxanide shows high activity against 4-week-old flukes (Boray 1986). The same dosages reach similar efficacies against *F. hepatica* in cattle. The reliable efficacy of this drug against 4- and 6-week-old flukes gives rafoxanide an advantage over strictly adulticidal drugs in the treatment of acute fasciolosis. In this case, the administration might be repeated after 3 weeks to eliminate maturing flukes that may have escaped the earlier treatment. In addition, this anthelmintic is also indicated for the treatment of haemonchosis, bunostomosis, and sheep

nasal bots (*Oestrus ovis*). The mode of action of rafoxanide is similar to that described for the chemically-related salicylanilide, closantel.

Following oral dosing, rafoxanide is absorbed from the small intestine into the bloodstream. Peak plasma levels occur between 24 and 48 hours. Its bioavailability, measured as AUC and Cmax, was 2.5–3-fold greater in 5–8-week-old suckling lambs compared to weaned lambs aged 21–22 weeks (Swan and Mulders 1993). Rafoxanide is extensively bound (>99%) to plasma proteins and has a long (16.6 days) terminal half-life. The blood is the primary source for the uptake of rafoxanide via the digestive system of the haematophagous helminths. Also, the efficacy of rafoxanide against immature liver flukes is due to its prolonged persistence in the plasma, with subsequent effects on maturing flukes as they reach the bile ducts. In addition, liver fluke infection did not alter the plasma disposition of rafoxanide in sheep (Benchaoui and McKellar 1993). The drug is not metabolized to any detectable degree by cattle or sheep liver. Following a single oral dose of 15 mg/kg in cattle, no residue of the compound is detectable in edible tissues at 28 days after treatment.

OXYCLOZANIDE. Oxyclozanide (3,3′,5,5′,6-pentachloro-2′-hydroxy salicylanilide) (Fig. 41.9) was introduced over 40 years ago for use against adult fluke infections in ruminants. It has been also used against tapeworms (*Moniezia* spp.) in sheep and cattle. This anthelmintic is marketed as an oral drench (aqueous suspension) containing oxyclozanide only or in combination with levamisole hydrochloride or oxfendazole. It is also formulated as a powder to be incorporated in the feed. The recommended dose rates are 10–15 mg/kg for cattle and 15 mg/kg for sheep and goats. The mechanism of action of oxyclozanide is similar to that described for closantel. Following its oral administration to sheep, the drug is extensively (greater than 99%) bound to plasma proteins, and the plasma concentration/time curve could be best described by a triexponential equation. Its terminal half-life (6.4 days) is shorter compared with closantel and rafoxanide (14.5 and 16.6 days, respectively) (Ali and Bogan 1987). The drug is excreted into the bile as a glucuronide metabolite. Figure 41.10 shows the comparative plasma profiles and some pharmacokinetic parameters for closantel, rafoxanide, and oxyclozanide following their respective oral administrations to sheep.



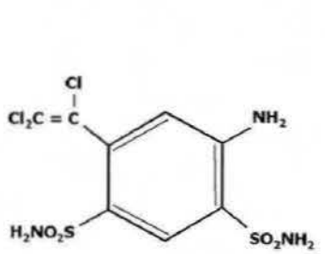


FIG. 41.10 Comparative plasma profiles of closantel (7.5 mg/kg), rafoxanide (7.5 mg/kg) and oxyclozanide (15 mg/kg) measured after their oral administration to sheep. The values of some kinetic parameters obtained for each compound are shown. Adapted from Ali and Bogan (1987). Cmax: peak plasma concentration; T1/2el: elimination half-life; AUC: area under the concentration-time curve.

BENZENESULFONAMIDES

CLORSULON. This anthelmintic is a benzenesulfonamide with the chemical formula 4-amino-6-trichloroethenyl-1,3-benzenedisulfonamide (Fig. 41.11). Clorsulon is highly effective against adult liver flukes in sheep and cattle. However, it is more effective in cattle than in sheep and goats. The recommended dose rate is 2 mg/kg body weight given by SC injection. Good efficacy against 8-week-old flukes is achieved following SC administration at 4–8 mg/kg. Oral administration at 3.75 mg/kg is effective for the treatment of adult liver flukes aged 14–16 weeks in both sheep and cattle. The recommended oral dose rate is 7 mg/kg, which is 100% effective for the treatment of 8-week-old flukes. The same dose rate is 99% effective for the treatment of adult specimens (14 weeks postinfection) in goats. The efficacy of clorsulon has been tested against infections with several other fluke species in ruminants. It was effective (>92%) against immature (8-week-old) *Fascioloides magna* in cattle and sheep at 21 mg/kg orally. Daily dosing at 7 mg/kg for 5 consecutive days has been 100% effective against adult and 92% effective against immature *Fasciola gigantica* in cattle. Clorsulon has poor efficacy against *Paramphistomum* spp.

The combination of clorsulon with ivermectin in an SC-injectable formulation was designed for simultaneous treatment of *F. hepatica* and nematode infections of cattle. The oral formulation of clorsulon also can be used concurrently with other anthelmintics (e.g., ivermectin, fenbendazole) with no reduction in efficacy of the individual products.

Chemically, clorsulon is similar to 1,3 diphosphoglycerate, an intermediary product of glycolysis. Consequently, this anthelmintic was shown to inhibit competitively the enzymes phosphoglycerate kinase and phosphoglyceromutase (Schulman and Valentino 1982). However, such disruption of glycolysis was observed in vitro with clorsulon concentrations many times greater than blood levels achieved in vivo. Thus, it is believed that clorsulon effects on the glycolitic pathway at therapeutic concentrations attained in vivo may not be relevant. Nevertheless, glycolysis is the main energy yielding pathway in the fluke and any disruption of this process would decrease glucose utilization and the production of metabolic end products (acetate and propionate) with a significant reduction in ATP levels within the parasite. Morphological changes in fluke specimens recovered from clorsulon-treated rats include severe necrosis of the gastrodermal cells and tegumental damage restricted to the cone and midbody regions of the fluke (Fairweather and Boray 1999; Meaney et al. 2003, 2004). It has also been shown that the gut was more severely affected than the tegument, which is consistent with the observation that oral ingestion is a main route of entry of clorsulon into the fluke (Meaney et al. 2005). Thus, the changes in the gut represent the direct consequence of drug action, while those observed in the tegument represent either the direct effect of transtegumental uptake of clorsulon from the bile or an indirect effect derived from gut disruption.

Clorsulon

FIG. 41.11 Chemical structure of clorsulon, a benzenesulfonamide flukicidal compound.

Clorsulon is marketed as an oral drench for sheep and cattle and as an injectable formulation (in combination with ivermectin) for SC administration to cattle. The recommended dosage of clorsulon for cattle and sheep is 7 mg/kg by oral drench. In commercial combination with ivermectin, clorsulon is administered SC to cattle at a rate of 2 mg/kg and ivermectin at 0.2 mg/kg. The oral drench is an aqueous suspension containing 8.5 mg/ml of clorsulon dissolved in propylen glycol/water (1/10). The pharmacokinetic behavior of clorsulon was studied in sheep and goats after administration of a single IV and after a single oral dose of 7 mg/kg (Sundlof and Whitlock 1992). These authors reported that the bioavailability of orally administered clorsulon was approximately 55% in goats and 60% in sheep. Peak plasma concentrations occurred at 14 hours and 15 hours after oral administration in goats and sheep, respectively. Besides, absorption from the GI tract effectively prolonged the elimination of clorsulon, increasing plasma elimination half-lives (about twofold) and MRTs (approximately three- to fourfold) in both sheep and goats. It has been shown that the rumen may substantially influence the absorption pattern and the resultant pharmacokinetic behavior and antiparasite activity of enterally delivered anthelmintic drugs. This fact has been thoroughly studied for benzimidazole anthelmintic

drugs. Similarly, when a suspension of clorsulon is deposited in the rumen, the adsorption of its particles to digesta solid content, the slow mixing and long digesta residence time, and the large rumen volume assist absorption by delaying the rate of passage of drug down the GI tract (Hennessy 1993). Thus, the rumen may act as a reservoir and prolong the duration of drug absorption and/or outflow down the GI tract. Indeed, the absorption pattern of clorsulon from the GI tract influences its pharmacokinetic behavior and, consequently, its elimination from plasma is delayed. In rats, clorsulon was shown to be bounded predominately to erythrocytes at doses below 4 mg/kg. In fact, the drug is bound to red blood cell carbonic anhydrase (Schulman et al. 1982). As explained above, this is the major route of entry of clorsulon into the fluke, and drug uptake by *F. hepatica* increases in direct proportion to the blood level.

Renal excretion of the parent drug is thought to be the main route of elimination of clorsulon, accounting for approximately 50% of the IV dose at 48 hours in both sheep and goats. On the other hand, up to 30% and 41% of the orally administered dose was recovered in urine in sheep and goats, respectively (Sundlof and Whitlock 1992). The elimination rate constant (kel) in goats was nearly twice as large as the value determined in sheep, and the AUC following IV administration in goats was only 63% of the value observed in sheep, indicating that goats are more effective in their ability to eliminate clorsulon than are sheep. These differences in drug disposition between sheep and goats may account for the reduced efficacy of clorsulon reported in goats.

Clorsulon is a safe drug with high therapeutic index. Acute toxicity of this antiparasitic has been assessed in mice, rats, sheep, and cattle. The LD_{50} in mice is an intraperitoneal (IP) dose of 761 mg/kg and more than 10,000 mg/kg orally. The latter dose causes no apparent toxicity in rats. Sheep infected with flukes have been dosed repeatedly with 5 mg/kg daily for 28 days or with single doses of 100 mg/kg with no apparent effect. Uninfected sheep tolerated 200 or 400 mg/kg without adverse reactions. A toxic dosage has not been identified in cattle. Oral doses of 7 mg (recommended) and 21 mg/kg on 3 consecutive days and single oral doses of 7, 70, and 175 mg/kg (i.e., up to 25 times the label dosage) have not affected weight gains, feed consumption, or clinical or histopathologic parameters adversely. In uninfected goats, experimental dosages up to 35 mg/kg every other day for three doses did not cause adverse reactions. Clorsulon is also considered safe for use in breeding and pregnant animals. Residue studies indicate a short half-life of clorsulon in tissues and milk. Milk taken from treated animals within 72 hours (six milkings) after treatment should not be used for human consumption, and beef animals should not be slaughtered within 8 days of treatment.

BENZIMIDAZOLES

The pharmacology of the broad-spectrum benzimidazole (BZD) anthelmintic compounds has been fully described in Chapter 40. Albendazole (used at 7.5 mg/kg in sheep and at 10 mg/kg in cattle) and the pro-BZD netobimin (20 mg/kg) are active against liver flukes older than 12 weeks. Fenbendazole is not effective against *F. hepatica*, but a single treatment at 5 mg/kg reduced *F. gigantica* infection in sheep by up to 95%. Luxabendazole is also an effective flukicidal BZD, which did not reach the market. However, the halogenated BZD thiol named *triclabendazole*, which does not have nematocidal activity, is the most widely used and potent flukicidal drug active against immature and mature stages of *F. hepatica*. Its pharmacological features are described below.

TRICLABENDAZOLE. Unlike other BZD compounds, the halogenated derivative triclabendazole (5-chloro-6(2–3-dichlorophenoxy)-2-methylthio-1H-benzimidazole) (TCBZ) (Fig. 41.12) holds an excellent efficacy against the adult and juvenile stages of *F. hepatica* (down to 1-week-old flukes), which is unlike other available flukicidal drugs (Boray et al. 1983). The high activity of TCBZ against immature flukes is significant because they represent the migratory stage of the parasite, which may produce serious tissue damage in the host. However, TCBZ activity appears to be restricted to *F. hepatica*, *F. gigantica*, *Fascioloides magna* and the lung fluke, *Paragonimus* spp. (Calpoviña et al. 1988), because the drug does not show clinical efficacy against nematodes, cestodes, and other trematode (*Dicrocoelium dendriticum*, *Paramphistomun* spp., and *Schistosoma mansoni*) parasites.

The precise mode of action of TCBZ has not yet been established. BZD nematodicidal activity is based on its binding to parasite β-tubulin (Lacey 1988), which inhibits polymerization into microtubules. Thus, all the functions ascribed to microtubules at the cellular level are altered (cell division, maintenance of cell shape, cell motility, cellular secretion, nutrient absorption, and intracellular

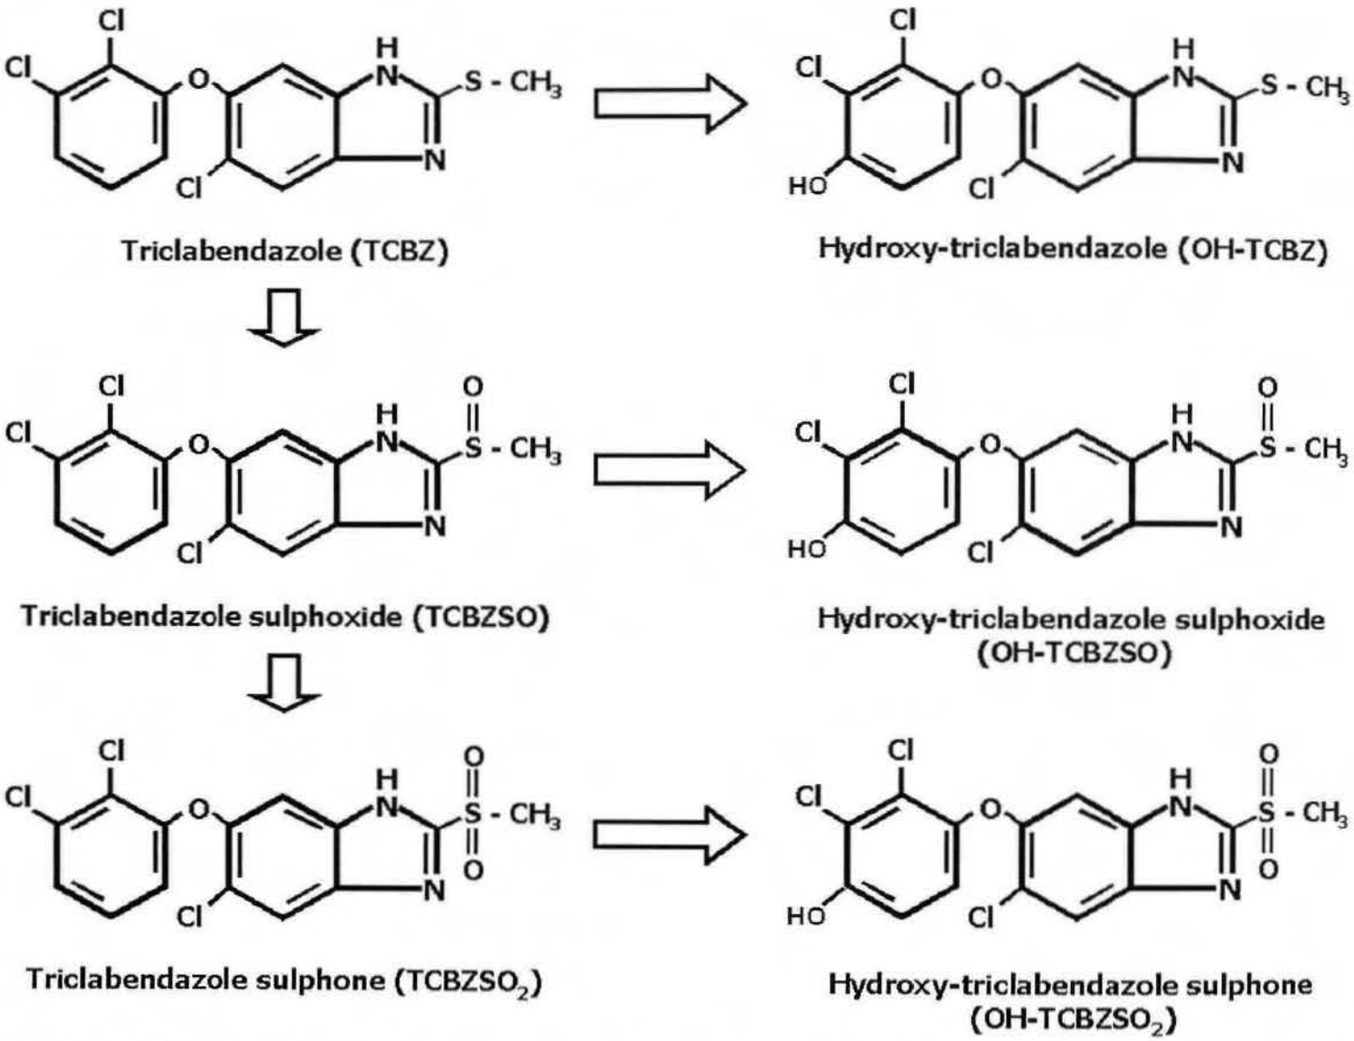

FIG. 41.12 Triclabendazole (TCBZ) and its main metabolites: chemical structures and metabolic pathways. See the text for further explanation of TCBZ metabolism.

transport). BZD methylcarbamate molecules such as albendazole or fenbendazole act upon nematode microtubules at the tubulin colchicine binding site (Lacey 1988). It is likely that a different site of action is involved in the flukicidal activity of TCBZ, which could also explain its lack of efficacy against other helminth parasites. However, there is morphological data that support the possible binding of TCBZ to the fluke's tubulin. The TCBZ sulphoxide metabolite (TCBZSO) blocks the transport of secretory bodies from the cell body to the tegumental surface, culminating in the total loss of the tegument (Stitt and Fairweather 1994). TCBZSO also inhibits the mitotic division of spermatogenic cells and the stem vitelline cells, all changes related to microtubule inhibition. It is likely that TCBZ/metabolites may target an alternative binding site on the tubulin molecule (Fairweather 2005).

The pharmacokinetics of TCBZ has been characterized in sheep (Hennessy et al. 1987), goats (Kinabo and Bogan 1988) and cattle (Sanyal 1995). TCBZ parent drug is not detectable in plasma after its oral administration to sheep and cattle, TCBZSO and TCBZ-sulphone ($TCBZSO_2$) being the metabolites recovered from the bloodstream of treated animals (see Fig. 41.13). These metabolites reach a peak plasma concentration after 18 and 36 hours posttreatment, respectively, in sheep. Furthermore, extremely low concentrations of TCBZ were

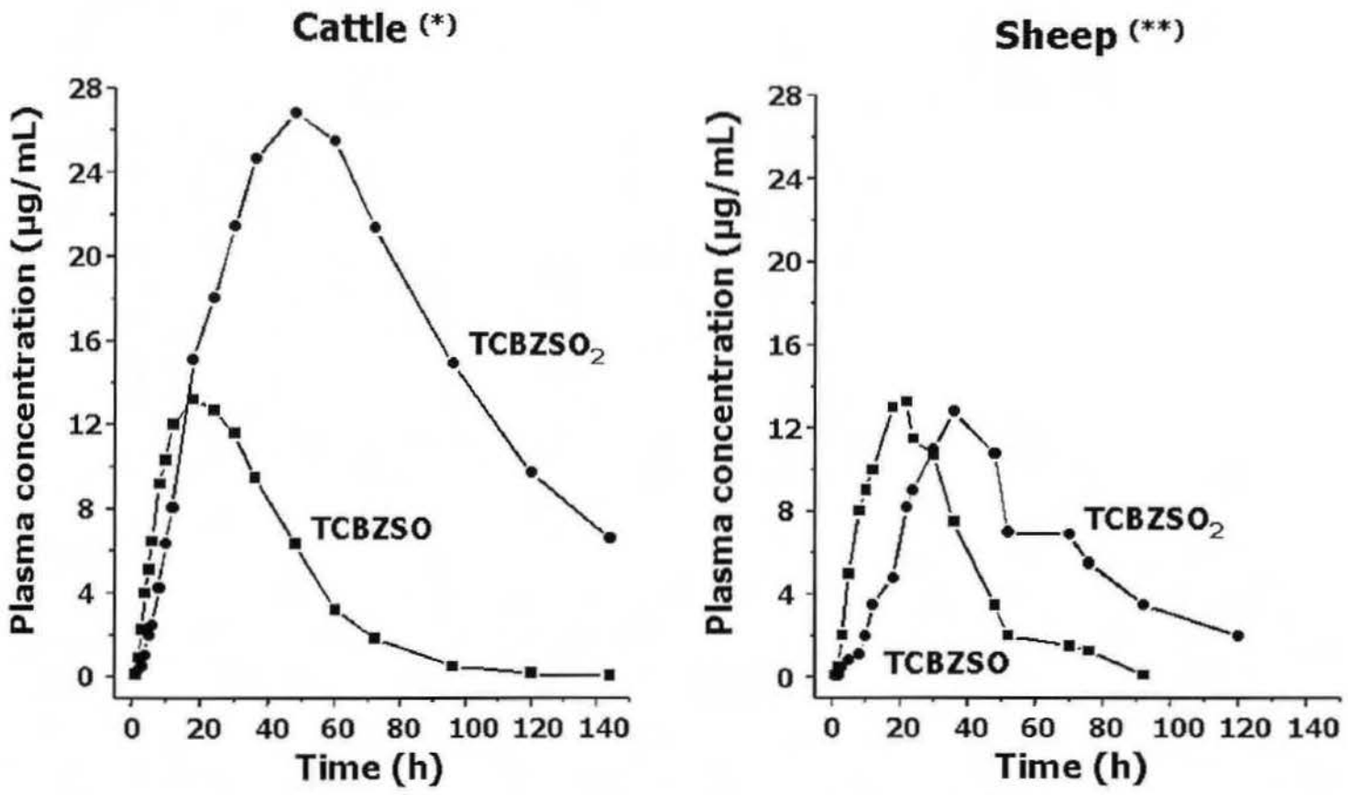

FIG. 41.13 Plasma concentration profiles of triclabendazole sulphoxide (TCBZSO) and sulphone ($TCBZSO_2$) obtained after triclabendazole administration to cattle (orally, 12 mg/kg) and sheep (intraruminal, 10 mg/kg). (*) Lanusse et al. (unpublished observations). (**) Adapted from Hennessy et al (1987).

recovered in bile; TCBZSO, $TCBZSO_2$, and the hydroxy-TCBZ derivatives were the major biliary metabolites found in sheep (Hennessy et al. 1987) (see Fig. 41.12). The metabolic fate of TCBZ and its metabolites was characterized in sheep (Virkel et al. 2006). Both FMO and cytochrome P450 enzymatic systems were found to be involved in the sulphoxidation and sulphonation of TCBZ in sheep liver. In addition, sheep ruminal microflora was able to reduce TCBZ sulphoxide derivatives, TCBZSO and hydroxy-TCBZSO, into TCBZ and hydroxy-TCBZ, respectively.

As it happens for other nematodicidal BZD sulphoxides, the sulphoxide metabolite of TCBZ is believed to have flukicidal activity. In fact, the tegument of *F. hepatica* is highly susceptible to TCBZSO, since the compound causes severe surface damage after relatively short time exposure (Stitt and Fairweather 1994). TCBZ metabolites bind strongly (>99%) to plasma proteins, specifically albumin. The long TCBZ metabolites' persistence in the bloodstream (over 120 hours posttreatment) and their high plasma concentrations compared to other BZD compounds correlate with their high plasma protein binding. These may contribute to its high flukicidal activity based on a high and prolonged drug exposure of the blood-feeding adult flukes. On the other hand, the metabolic conversion of TCBZSO into TCBZ in the rumen may give rise to a source of the main active metabolite in the liver (Virkel et al. 2006). Thus, the sulphoreduction of hydroxy-TCBZSO into hydroxy-TCBZ may be relevant as well, although the mode of action and/or the anthelmintic activity (if any) of these metabolites have not been established. Approximately 45% of the administered dose is eliminated by bile and only 6.5% is excreted in urine, mainly as TCBZSO and $TCBZSO_2$ (Hennessy et al. 1987).

Flukicidal drugs can reach target sites within *F. hepatica* either by oral ingestion of blood or by transtegumental diffusion. The large absorptive surface area of the fluke's

tegument may have a major role in drug diffusion from the surrounding medium. Studies on ex vivo drug diffusion into TCBZ-susceptible *F. hepatica*, demonstrated that TCBZ, TCBZSO, and $TCBZSO_2$ have the capability to penetrate the fluke's tegument (Alvarez et al. 2004; Mottier et al. 2004). Unlike the uptake pattern previously observed for albendazole (Alvarez et al. 2001), the parent TCBZ and its sulphoxide and sulphone metabolites showed a similar ability to penetrate into the trematode parasite. However, the diffusion of the hydroxy-derivatives into the fluke was lower than that observed for TCBZ, TCBZSO, and $TCBZSO_2$ (see Fig. 41.14). These findings agree with the high correlation observed between lipophilicity and drug concentrations measured within the parasite. Those studies demonstrated that the higher the lipophilicity, the greater the ability of the BZD molecules to cross through the helminth external surfaces. These studies have also shown that the composition and physicochemical characteristics of the incubation medium drastically affect the diffusion of BZD anthelmintics into *F. hepatica*.

Since TCBZ is the most widely used flukicide due to its excellent activity against both the mature and immature stages of *F. hepatica*, the selection of TCBZ-resistant populations is now an emerging problem in several areas of the

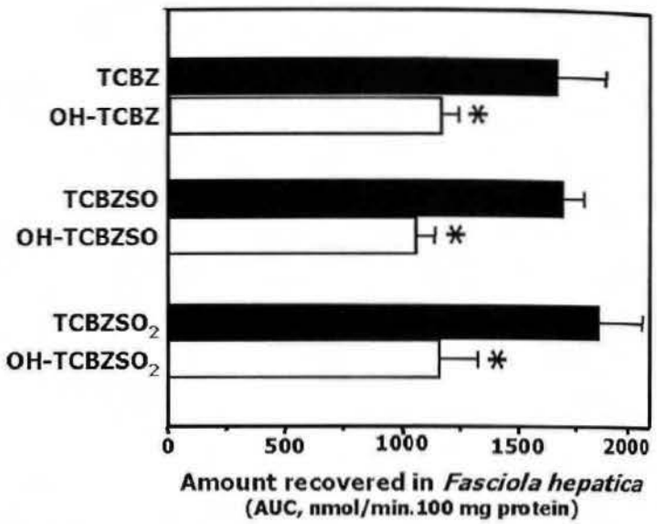

FIG. 41.14 Comparative ex vivo diffusion of triclabendazole (TCBZ), TCBZ-sulphoxide (TCBZSO), TCBZ-sulphone ($TCBZSO_2$) and its hydroxylated metabolites into adult specimens of *Fasciola hepatica*. TCBZ, TCBZSO and $TCBZSO_2$ concentrations measured within the parasite are significantly higher (*$P<0.05$) than those of their hydroxylated metabolites. See the text for further explanations. Adapted from Mottier et al. (2004).

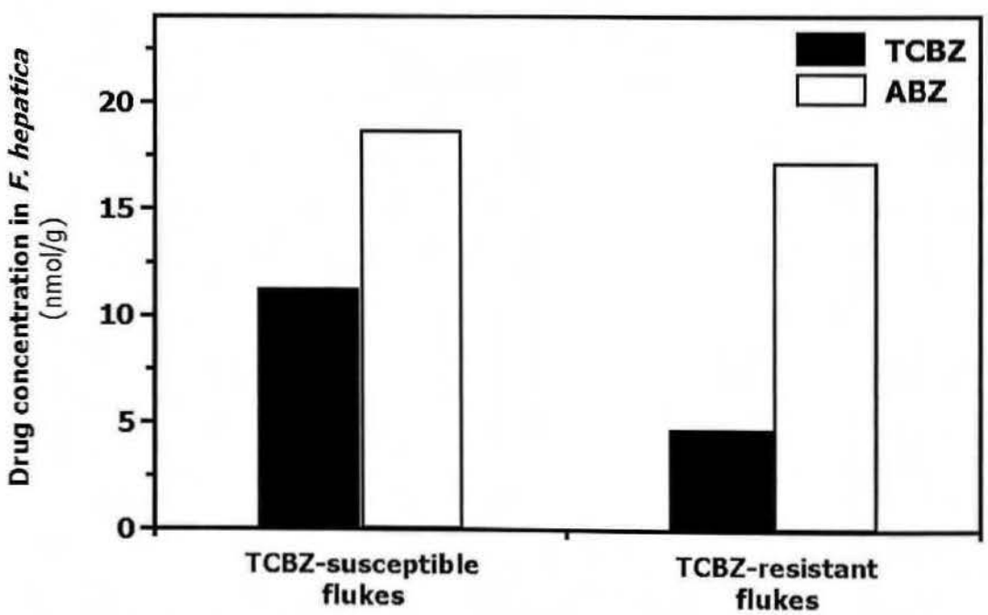

FIG. 41.15 Comparative diffusion of triclabendazole (TCBZ) and albendazole (ABZ) into adult specimens of TCBZ-susceptible and -resistant *F. hepatica*. See the text for further explanation. Adapted from Mottier et al. (2006).

world (Fairweather 2005). BZD resistance in *H. contortus* has been associated with the loss of high-affinity binding (Lubega and Prichard 1991) and an alteration of the β-tubulin isoform pattern. Although the flukicidal activity of TCBZ remains to be fully understood, there is data to support a microtubule-based action of this compound (Stitt and Fairweather 1994). However, it has been shown that the TCBZ-resistant phenotype in *F. hepatica* is not associated with residue changes in the primary amino acid sequence in β-tubulin (Robinson et al. 2002). This suggests that there may be an alternative mechanism of TCBZ resistance. In fact, the amount of TCBZ recovered from resistant flukes was significantly lower (~50%) than that measured in susceptible parasites. Increased TCBZ oxidative metabolism by the fluke and enhanced drug efflux mediated by ATP-dependent transmembrane transporters may account for the reduced drug accumulation observed in resistant flukes (Alvarez et al. 2005; Mottier et al. 2006), and have been proposed as potential mechanisms of TCBZ resistance in *F. hepatica*. Conversely, albendazole accumulation was similar in both susceptible and resistant flukes, which correlates with the observed high efficacy of this drug against TCBZ-resistant flukes in the field (Coles and Stafford 2001) (see Fig. 41.15)

TCBZ is administered orally to cattle (12 mg/kg), sheep (10 mg/kg) and goats (15 mg/kg). It is indicated for the treatment and control of all stages of TCBZ-susceptible *F. hepatica* from 2-day-old early immature to mature fluke and so is effective against both acute and chronic fasciolosis. Combined formulations containing TCBZ and different antinematodal drugs (abamectin, levamisole) are available in different countries. TCBZ is not indicated for use in lactating animals producing milk for human consumption, or in pregnant animals that are intended to produce milk for human consumption within 2 months of expected parturition. TCBZ can be administered at any stage of pregnancy. A withdrawal time of 56 days (meat) has been established for TCBZ in sheep and cattle.

PHENOXYALKANES

DIAMPHENETHIDE. This flukicidal molecule is a phenoxyalkane (N,N'-[oxybis(2,1-ethanediyloxy-4,1-phenylene)]bisacetamide) (Fig. 41.16). Diamphenethide is exceptionally effective against early immature flukes from 1 day to 6 weeks of age. Consequently, it is used for treatment of acute fasciolosis resulting from immature forms of *F. hepatica* migrating through the liver parenchyma of sheep. A dosage of 100 mg/kg is almost 100% effective against flukes from 1 to 63 days of age. However, its activity progressively decreases as the flukes develop to maturity. This is in direct contrast to other currently used fasciolicides, which tend to be less active against younger flukes. This fact could be a drawback for the clinical use of diamphenethide but the drug may be useful in prophylactic programs against liver fluke disease in sheep. A chemoprophylactic effect has been achieved as a result of strategic treatments with diamphenethide in both sheep and cattle (Enzie et al. 1980). At a dosage of 10 mg/kg of body weight (10% of the recommended dose), the drug was 87% effective in preventing establishment of *F. hepatica* infections in sheep that were given the drug daily for 14 days, and was 96% effective in sheep that were given the drug for 21 days (Enzie et al. 1980). The use of a controlled-release device of diamphenethide for the prophylaxis of fasciolosis in ruminants has also been proposed (Rew and Knight 1980).

The efficacy of diamphenethide depends upon deacetylation of the drug by liver enzymes (deacetylases) to an amine metabolite. Diamphenethide is not active in vitro, but its deacetylated (amine) metabolite, (DAMD), has flukicidal activity against liver flukes. The exact mechanism of action of DAMD remains not well established. Although it was shown that DAMD caused severe morphological damage to *F. hepatica* in vitro, energy metabolism is not the prime target for this metabolite (Fairweather and Boray 1999). DAMD-induced disruption of the tegument and osmoregulatory system of the fluke was thoroughly described using transmission electron microscopy (Anderson and Fairweather 1995). Morphological changes include swelling of the in-foldings of the basal plasma membrane leading to flooding of the syncytium and eventual sloughing of the tegument. Further information on the mode of action of DAMD can be obtained from Fairweather and Boray (1999).

Diamphenethide is administered as an oral suspension at 100 mg/kg in sheep and goats. Diamphenethide is absorbed into the blood after oral treatment and readily metabolized in the liver. High concentrations of two active deacetylated metabolites, monoamino- (MAMD) and diamino-diamphenethide (DAMD), are produced in liver parenchyma, where immature flukes are found until at least 7 weeks after infection. Metabolites reach high concentrations in the liver parenchyma but are thought to be

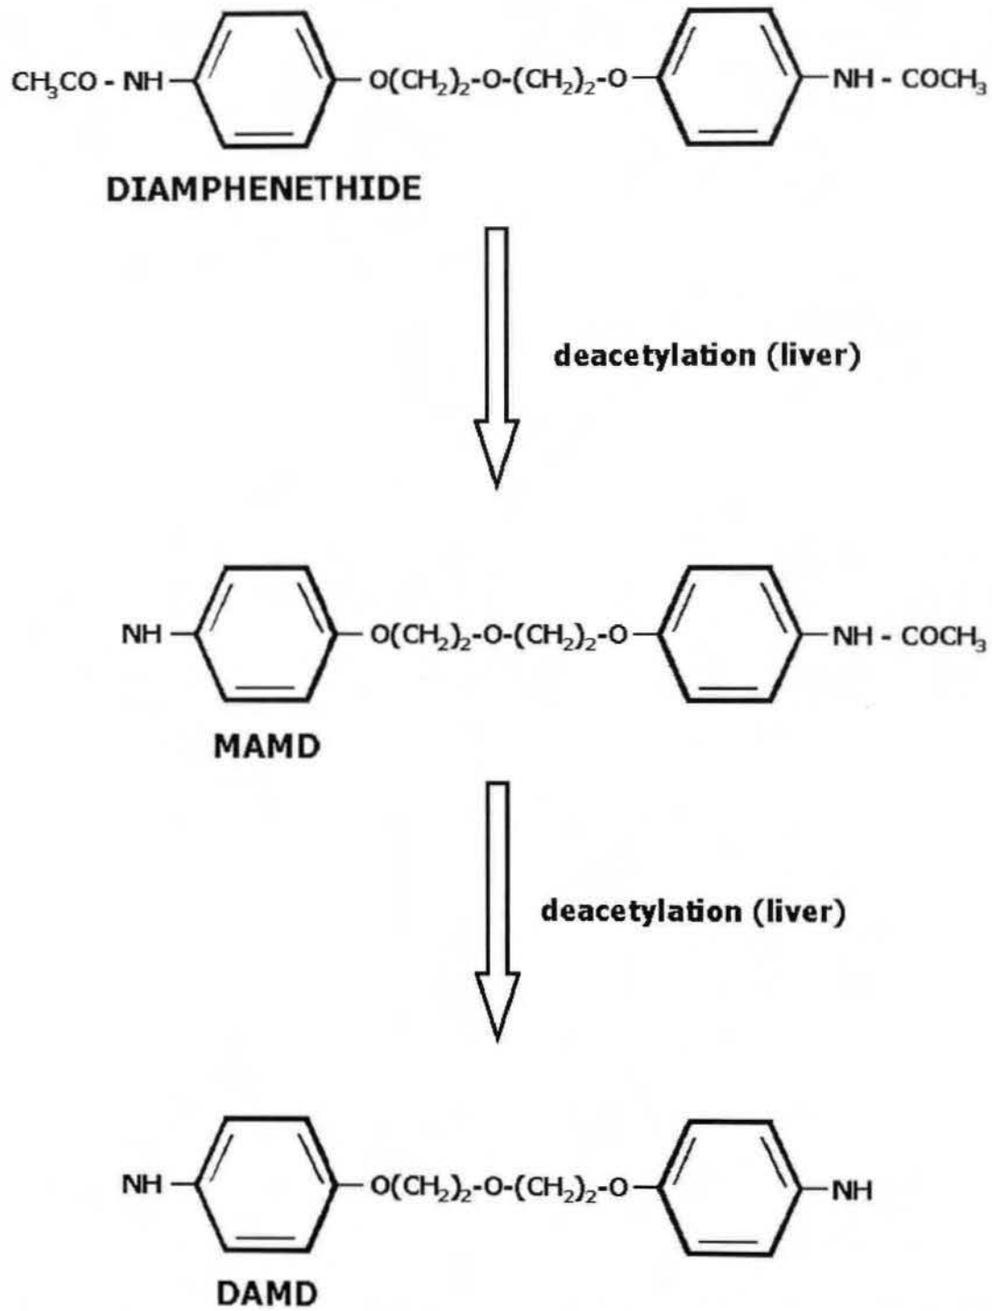

FIG. 41.16 Diamphenethide: chemical structure and metabolic fate. Liver deacetylation of the parent drug converts it into two active diamino-metabolites: monoamino-diamphenethide (MAMD) and diamino-diamphenethide (DAMD).

rapidly biotransformed and eliminated into the bile. Only small amounts of MAMD and DAMD may escape into the bloodstream but become diluted. That is why the quantity of active metabolites reaching mature blood-sucking flukes by both oral ingestion or tegumental diffusion is small. Therefore, efficacy against adult stages located in the bile ducts is reduced.

Safety of diamphenethide for the host can be explained

on the basis of destruction of the metabolites by the liver and dilution in blood so that only small quantities reach other tissues. Its greatest concentrations are measured in the liver and gallbladder content (at 3 days posttreatment). It should be noted that adult flukes reside in intimate association with the biliary system. At 7 days after dosing, concentrations of diamphenethide in these sites are reduced approximately tenfold, to a range of only 0.1–0.5 ppm, while concentrations in the musculature are approximately 0.02 ppm. In the United Kingdom, animals intended for human consumption are permitted to be slaughtered 7 days after treatment. The usual oral dose (100 mg/kg) in sheep is apparently safe. A single oral dose four times the therapeutic dosage (400 mg/kg) produces no toxic signs. At higher dosages, toxic effects include temporary impairment of vision and loss of wool. Pastured sheep are less susceptible to toxic effects than housed sheep. There appear to be no significant contraindications for use of diamphenethide. Pregnant ewes dosed with 200 mg/kg once weekly on two, three, or four consecutive occasions during the 21-week gestation period exhibited no adverse effects on fertility or teratogenic effects in their offspring.

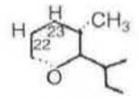
GENERAL PHARMACOLOGY: AVERMECTINS AND MILBEMYCINS

The integration of available information on the host-parasite–environment relationship with a more complete understanding of the pharmacological properties of existing antiparasitic drugs should assist with more efficient parasite control in domestic animals. The time of parasite exposure to active drug concentrations determines the efficacy and/or persistence of activity for most of the anthelmintic drugs used in veterinary medicine. The characterization of drug concentration profiles in tissues of parasite location and within target parasites provides a basis for understanding the differences in therapeutic and preventive efficacies observed for the different anthelmintic chemical families.



The *avermectins* and *milbemycins* are closely related 16-member macrocyclic lactones (ML), produced through fermentation by soil dwelling actinomycetes (*Streptomyces*). It was the unique combination killing of endo- and ectoparasites that gave rise to the embracing name *endectocide* by which the MLs are recognized (Shoop et al. 1995a). Information on the antiparasitic properties of the different ML compounds in all animal species has been thoroughly reviewed elsewhere (Campbell 1985; Shoop et al. 1995a; McKellar and Benchaoui 1996). The book recently edited by Vercruysse and Rew (2002), specifically devoted to the MLs, is recommended for readers interested in any further detailed issue within the topic. Enormous progress on the comprehension of the relationship among disposition kinetics, tissue distribution, and the patterns of antiparasitic persistence for the ML molecules has been

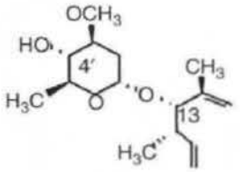

FIG. 42.1 Chemical structures of the main avermectin compounds used in veterinary medicine. The main chemical differences between abamectin (the natural fermentation product) and other avermectin-type molecules are shown. The commercially available preparations of abamectin and ivermectin contain at least 80% of the avermectin B_{1a} (the a-component has a secondary butyl side chain at the 25-position) and no more than 20% of avermectin B_{1b} (the b-component has an isopropyl substituent at the 25-position). Eprinomectin contains at least 90% of the B_{1a} and no more than 10% of the B_{1b} component.

achieved, particularly in ruminant species. The purpose of this chapter is to provide an updated and integrated overview of the main basic pharmacological features of the ML compounds, which account for their outstanding long-persistence broad-spectrum antiparasitic activity. The MLs are now considered the most widely used broad-spectrum antipararasitic drugs in veterinary medicine.

Avermectins are produced as a mixture of different components from fermentation of *Streptomyces avermitilis*. These natural products are denoted as A (those containing a methoxy group at the 5-position) and B (with a hydroxy group at the 5-position). The highest anthelmintic potency is held by the B1 homologs. The avermectin's family includes a series of natural and semisynthetic molecules, such as *abamectin, ivermectin, doramectin, eprinomectin,* and *selamectin*. Abamectin is the naturally occurring avermectin approved for animal use and the starting material for the production of ivermectin. In fact, ivermectin, the first marketed endectocide molecule, is a semisynthetic derivative of the avermectin family. Ivermectin is the generic name given to a mixture of two chemically modified avermectins containing at least 80% of 22–23-

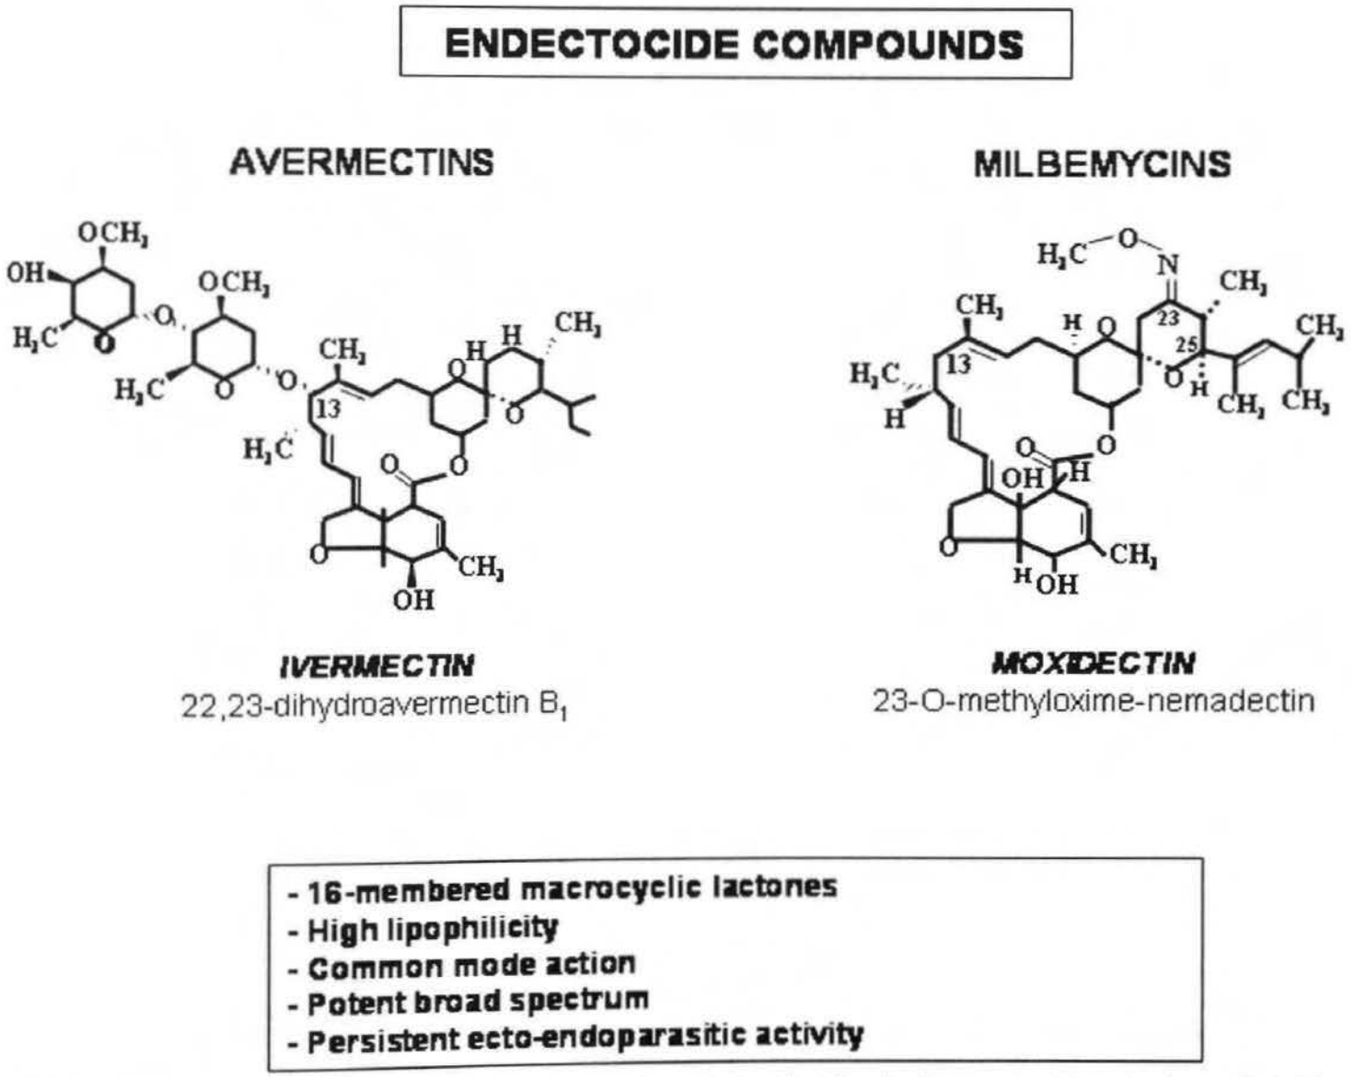

FIG. 42.2 Comparison between the avermectin (ivermectin) and milbemycin (moxidectin) molecular structures. The main pharmacological features shared by compounds in both families are listed. The main chemical differences between ivermectin and moxidectin are at the 13-, 23-, and 25-positions (see text for further explanation).

dihydroavermectin B1a and less than 20% of 22–23-dihydroavermectin B1b (Fisher and Mrozik 1989). Doramectin was obtained by mutational biosynthesis in which the precursor (cyclohexanecarboxylic acid) was fed to a mutant strain of *Streptomyces avermitilis* (Goudie et al. 1993). Eprinomectin is a semisynthetic avermectin compound, developed for topical use in cattle (Shoop et al. 1996). Selamectin is a semisynthetic monosaccaride oxime derivative of doramectin more recently introduced into the market for parasite control in dogs and cats (Bishop et al. 2000). The main chemical differences among the avermectin-type compounds are shown in Figure 42.1. It has been shown that minor chemical changes may have a profound impact on the activity of the avermectin analogs. For instance, substitution of the C-5 hydroxy with an oxo- substituent on ivermectin or doramectin monosaccharides can drastically reduce activity against *Haemonchus contortus* larvae.

Nemadectin, moxidectin, and *milbemycin oxime* belong to the *milbemycin* family. Milbemycin oxime consists of two oxime derivatives (A_4 and A_3 components) of the 5-didehydromilbemycin in a 80:20 ratio. Moxidectin is a milbemycin compound produced by a combination of fermentation and chemical synthesis. Moxidectin (23-O-methyloxime-nemadectin) is obtained by chemical modification of nemadectin, the natural compound produced when *Streptomyces cyaneogriseus* is grown under controlled culture conditions (Takiguchi et al. 1980). The molecular structures of the two endectocide families are superimposable (Shoop et al. 1995a); however, milbemycins do not have the C_{13} disaccharide substituent in the macrolide ring (Fig. 42.2). Additionally, moxidectin differs from ivermectin at the 23-position where it possesses a metoxime moiety. Moxidectin also has a differential substituted olefinic side chain at the 25-position. In spite of these chemical differences, both families share some structural and physicochemical properties and broad-spectrum antiparasitic activity against nematodes and arthropods at extremely low dosage rates (Fig. 42.2).

Various compounds from both families are used in livestock, companion animals, wildlife species, and humans (ivermectin). Ivermectin, doramectin, and moxidectin, currently marketed as injectable, pour-on (cattle), and oral (sheep, goats) formulations, are the most commonly used MLs worldwide to control endo- and ectoparasites in livestock. Exceptional potency, high lipophilicity, and the prolonged persistence of their potent broad-spectrum activity are distinctive features among antiparasitic drugs.

MECHANISM OF ACTION: ECTO-ENDOPARASITICIDAL ACTIVITY

The broad-spectrum ecto-endoparasitic activity of the MLs from both families includes selective toxic effects on insects, acarines, and nematodes. However, they do not possess efficacy against cestode and trematode parasites. The MLs induce reduction in motor activity and paralysis in both arthropods and nematodes. The paralytic effects are mediated through GABA and/or glutamate-gated chloride channels (GluCl), collectively known as *ligand-gated chloride channels*. MLs may act on both receptors, and a putative GABA-receptor subunit has been localized along the ventral nerve cord and several neurons in the head of *H. contortus* (Blackhall et al. 2003). However, considerably higher ML concentrations are required for the GABA-mediated effects than for those on the GluCl channels. In fact, a high affinity binding to GluCl channels, producing a slow and irreversible increase in chloride membrane conductance (Forrester et al. 2003), hyperpolarization, and flaccid paralysis of the invertebrate somatic muscles, is now proposed as a main mode of action (Martin et al. 2002; Geary 2005). The ML endectocides cause paralysis and death of both arthropod and nematode parasites due to their paralytic effects on the pharyngeal pump (Geary et al. 1999), which affects nutrient ingestion, and on the parasite somatic musculature limiting its ability to remain at the site of predilection in the host. In addition, inhibitory effects of the MLs on the female reproductive system may explain the observed reductions in parasite egg production (Fellowes et al. 2000). In *H. contortus*, the pharynx appears to be the most sensitive of the affected muscles (Sheriff et al. 2005). A schematic representation of the proposed main mode of action for the ML endectocides is shown in Figure 42.3.

The GluCl channels are members of the ligand-gated ion channel superfamily uniquely found in invertebrates. Some channel subunits have now been cloned from different nematode parasites, including the free-living nematodes *Caenorhabditis elegans*, *H. contortus*, and *Cooperia* spp. (Forrester et al. 2003; Njue and Prichard 2004), which has facilitated enormous progress on the understanding of the mode of action and mechanisms of resistance for the MLs. A good correlation between the presence of GluCl on neurons and muscle cells and the electrophysiological effects induced by MLs has been observed (Martin et al. 2002). Although several GluCl channel subunits have been identified, the sensitivity to these drugs

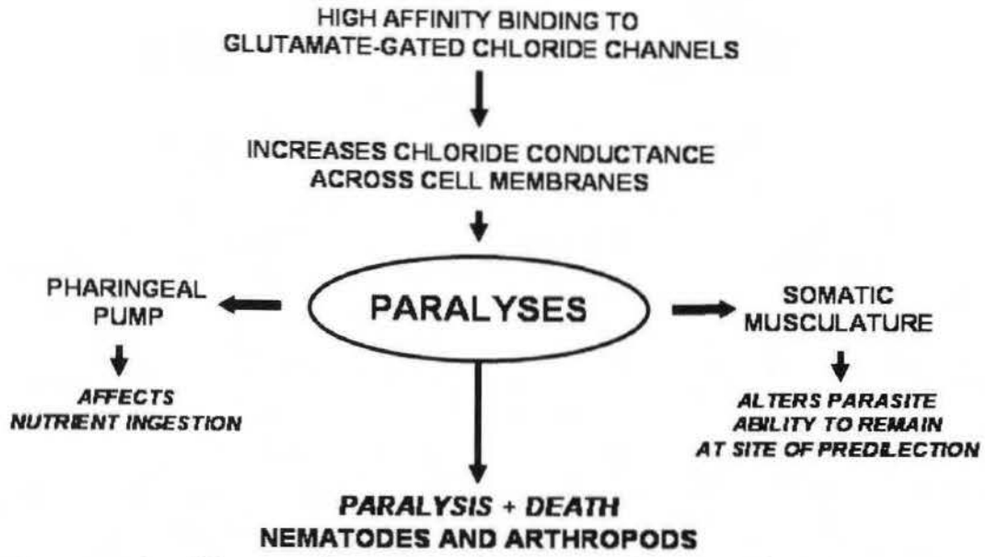

FIG. 42.3 Schematic representation of the proposed mode of action for the macrocyclic lactone endectocides.

seems to be associated with the alfa-subunit of the receptor (Arena et al. 1992; Cully et al. 1994; Njue and Prichard 2004), which is encoded by different genes indicating that nematode resistance to these compounds may be polygenic.

The different ML compounds exhibit a similar, but not identical, spectrum of activity against arthropod and nematode parasites and also show differences in the persistence of their antiparasitic activity. Even though compounds in both the avermectin and milbemycin families appear to have the same mode of action, there is now evidence of some subtle pharmacodynamic differences between families, which seem to account for a higher pharmacological potency of moxidectin compared to ivermectin, particularly evident against resistant nematode parasites. These pharmacodynamic differences have been observed at the GluCl channel where moxidectin is 2.5-fold more potent than ivermectin in terms of the required EC50 to activate this receptor expressed in *Xenopus* oocytes (reviewed by Prichard et al. 2003).

Additionally, the drug transport P-glycoprotein (P-GP) acts as an efflux pump for ML compounds lowering the local drug concentration achieved at the GluCl receptor site of action. *H. contortus* contains at least four P-GP genes (Sangster and Gill 1999) and data supporting their association with resistance to ivermectin are now available. Recently reported data indicate that a number of different P-GPs are overexpressed in resistant *H. contortus* and that ivermectin is a significantly better ligand for P-GP transport compared to moxidectin (Prichard and Roulet 2005). This enhanced ivermectin efflux may account for lower active concentrations being achieved at the receptor site in comparison to moxidectin. Overall, novel scientific data demonstrate minor pharmacodynamic differences between ivermectin and moxidectin, which could explain some differences in spectrum, potency, and the advantageous pattern of moxidectin efficacy against ivermectin-resistant nematodes of sheep, goats, and cattle.

PHARMACOKINETICS

EXCHANGE BETWEEN BLOODSTREAM AND TARGET TISSUES. The clinical efficacy of the MLs is closely related to their pharmacokinetic behavior, being the time of parasite exposure to active drug concentrations, relevant to obtain optimal and persistent antiparasitic activity. Their antiparasitic spectrum and efficacy patterns are similar; however, each compound has its own dosage limiting species. Differences in physicochemical properties among them may account for differences in formulation flexibility, kinetic behavior, and the potency/persistence of their endectocide activity. Thus, even slight modifications to the disposition kinetics or to the pattern of plasma/

tissue exchange may notably affect the persistence of their antiparasitic effect.

An enormous effort has been devoted to characterize the kinetics of the different MLs in different species. The work on the comparative plasma (Lanusse et al. 1997; Toutain et al. 1997) and target tissues (Lifschitz et al. 1999a, 2000; Sallovitz et al. 2003) disposition kinetics of ivermectin, doramectin, and moxidectin in cattle and disposition of doramectin (Hennessy et al. 2000; Carceles et al. 2001) and moxidectin (Alvinerie et al. 1998a) in sheep and goats, including evidences on their metabolic stability in the digestive tract (Lifschitz et al. 2005b) and involvement of lymphatic transport on intestinal absorption (Lespine et al. 2006) have contributed greatly to the understanding of the overall ML pharmacokinetic properties. Additionally, the characterization of the plasma/milk profiles of eprinomectin in cattle and goats (Shoop et al. 1996; Alvinerie et al. 1999b) and the studies on the comparative milk excretion patterns of different MLs in dairy sheep and their impact on drug residue profiles in milk-derived products (Imperiale et al. 2004a) have further contributed to the knowledge on ML kinetic behavior. The main pharmacokinetic features accounting for the persistent broad-spectrum antiparasitic activity of endectocides in ruminants are summarized in Figure 42.4.

Plasma concentration profiles may help predict the persistence of antiparasitic activity. However, the measurement of drug concentration profiles at the site of parasite location permits a more direct interpretation and provides a basis for understanding the differences in therapeutic and preventive efficacies observed for MLs. The characterization of drug concentrations at the sites of parasite infection for moxidectin, ivermectin, and doramectin in cattle, and the characterization of the kinetic disposition of doramectin in fluid and particulate digesta throughout the gastrointestinal tract in sheep, represent a considerable contribution to understanding the comparative persistence of activity of these compounds in ruminants. The highly lipophilic MLs are extensively distributed from the bloodstream to different tissues. Their extensive tissue distribution agrees with the large availability of these drugs in different parasite location tissues such as the gastrointestinal mucosal tissues, lungs, and skin in cattle (see Fig. 42.5), where concentrations markedly greater than those observed in plasma were measured during 50–60 days posttreatment. A strong correlation between plasma and

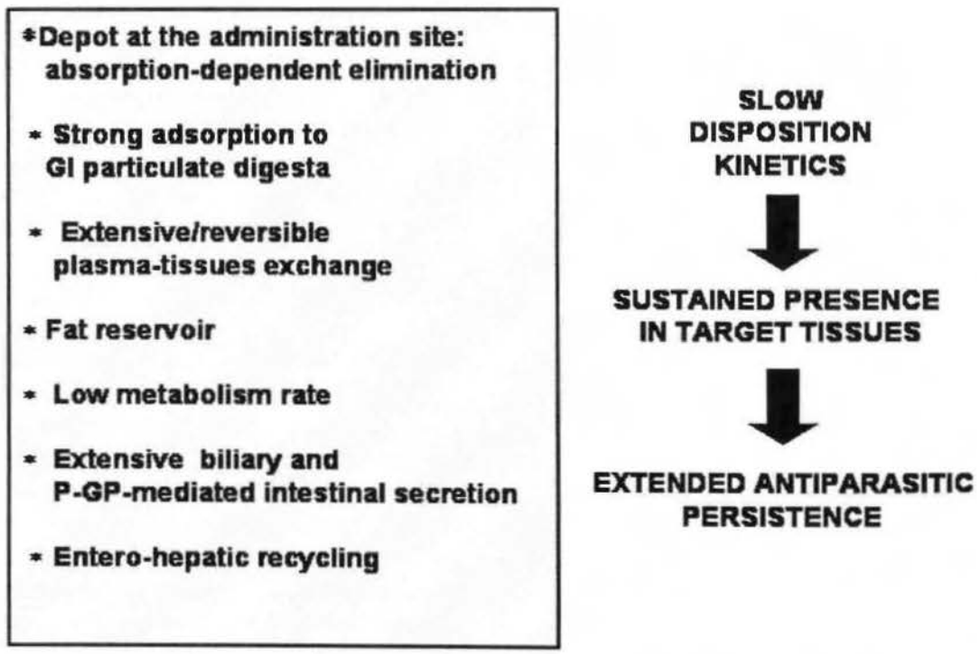

FIG. 42.4 Summary of the main pharmacokinetic features accounting for the extended broad-spectrum antiparasitic persistence of the macrocyclic lactone compounds in ruminants. GI: gastrointestinal tract; P-GP: P-glycoprotein. Adapted from Lifschitz et al. 2002a.

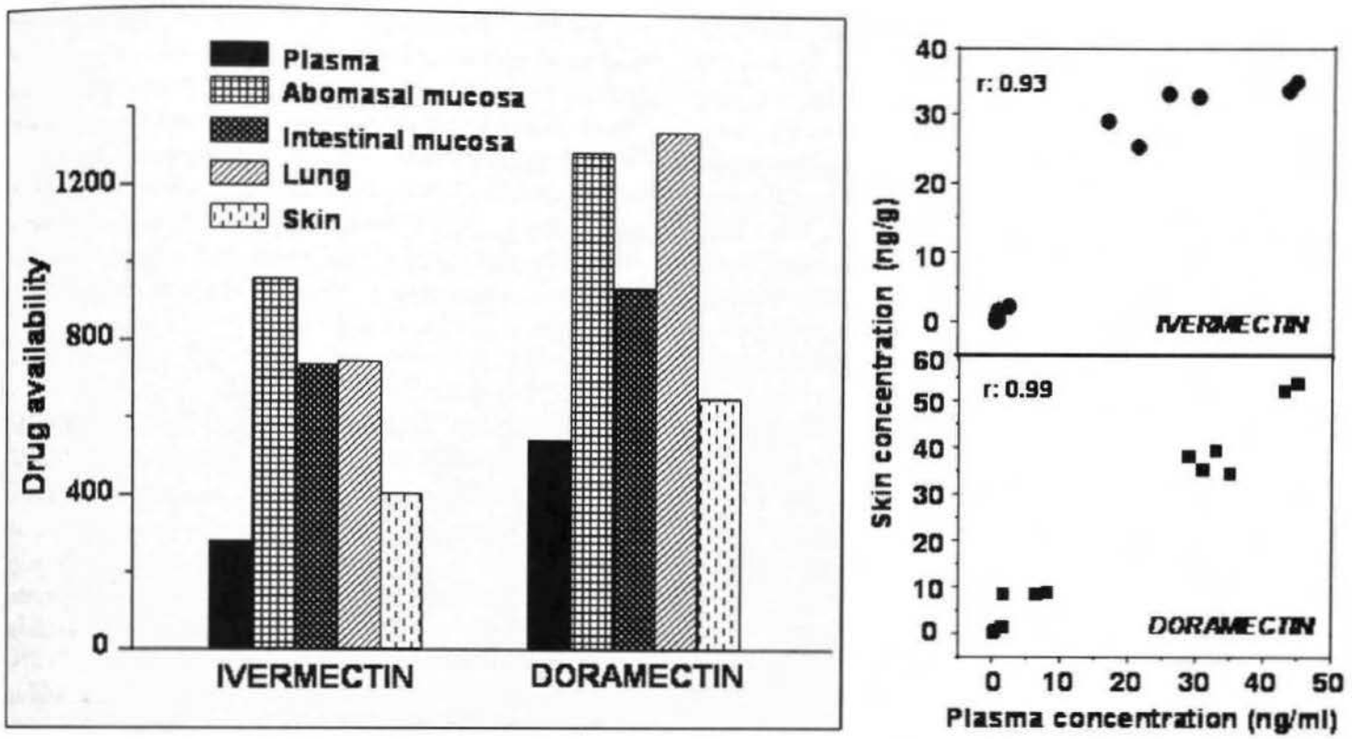

FIG. 42.5 Pattern of ivermectin and doramectin distribution to parasite location tissues in subcutaneously treated calves (0.2 mg/kg). Drug availability is expressed as area under the concentration vs. time curve (AUC) in ng.day/ml (plasma) and ng.day/g (target tissues). The correlations between drug concentrations measured in plasma and in a target tissue (skin) are shown in the right panel. r: correlation coefficient. Data from Lifschitz et al. 2000.

tissue concentration profiles for the ML compounds has been observed. The high correlation coefficients obtained showed the degree of association between ML concentrations in the bloodstream and those measured in tissues of parasite location. Despite the high correlation observed between concentrations in plasma and in tissues/fluids, ivermectin, doramectin, and moxidectin concentrations were greater in all target tissues compared to plasma.

MLs are highly effective against adult and larval stages of most gastrointestinal nematodes and *Dictyocaulus viviparus* in lung in cattle, exerting a prolonged protective effect. The achievement of high drug availability in lung tissue may explain their excellent activity against lungworms. The pulmonary tract was the target tissue in which the highest doramectin concentrations were recovered in parenterally treated cattle (Lifschitz et al. 2000). The persistence of the broad-spectrum anthelmintic activity of the MLs against adult and immature gastrointestinal parasites is facilitated by their advantageous pattern of distribution and prolonged residence in the digestive mucosal tissue. Differences in the plasma pharmacokinetic profiles between doramectin and ivermectin have been reported in cattle. Following intravenous administration of an aqueous micelle formulation to determine the intrinsic kinetic features of the compounds, higher plasma concentrations and delayed elimination of doramectin compared to ivermectin were reported (Goudie et al. 1993). After subcutaneous administration of the commercially available formulations to cattle, higher plasma profiles and extended plasma residence were observed for doramectin compared to ivermectin. The kinetic variables obtained for ivermectin and doramectin in tissues of parasite location are consistent with the described plasma kinetics data. Enhanced availability and prolonged time of residence in target tissues were observed for doramectin compared to ivermectin. The oil-based formulation of doramectin and perhaps a slowed metabolic rate based on the presence of the cyclohexyl group at C_{25} (Goudie et al. 1993) may contribute to the higher plasma and target tissues drug availability of doramectin compared to ivermectin.

Moxidectin is the most lipophilic endectocide substance; its high lipophilicity accounts for a wide tissue distribution (volume of distribution = 13.6 l/kg) and long residence in plasma, which is clearly reflected in the tissue pharmacokinetic results obtained in cattle. Distribution of the drug into adipose tissue accounts for the large distribution obtained for this compound compared to other antiparasitic drugs. The concentration of moxidectin in fat after 28 days of treatment in cattle has been shown to be ninetyfold higher than that detected in plasma (Zulalian et al. 1994). The large tissue distribution of moxidectin in cattle agrees with the high availability of moxidectin in the gastrointestinal mucosal tissues, lungs, and skin with concentrations ranging between 1 and 2 ng/g at 28 days posttreament, and with the extended detection of moxidectin concentrations >0.1 ng/g up to 58 days posttreatment in those tissues. The high Cmax values and total drug availability obtained in tissues where target parasites are located is in agreement with the extensive tissue distribution of moxidectin and may be relevant in terms of antiparasitic activity against internal and external parasites. Long residence times for moxidectin (between 6.8 and 11.3 days) were obtained in the different sites of parasite location, which agrees with the extended residence of moxidectin reported in fat and in the bloodstream (Alvinerie and Galtier 1997; Lanusse et al. 1997). Not surprisingly, moxidectin depletion half-lives in target tissues ranged from 7.73 (skin) to 11.8 (intestinal mucosa) days (Lifschitz et al. 1999a), which were significantly longer than those determined for ivermectin and doramectin in the same tissues. The deposit of moxidectin in adipose tissue may act as a drug reservoir that contributes to the long persistence of this molecule in the bloodstream and in different tissues of parasite location.

A considerable excretion of ivermectin, moxidectin, and doramectin occurs via the mammary gland, which invalidates their use in dairy animals. In an effort to identify an ML molecule that could be used in dairy cattle, the avermectin-derivative named *eprinomectin* has been introduced, which was developed for topical administration to cattle. While the milk/plasma ratio for ivermectin and moxidectin is close to 1 in sheep, goats, and cattle (Alvinerie et al. 1993, 1996; Imperiale et al. 2004b), the milk/plasma partitioning for eprinomectin in topically treated cattle falls between 0.1 and 0.2 (Shoop et al. 1996; Alvinerie et al. 1999b). These results indicate that eprinomectin, in addtion to its antiparasitic potency and broad spectrum, has a substantially reduced distribution to milk, compared to other MLs, which are probably based in some minor changes introduced to their chemical structure. In fact, changes to the milk partitioning coefficients in lactating dairy animals were achieved by manipulation of the avermectin molecule. The C4″-epi-amino analogues unsaturated at C22–23 showed that the lowest distribution into the milk is eprinomectin, 4″-epi-acetylamino-4″-deoxy avermectin B_1 (see Fig. 42.1), the best performed compound in terms of broad-spectrum antiparasitic activity.

METABOLISM, BILE AND INTESTINAL EXCRETION, AND INVOLVEMENT OF DRUG TRANSPORT SYSTEMS. Although some metabolic products have been recovered in plasma after administration of different MLs to cattle, these molecules are minimally metabolized in sheep and cattle, with bile and feces the major routes of excretion for unchanged parent drugs. The major liver metabolite of ivermectin in cattle is a 24-hydroxy-methyl-dihydroavermectin B_{1a} derivative (Chiu et al. 1987), identical to that produced by steer and rat microsomes in vitro (Miwa et al. 1982). Similarly, a doramectin metabolite accounting for 5.75% of the total recovered parent drug was detected in plasma between 8 h and 45 days postadministration of doramectin. The metabolism of moxidectin has been shown to produce the C_{29-30} and the C_{14} mono-hydroxymetyl derivatives as the main metabolic products. These and other hydroxylated metabolites have been recovered from different tissues of moxidectin-treated cattle (Zulalian et al. 1994). More extensive biotransformation of moxidectin compared to ivermectin and doramectin, would agree with the higher ratio of metabolites/parent drug recovered in plasma of moxidectin-treated animals. Interestingly, while 90% of the fat residue at 21 days posttreatment is moxidectin parent drug, ivermectin parent compound accounts for only 18% of the total fat residue at the same time posttreatment in cattle.

The avermectins are excreted in high concentration in bile and feces of treated cattle. Twenty-five % of an intraruminally administered dose of doramectin in sheep is secreted in bile, with 20% of biliary metabolites being enterohepatically recycled (Hennessy et al. 2000). Consistently, high concentrations of unchanged moxidectin are excreted in bile and feces (Zulalian et al. 1994), with concentrations greater than 2 ng/ml (ng/g) being recovered both in bile and feces up to 48 days posttreatment in cattle (Lifschitz

et al. 1999a). As pointed out by Hennessy (2000), the extent to which the biliary secreted drug and metabolites are presented to the gut lumen, are reabsorbed as free compound, and participate in the enterohepatic cycle is a major contributor to parasite exposure.

The MLs abamectin, ivermectin, and moxidectin (Pouliot et al. 1997; Dupuy et al. 2001), among many other substances, have been shown to be substrates of the P-GP transport protein. In the mammalian host, P-GP participates in the mechanism of active biliary and intestinal secretion of different molecules from the bloodstream to the gastrointestinal tract. The transepithelial intestinal secretion plays a major role in the elimination of ivermectin in the rat (Laffont et al. 2002). Ivermectin clearance from the small intestine accounted for 27% of the total drug clearance, while bile secretion accounted for only 5% of the total clearance in the rat. P-GP seems to be involved in the mechanism of ivermectin and moxidectin resistance in nematodes and concurrent use of verapamil (P-GP substrate) enhanced the efficacy of ivermectin and moxidectin against resistant *H. contortus* (Molento and Prichard 1999). Some studies showed that verapamil induces a significant alteration in the plasma disposition and availability of ivermectin in sheep (Molento et al. 2004) and rats (Alvinerie et al. 1999a), and a recent report suggests that verapamil and/or its metabolites affect the P-GP–mediated efflux of moxidectin in cultured rat hepatocytes (Dupuy et al. 2001). Loperamide, an opioid derivative that reduces gastrointestinal secretions and motility, markedly enhances the systemic availability of moxidectin (cattle) and ivermectin (rat) (Lifschitz et al. 2002b, 2004b). The delayed intestinal transit caused by loperamide and a potential competition between the ML and loperamide for the P-GP–mediated bile/intestinal secretion processes, may account for the observed enhancement in MLs' availabilities. As stated here, different pharmacological approaches to delay the bile/intestinal secretions and to extend the plasma-intestine recycling time of endectocide molecules are currently being investigated and their implications on parasite control need evaluation. Recent work demonstrated that the presence of P-GP–modulating agents enhanced ivermectin accumulation in the intestinal wall and its serosal transfer both in vitro and in vivo (Ballent et al. 2006). Itraconazole, an antifungal and P-GP substrate compound, drastically affected ivermectin disposition kinetics from the bloodstream and digestive tract. The itraconazole-mediated modulation of P-GP activity induced a markedly greater effect on ivermectin kinetics in male compared to female animals (Lifschitz et al. 2005a).

PHARMACOKINETIC-PHARMACODYNAMIC RELATIONSHIP

The MLs induce a paralytic effect on the pharynx and somatic musculature of nematodes. Using in vitro assays, 1 nM ivermectin concentrations paralyze the pharynx of *H. contortus* (Geary et al. 1993) and inhibit larval development of trichotrongyloid nematodes (Gill and Lacey 1998), while much higher concentrations of ivermectin are needed to obtain an inhibitory effect of larval motility (Gill et al. 1991). The pharynx is more sensitive than axial muscle to the paralyzing action of ivermectin, suggesting that interruption of pharyngeal function, as well as nutrient ingestion and excretion, may be critical to the anthelmintic action of ivermectin and related drugs. Considering that 1 nM of ivermectin equals 0.87 ng/g, it may be possible to establish a correlation between the concentrations used in these in vitro assays with those obtained in target tissues after in vivo treatment. Therefore, it could be assumed that the period of time during which drug concentrations are above 1 ng/g in target tissues would be indicative of the period during which a paralytic effect on nematode pharyngeal pump occurs.

The ML concentrations required at the site of parasite location to inhibit parasite establishment or development have not been determined. However, it has been theoretically assumed that the period of time during which drug concentrations are above 1 ng/g (the ivermectin concentration equivalent to that required to paralyze the pharynx of *H. contortus* in different in vitro pharmacodynamic assays) in target tissues, would be indicative of the period during which the in vivo anthelmintic activity may persist. While ivermectin concentrations were >1 ng/g in gastrointestinal mucosal tissue and lung tissue for 18 days posttreatment, doramectin and moxidectin profiles remained above that level for 38 days postadministration (Lifschitz et al. 2000). The comparison between these time periods and those obtained in different persistence efficacy trials are interesting. The increase of fecal egg counts after ivermectin and doramectin administration to cattle indicate that reinfection begins 2–3 weeks and 3–4 weeks after each treatment, respectively (Ranjan et al. 1997). The characterization of drug concentrations in target tissues is useful to estimate the period of time posttreatment in which the

endectocide levels at the site of parasite location remain efficacious. Understanding the relationship between drug concentrations achieved in target tissues and the persistence of activity estimated in parasitological field trials seems to be a critical step to establish the pharmacokinetic-pharmacodynamic correlation for MLs in ruminant species (see Fig. 42.6).

ML compounds have a broad spectrum of activity against adult and larval forms of many gastrointestinal nematodes in cattle. However, this pattern of efficacy varies among different nematode parasites and *Cooperia* spp. seems to be the dose-limiting nematode parasite for these compounds. While the reason for this differential susceptibility among different nematodes remains unknown, the evaluation of ML concentrations in different sections of the gastrointestinal tract provided some useful information. High moxidectin concentrations were detected in both abomasal and small intestinal mucosal tissues up to 58 days posttreatment, which accounted for the large AUC values observed in both target sites. These concentration profiles obtained in the mucosal tissue were greater than those obtained in abomasal and intestinal fluids. Only low moxidectin concentrations (below 1 ng/ml) were found in abomasal fluid following its subcutaneous administration to cattle, which is in agreement with the data previously reported for ivermectin (Bogan and McKellar 1988), where the drug was not detected in abomasal fluid, even when administered at 10 times the therapeutic dose in sheep. The greater moxidectin concentrations observed in the small intestinal fluid collected distal of the bile duct, compared with the abomasal fluid, may be associated with the biliary excretion of the drug. The higher lipid composition of the gastrointestinal mucosa compared to the fluids, considered as a more polar medium, may account for the greater moxidectin availability found in the mucosal tissues. The high availability and extended residence of moxidectin in the abomasal and intestinal mucosal tissues agree with the reported persistence of the anthelmintic effects of the drug against *Ostertagia ostertagi*, and other nematodes, for at least 35 days posttreatment (Vercruysse et al. 1997). Although differences in feeding mechanisms and site of location in the digestive tract among different nematodes should be considered to understand the overall action of the ML endectocides, the persistence of the broad-spectrum anthelmintic activity of the drug against adult and immature gastrointestinal parasites

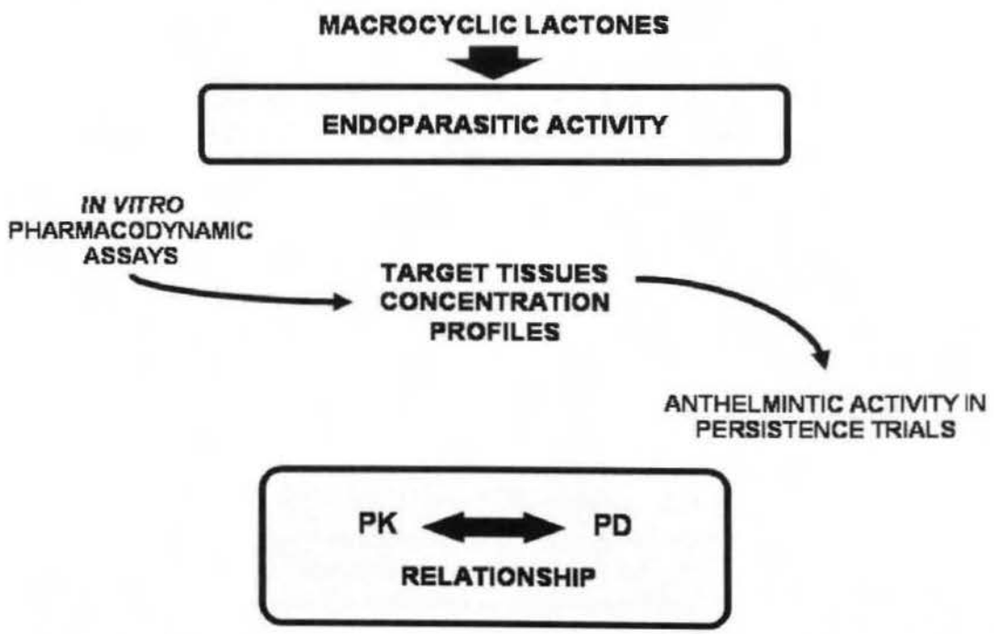

FIG. 42.6 Schematic illustration of the relationship between the pharmacokinetic (PK) behavior and pharmacodynamic (PD) endoparasitic activity for endectocide compounds in ruminants. See the text for further explanation.

is facilitated by its pattern of distribution and prolonged residence in the digestive mucosa. The described pharmacokinetic differences between moxidectin and ivermectin combined with some subtle mechanistic pharmacodynamic differences (see the section "Mechanism of Action"), are likely to be responsible for the observed differences in potency, spectrum, and expression of resistance seen between both molecules belonging to different ML families. The overall comparison of the pharmacological properties of moxidectin and ivermectin are shown in Figure 42.7.

ML endectocides are highly effective in eliminating mites and suckling lice species. The pattern of ivermectin and doramectin disposition in skin tissue showed that high concentrations of both molecules (>27 ng/g) are attained during the first 8 days posttreatment (Lifschitz et al. 2000). The sustained presence of high concentrations of ivermectin and doramectin in skin were reflected in the prolonged mean residence times values (6.8 and 9.3 days, respectively), which may also account for the efficacy of these drugs against single host ticks. The duration of effective levels of endectocide compounds in plasma may be important in the treatment of tick infestations, since this parasite can accumulate lethal drug concentrations through its feeding activity over a period of several days. Drug uptake and efficacy against arthropod ectoparasites can be markedly influenced by parasite feeding habits. Thus, the lower efficacy of the MLs against biting lice can be attributed to the lower exposure of this ectoparasite to body fluids containing drug. Moxidectin concentrations greater than 9 ng/g were detected during the first 8 days posttreatment in the skin of treated cattle (Lifschitz et al. 1999a), with a peak concentration of 84.2 ng/g achieved at day 1 postadministration. Drug concentrations in skin declined gradually with time posttreatment, as shown for other tissues, being detectable up to 58 days (>0.2 ng/g). These high moxidectin concentrations and its sustained presence in the skin account for the excellent efficacy of the drug against different ectoparasites in ruminants. Interestingly, the moxidectin and doramectin concentration profiles in the skin (dermis and epidermis) were greater than those found in the hypodermal tissue; moxidectin total availability in skin was six times greater than that observed in the subcutaneous tissue. Blood vessels in the skin are limited to the dermis, which receives the largest vascular supply. The dermis participates in the exchange of compounds between blood and tissues and as a fat reservoir (Monteiro-Riviere 1991); this physiological role of the

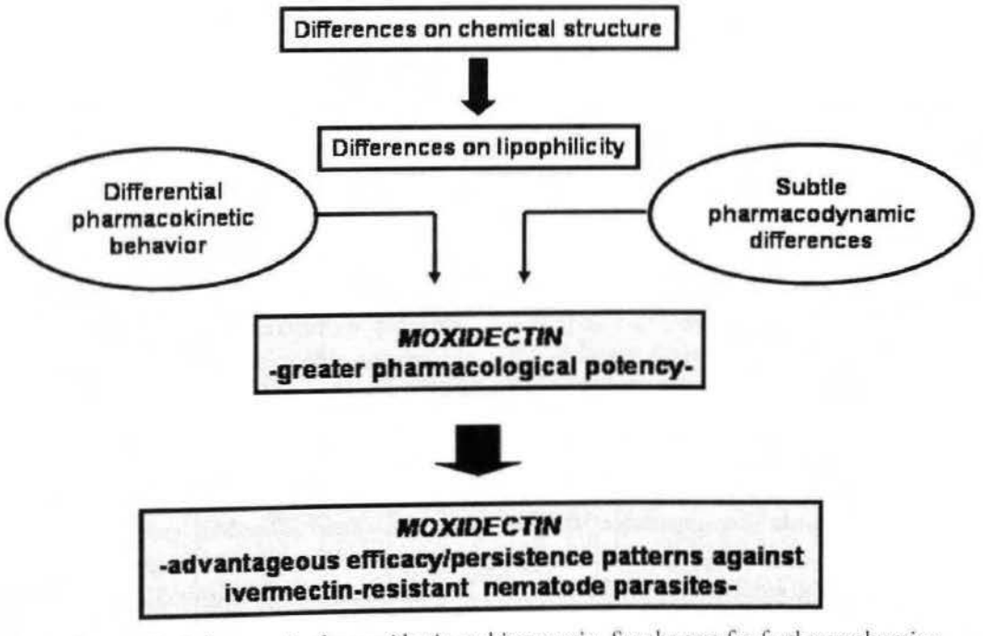

FIG. 42.7 Comparative pharmacological properties for moxidectin and ivermectin. See the text for further explanation.

dermis and the high lipophilicity of the MLs, may explain the differential distribution pattern in the skin, accounting for their higher availability in the dermis compared to the subcutaneous tissue. The arthropod ectoparasites are exposed to systemic agents during feeding; the nature of their food source, frequency and duration of feeding can have a marked influence in drug uptake and efficacy (Jackson 1989).

THERAPEUTIC USES: ANIMAL SPECIES-SPECIFIC CONSIDERATIONS

The ML compounds have exceptional potency and a broad spectrum of activity against nematodes and arthropods of different animal species. Their lack of efficacy against trematodes and cestodes may be related to the deficiency of ML specific binding sites in these parasites (Shoop et al. 1995b). Unlike benzimidazole anthelmintics, the MLs do not posses ovicidal activity. Compounds from both endectocide families share a similar broad spectrum against endo- and ectoparasites; however, some differences in activity against specific parasites may be observed among different ML molecules. A 0.2 mg/kg dose rate is required for avermectin and milbemycin compounds to eliminate their dose-limiting nematode species such as *Cooperia* spp. and *Nematodirus* spp. and to achieve the full broad-spectrum antiparasitic claim in ruminants (Shoop et al. 1995a). Extensive and detailed information on the spectrum of ecto-endoparasitic activity and on the preventive and therapeutic uses of the ML compounds in different animal species has been thoroughly reviewed elsewhere (Armour et al. 1980; Campbell 1989; McKellar and Benchaoui 1996; Vercruysse and Rew 2002). Readers are also referred to the 8th edition of this text (Reinemeyer and Courtney 2001) for additional specific information regarding the MLs' spectrum of antiparasitic activity. However, some overall concepts on the recommended use of the MLs in different animal species are summarized below.

RUMINANTS. ML compounds are available to be administered to ruminants by subcutaneous (cattle, sheep), oral (sheep and goats) (0.2 mg/kg), and topical (cattle) (0.5 mg/kg) formulations. MLs are highly effective against immature and adult stages of different gastrointestinal nematode species from ruminants such as *Ostertagia* spp. (including inhibited EL_4 in cattle), *Haemonchus* spp., *Cooperia* spp., *Nematodirus* spp., *Trichostrongylus* spp., *Strongyloides* spp., *Bunostomum* spp., *Trichuris* spp. and *Oesophagostomum* spp. and *Chabertia ovina*. MLs also possess high efficacy against lungworms (*Dictyocaulus* spp.) in sheep and cattle. The MLs are active against most of the nematode parasites affecting goats. However, the low systemic availability of some ML compounds obtained in goats (Scott et al. 1990; Alvinerie et al. 1999c) has restricted their use to extralabel prescriptions given at higher dose rates (0.3–0.4 mg/kg) for both oral and parenteral preparations.

Arthropod parasites controlled by MLs include mites (*Sarcoptes bovis, Psoroptes ovis*), oestrid larvae (*Hypoderma bovis, H. lineatum, Oestrus ovis*), and sucking lice (*Linognathus vituli, L. pedalis* and *Hematopinus eurysternus*). Ivermectin, abamectin, and doramectin are highly effective against *Dermatobia hominis* infestations. While ivermectin and abamectin aid in the control of the screwworm, *Cochliomya hominivorax*, doramectin has demonstrated a distinctive 100% protection for 21 days postinfection in calves (Moya-Borja et al. 1997). The specific distribution of the MLs in the different skin layers and their prolonged residence agree with their pattern of ectoparasiticide activity. The lower efficacy of the MLs subcutaneously administered against biting (*Damalinia* spp.) compared to sucking lices may be associated with the superficial feeding of these parasites, particularly on sloughed epidermal cells, which may contain low drug concentrations. The pour-on formulations are highly effective to control both sucking and biting lice. MLs are slightly less effective in controlling the sheep ked (*Melophagus ovinus*). MLs are highly efficacious against cattle ticks (*Boophilus microplus*). Ticks are exposed to systemic agents such as endectocides during feeding; therefore, the frequency and duration of feeding may have a marked influence in drug uptake and efficacy. The ML induces either tick mortality, lower engorgement, or fewer viable eggs. The injectable ivermectin preparation (1%) shows activity against ticks during 7 days posttreatment. Moxidectin and doramectin provide effective control of ticks for 28 days posttreatment, which is extended up to 75 days in the case of the long-acting 3.15% ivermectin formulations. The ML endectocides contribute to the control of *Haematobia irritans* (horn fly) in cattle. These compounds kill the adult flies and inhibit larval development in cattle dung. Development of the *H. irritans* fly may be reduced over 4 weeks after treatment with some ML compounds in cattle.

The concept of antiparasitic persistence acquired a great clinical significance after the discovery and commercial development of the ML endectocide compounds. The intrinsic properties of the MLs and/or their pharmacotechnical preparations allow a sustainable persistence of the active drug in the animal body, and therefore, prevent the establishment of new nematode burdens for several days after treatment. Large variations in the duration of the MLs' persistence of antiparasitic activity have been reported, particularly in cattle. The high variability is based on the parasites genera involved, the type of formulation used, different host-related factors, and the design of the experimental trials. For instance, the classic 1% ivermectin and abamectin formulations subcutaneously administered to cattle showed a persistent activity against *Cooperia* spp., *Ostertagia* spp., and *Dictyocaulus* spp. during 7, 14, and 28 days posttreatment. Longer protection periods against the same nematode parasites have been reported for moxidectin and doramectin. In fact doramectin showed a protection period between 21 and 35 days against *O. ostertagi* and 14–28 days for *Cooperia* spp. (Vercruysse et al. 2000). Moxidectin provides a protection against *Ostertagia* spp. and *Dictyocaulus* spp. during 35 and 42 days, respectively (Vercruysse et al. 1997). The ML pour-on formulations protect against nematode reinfection during the same period as that obtained after the subcutaneous treatments in cattle. The available ivermectin sustained-released bolus and the more recently introduced highly concentrated long-acting formulations (ivermectin and moxidectin) recommended for use at higher dose rates (between 0.63 and 1 mg/kg, respectively) dramatically increase the protection periods (between 60 and up to 150 days) against cattle endoparasites.

SWINE. The MLs are licensed to be used in pigs by subcutaneous (ivermectin, moxidectin), intramuscular (doramectin) administration at 0.3 mg/kg, and oral feed-formulation (ivermectin) at 0.1 mg/kg over 7 days to control endo- and ectoparasites. These compounds are active against immature and adult stages of *Ascaris suum, Hyostrongylus rubidus, Strongyloides ransomi, Oesophagostomum* spp., *Metastrongylus* spp., *Stephanurus dentatus*, and the intestinal (but not muscular) stages of *Trichinella spiralis*. Ivermectin efficacy against *Trichuris suis* is highly variable (between 60 and 95%). The MLs present high activity against the most common ectoparasites affecting swine herds: sucking lice (*H. suis*) and mange mites (*S. scabiei var. suis*).

HORSES. Ivermectin (0.2 mg/kg) and moxidectin (0.4 mg/kg) are the only MLs available to be used in horses by either oral paste or gel formulations. Both compounds are highly effective against *Parascaris equorum, Oxyuris equi*, stomach worms *(Draschia megastoma, Habronema* spp., *Trichostrongylus axei), Strongyloides westeri*, and lungworms *(D. arnfieldi)*. Both compounds are effective to control adult and larval stages of large strongyles *(Strongylus vulgaris, S. equinus, S. edentatus)*, adult small stronglyles *(Cyathostomes), Gasterophilus nasalis*, and *Onchocerca* spp. *microfilariae*. Consistently with the observed longer residence time in the bloodstream and tissues (Perez et al. 1999), moxidectin shows an extended period of protection against most of the target parasites in horses compared to ivermectin (Demeulenaere et al. 1997). The most important differences in the comparative efficacy of ivermectin and moxidectin in horses have been observed against mucosal larvae of *Cyathostomes* and *Gasterophilus* larvae. Ivermectin has lower efficacy than moxidectin against encysted *Cyathostomes* (Xiao et al. 1994; Monahan et al. 1996). However, while ivermectin is highly active (>99%) against all instars of *Gasterophilus intestinalis*, moxidectin shows a variable activity that ranges between 20 and 99% of efficacy when administered at recommended doses.

DOGS AND CATS. The overall efficacy and safety of the MLs designed for other species should not be assumed for dogs. It is now well known that collie dogs and other dog breeds are particularly sensitive to ivermectin (see the section "Safety and Toxicity"). Thus, ivermectin is licensed for specific therapeutic uses in dogs and cats. The available preparations are chewable formulations containing ivermectin to be administered at low doses 0.006 mg/kg (dogs) or 0.024 mg/kg (cats) as preventive against dirofilariasis. Ivermectin is effective against third and fourth stages of *Dirofilaria immitis* (Campbell 1989). Ivermectin and moxidectin approved formulations have a limited spectrum of activity against gastrointestinal nematodes in dogs and cats. However, ivermectin administered orally at higher doses (between 0.05 mg/kg and 0.2 mg/kg) may reach good efficacy against various nematode parasites (*Ancylostoma caninum, Trichuris vulpis, Toxocara canis* and *Capillaria aerophila*). Different studies have shown that two

ivermectin subcutaneous doses (0.2 mg/kg) are enough to clear otodectic, sarcoptic, and notoedric mange infestations (Campbell 1989). Ivermectin is also used in the control of demodectic mange infestations in dogs at higher dosages and prolonged regimens. However, the therapeutic uses of ivermectin in dogs and cats, apart from the prevention of *D. immitis*, should be considered as an extralabel use.

Milbemycin oxime administered at 0.5 mg/kg is effective against developmental stages of *D. immitis, T. canis, T. leonina, A. caninum and T. vulpis*. Moxidectin has been introduced as a tablet (0.003 mg/kg) and long-acting sustained release injectable formulation (0.17 mg/kg) to prevent *D. immitis* infection. This injectable formulation is also useful to control *A. caninum*. Selamectin, a new avermectin compound (see Fig. 42.1) introduced as a topical formulation for dogs and cats, is active against different endo- and ectoparasites at 6 mg/kg. A greater selamectin systemic availability was observed in cats compared to that obtained in dogs (Sarasola et al. 2002). It is highly efficacious against infective stages of heartworm (*D. immitis*), *T. canis*, *T. leonina*, *A. tubaeforme*, and *T. cati*. Selamectin is also effective against ectoparasites such as fleas (*Ctenocephalides cati)*, mites (*Otodectes cynotis, S. scabiei*), and ticks (*R. sanguineous* and *Dermacentor variabilis*).

RESISTANCE

The antiparasitic strategies based almost exclusively on chemical control have been threatened by the emergence of nematode parasites resistant to the various anthelmintic chemical classes, including now the ML compounds. The increasing selection pressure on the gastrointestinal nematodes due to the high frequency of ML treatments was relevant for the development of resistance to these compounds. Changes on the glutamated-gated chloride channels structure and an increased expression of different proteins involved in drug efflux (P-GP) have been postulated as the main mechanism of resistance to the MLs in nematodes (see "Mode of Action"). It has been shown that *H. contortus* resistant to ivermectin possess an increased level of P-GP expression and that the coapplication of verapamil (a MDR-reversing agent) increased the efficacy of ivermectin and moxidectin against resistant strains of *H. contortus* (reviewed by Prichard 2002).

Initially, resistance to the MLs (largely to ivermectin) was observed in sheep and goat nematodes, particularly in *H. contortus*. However, the phenomenon has been widespread and other nematode species from small ruminants have developed resistance to the ML compounds. Field strains of *Teladorsagia circumcincta* and *T. colubriformis* resistant to ivermectin have been identified around the world. In addition, the intensive worldwide use of the different ML compounds over the last 25 years (since the introduction of ivermectin in the early '80s), has resulted in the emergence of ML resistance in cattle nematodes. In fact, different field strains of *Cooperia* spp., the dose-limiting parasite for the MLs, and *Trichostrongylus* spp. have been identified as resistant to the ML compounds (Vermunt et al. 1995; Coles et al.1998; Fiel et al. 2001). It should be noted that moxidectin conserves activity against certain ivermectin-resistant isolates, which is probably due to its differential kinetic and dynamic behavior compared to ivermectin (see Fig. 42.7).

A diminution of the selection pressure, reducing the number of treatments per year together with an integrated antiparasitic control is urgently required to prolong the usefulness of the broad-spectrum parasite control of the MLs in food-animal production. Detailed information on the parasite resistance against ML compounds in ruminant species has been reviewed by Prichard (2002) and Wolstenholme et al. (2004). Despite the widespread resistance of different equine parasites to different anthelmintics, and taking into account that ivermectin has been used in horses for 20 years, there are still no reports of *Cyathostomes* resistance (Kaplan 2002). Considering that ivermectin is the single most commonly used anthelmintic in horses, it seems that emergence of resistance would be inevitable. There are no reports of resistant heartworms, in spite of the fact that MLs have been extensively used to prevent infections in dogs on a monthly basis.

AVAILABLE PHARMACEUTICAL PREPARATIONS

Different delivery systems have been developed to administer the ML compounds to the different animal species. The available preparations include injectable solutions, oral drenches, tablets, pastes, in feed premix, pour-on formulations, and a sustained released bolus (ivermectin). An oral paste containing 1.87% of ivermectin is available for horses. In-feed formulation of ivermectin for pigs is rec-

ommended over 7 consecutive days at 0.1 mg/kg per day. Ivermectin is also formulated in a micelar solution for oral drench use in sheep and goats, and as tablet and chewable preparations for oral administration in dogs and cats. The pioneer and extensively worldwide-distributed ivermectin 1% injectable formulation for subcutaneous administration (0.2 mg/kg)in sheep and cattle (Ivomec®, Merial Ltd.) is formulated in propylene glycol (60%) and glycerol formulation (40%). A topical ivermectin formulation is also commercialized to use against the whole range of ecto- and endoparasites of cattle at 0.5 mg/kg.

Pharmaceutical technology has been applied to develop different drug formulations and delivery systems to optimize the pharmacological potency of ivermectin and other ML endectocides currently available. It has been confirmed that extended residence times of ivermectin in plasma and target tissues and the prolonged persistence of its anthelmintic activity, are obtained following the administration of an alternative oil-based formulation to cattle, compared to the standard preparation (Lifschitz et al. 1999b). Recently developed injectable long-acting formulations for cattle are essentially oil-based or thixotropic (3.15%) preparations that account for a slow absorption process from the subcutaneous space and a long persistence of active ivermectin concentrations in the bloodstream and target tissues (Lifschitz et al. 1999b, 2005c). This 3.15% ivermectin formulation (Ivomec Gold®, Merial Ltd.) given at higher doses rates (0.63 mg/kg) has persistent efficacy against cattle gastrointestinal and lung nematodes for up to 77 days and ticks for up to 75 days. Following the same concept of the extended antiparasitic persistence, other similar (generic) highly concentrated (3.15% and 3.50%) ivermectin preparations have been recently introduced into the cattle market in some countries. Another recently developed technology incorporates eprinomectin in a long-acting preparation based on poly (lactic-co-glycolic) acid copolymer, which extends its persistent activity against nematodes for up to 120 days (Marley and Tejwani 2005).

The development of the sustained-release bolus technology for the administration of antiparasitic drugs was considered an important advance for parasite control. The ivermectin sustained-release device is an osmotic bolus delivering 12.7 mg of ivermectin per day over 135 days postadministration to cattle. The excellent release performance of an ivermectin sustained-release bolus was confirmed measuring the plasma and fecal concentration profiles up to 160 days postadministration in cattle, being 90% of the total dose released from the bolus excreted in feces (Alvinerie et al. 1998b).

Controlled-release capsules providing 1.6 mg of ivermectin per day over 100 days have been commercialized for use in sheep. More recently, novel delivery technology has been applied to develop a sequential-release formulation for use in sheep, which delivers ivermectin and albendazole alternately (Gogolewsky et al. 2005). This ivermectin/albendazole sequential delivery (10 days of ivermectin followed by 20 days of albendazole release, with the same alternating release cycles for each molecule to cover 100 days posttreatment) has been designed to assure the exposure of incoming parasite larvae to two chemicals with different modes of action, which could delay the development of resistance to each of the anthelmintic agents.

Doramectin is available in an oil-based formulation containing sesame oil/ethyl oleate (90:10) to be administered by the subcutaneous and intramuscular routes to cattle. A doramectin pour-on preparation is licensed to be used in cattle at 0.5 mg/kg. Moxidectin is available to be administered as injectable, pour-on (cattle), and oral (sheep and horses) formulations. A 1% nonaqueous moxidectin formulation is currently available for subcutaneous injection in cattle, sheep (0.2 mg/kg), and pigs (0.3 mg/kg). Novel moxidectin long-acting preparations for use in sheep (2%) and cattle (10%) are now available for use at higher dose rates (1 mg/kg) to cover extended antiparasitic protection periods (between 60 and 150 days). A long-acting sustained release injectable formulation for dogs (0.17 mg/kg) designed to prevent *D. immitis* infection is currently available. A moxidectin gel preparation to be administered orally at 0.4 mg/kg to horses is also available in the veterinary pharmaceutical market.

Eprinomectin is approved as a topical formulation for use in beef and dairy cattle. Both the eprinomectin and moxidectin pour-on formulations are now indicated in some countries in lactating dairy cows with zero milk withdrawal time. Selamectin is formulated as a solution (6 and 12%) in an isopropyl alcohol/dipropylene glycol methyl-ether vehicle to be used in dogs and cats at a dose range between 6 and 12 mg/kg (Bishop et al. 2000). Tables 42.1 and 42.2 summarize the information on the available formulations and recommended dose rates for avermectin and milbemycin compounds, respectively, in the different animal species.

TABLE 42.1 Formulations of avermectin-type compounds commercially available for use in different animal species

Drug	Formulation and Administration Route	Dose Rate	Target Species
IVERMECTIN (Ivomec®, Merial Ltd.)	1% injectable formulation in propylene glycol/glycerol formal (60:40) (SC)	0.2 mg/kg	Cattle, sheep
		0.3 mg/kg	Pigs
		0.4 mg/kg	Goats
	3.15% injectable oil-based long-acting formulation (SC)	0.63 mg/kg	Cattle
	0.5% transdermal formulation in isopropyl alcohol (pour-on)	0.5 mg/kg	Cattle
	Sustained release bolus (oral)	12 mg/day for 135 days	Cattle
	Controlled released capsules (oral)	1.6 mg/day for 100 days	Sheep
	Micelar drench formulation (oral)	0.2 mg/kg	Sheep
		0.4 mg/kg	Goats
	Liquid solution (oral)(#)	0.2 mg/kg	Horses
	1.87% paste formulation in a titanium dioxide and propylene glycol vehicle (oral) (#)	0.2 mg/kg	Horses
	In feed formulation (Premix) (oral)	0.1 mg/kg for 7 days	Pigs
	Flavored chewable and tablets formulation (oral) (##)	0.006 mg/kg	Dogs
		0.024 mg/kg	Cats
ABAMECTIN (Duotin®, Merial Ltd.)	1% injectable formulation in propylene glycol/glycerol formal (60:40) (SC)	0.2 mg/kg	Cattle, sheep
DORAMECTIN (Dectomax®, Pfizer)	1% injectable formulation in sesame oil/ethyl oleate (90:10) (SC, IM)	0.2 mg/kg	Cattle, sheep
		0.3 mg/kg	Pigs
	0.5% transdermal formulation (pour-on)	0.5 mg/kg	Cattle

DRUG AND HOST-RELATED FACTORS AFFECTING PHARMACOKINETICS AND EFFICACY IN RUMINANTS

As described in this chapter, the MLs are highly lipophilic substances that dissolve in most organic solvents. They are large molecules and despite possessing two sugar rings and two hydroxyl groups (avermectins) are relatively insoluble in water. Moxidectin solubility in water is greater than that of ivermectin and doramectin. These and other physicochemical differences between the ML molecules may account for differences in formulation flexibility and in their resultant kinetic behavior. The aqueous solubility of an active ingredient and the features of its pharmacotechnical preparation may influence the systemic availability, which relies on the rate and extent of absorption of a drug from the site of subcutaneous injection to the bloodstream. The vehicle in which the endectocide compounds are formulated may play a relevant role in their absorption kinetics and resultant plasma availability. The plasma profiles of ivermectin (Lo et al. 1985) and doramectin (Wicks et al. 1993) in cattle have been shown to be substantially affected by the composition of the administered formulation. Following parenteral administration, the low solubility of ivermectin and doramectin in water and its deposition in subcutaneous tissue favor a slow absorption from the injection site and provide prolonged duration in the bloodstream. Lanusse and co-workers (1997) characterized the comparative plasma disposition kinetics of ivermectin, moxidectin, and doramectin after their subcutaneous administration of the formulations commercially available for administration to cattle. While ivermectin was administered as the nonaqueous (60% propylene glycol/40% glycerol formal) preparation, an oil-based formulation of doramectin containing sesame oil/ethyl oleate (90 : 10) was administered to the experimental animals. The absorption of moxidectin, administered as an aqueous-based solution, from the site of subcutaneous injection was significantly faster than those of ivermectin and doramectin. Moxidectin peak plasma concentrations were achieved significantly earlier (8 h) than those of ivermectin (4 d) and doramectin (6 d posttreatment). It seems likely that moxidectin administered as an aqueous solution was more rapidly available for absorption from the subcutaneous tissue than both ivermectin and doramectin formulated in nonaqueous formulations, which agrees with the values of absorption half-lives obtained for moxidectin (1.32 h), ivermectin (39.2 h), and doramectin (56.4 h). The low solubility and the deposition of the ivermectin and doramectin nonaqueous preparations in the subcutaneous tissues favor a slow absorption from the site of injection, which may account for their prolonged residence in the bloodstream in cattle.

Several generic formulations of ivermectin have been introduced into the pharmaceutical market in different regions of the world after the expiration of the original patent of the first approved (innovator) ivermectin formulation (Ivomec®, Merial). The most of the available ivermectin generic preparations (some of them are now very well established in the pharmaceutical market) contain basically the same vehicle composition used in the innovator ivermectin formulation, but information on the comparative kinetic behavior of generic preparations in standardized pharmacokinetic trials is scarce. Lifschitz et al. (2004a) found marked differences on the absorption kinetics of ivermectin given by subcutaneous injection to cattle as four different generic (1%) formulations. The composition and quality of the vehicles and/or excipients used in the pharmacotechnical elaboration of ML formulations may be relevant to its pharmacokinetic behavior. The differences observed on the systemic availability and drug disposition kinetics among generic formulations may be reflected in the efficacy and persistence of their antiparasitic activity. Since the direct relationship between time of persistence of drug concentrations and extended efficacy against endo- and ectoparasites has been demonstrated, slight differences in formulation account for changes to the plasma kinetics and exposure of target parasites to active drug concentrations. This study was useful to build up a "conscience" on the relevance that the switchability among generic ML formulations might have on parasite control. Considering the necessary precautions to be adopted to avoid/delay the development of ML resistance in cattle nematode parasites, standardized quality control of generic formulations may greatly contribute to optimized drug use.

A number of factors affecting drug kinetics and the persistence of the antiparasitic efficacy of the ML have been identified. Among them are the animal species/breed, level of feed intake, nutritional status/body composition, influence of parasitism, formulation of dosage form, route of administration, etc. (reviewed by Lanusse and Prichard 1993; McKellar and Benchaoui 1996; Hennessy and Alvinerie 2002) (see Table 42.3). A series of relevant studies to compare the plasma profiles of MLs in different species have been reported (Alvinerie and Galtier 1997). From

TABLE 42.3 Drug and host-related factors affecting the kinetics and efficacy of the macrocyclic lactones in ruminants

Pharmacokinetic modifications	* Type of drug formulation * Route of administration
↓	
Changes on drug concentrations in target tissues	* Licking behavior (topical treatment) * Animal species * Animal breed * Nutritional condition and/or body composition
↓	
Modified efficacy and/or antiparasitic persistence	* Type of diet and/or level of feed intake (oral treatment) * Parasitism and/or modified gastrointestinal transit time * P-GP–mediated changes on drug absorption and/or excretion
↓	

The drug and host-related factors listed on the right may induce pharmacokinetic modifications resulting in modified drug efficacy/persistence. See the text for further explanation.

those comparisons, the consistently lower systemic availability of moxidectin (oral treatment) and ivermectin (SC treatment) observed in goats compared to sheep, emerges as a relevant finding. The influence of the route of administration on the plasma availability of the MLs has been extensively studied in ruminant species. For instance, both ivermectin and moxidectin are markedly less absorbed following oral administration to sheep compared to their subcutaneous injection. The reduced systemic availability observed following oral treatment accounted for lower milk residues excretion in orally treated dairy sheep compared to those observed after the injectable treatment (Imperiale et al. 2004b).

The ML has been traditionally administered by subcutaneous injection to cattle. However, formulations for their topical administration (pour-on) are currently marketed worldwide. Some practical advantages of the topical compared to other routes of administration have accounted for its great acceptance for parasite control in cattle. Some information is available on the plasma kinetic behavior of avermectins given topically to cattle (Gayrard et al. 1999). The plasma and tissue disposition kinetics of moxidectin and doramectin (Sallovitz et al. 2003, 2005) administered pour-on to cattle have recently been characterized. Lower moxidectin and doramectin plasma concentrations were measured following topical treatment compared to the subcutaneous injection of both compounds in cattle in spite of the use of a 2.5-fold higher dose rate for the pour-on administration (see Fig. 42.8). The absorption rate of topically administered moxidectin and its plasma availability were significantly higher in Holstein compared to Aberdeen Angus calves (Sallovitz et al. 2002), which may have considerable practical implications in terms of drug activity/persistence. Topically administered moxidectin is extensively distributed to different target tissues, including gastrointestinal mucosa, lungs, and different dermal layers. A cutaneous depot of the topically administered drug accounts for slow and sustained absorption, and agrees with the high moxidectin and doramectin concentrations measured in the epidermis and dermis of the skin from different anatomical regions.

It has been shown (Laffont et al. 2001) that the plasma and fecal disposition of ivermectin topically administered to cattle is markedly influenced by the natural licking behavior of treated animals. Higher and more variable systemic availability of ivermectin was observed in licker cattle, compared to animals whose licking behavior was prevented. These earlier results suggested that natural licking behavior may have a major influence on the kinetics of pour-on–administered MLs. More recent work (Sallovitz et al. 2005) showed that a 2-day-long licking prevention period after the pour-on treatment was sufficient to significantly reduce the doramectin concentrations measured in plasma during the first 9 days posttreatment. The animals in the free-licking group ingested topically administered doramectin by self and/or allo-licking, which accounted for the higher peak concentration observed in plasma as well as for the enhanced drug availability compared to the licking-restricted animals. As shown for moxidectin, a slow release of doramectin from the skin can be given by formation of a skin depot after the topical treatment, where the high lipophilicity facilitates drug retention in the lipid contents of the skin (fat tissue in the dermis and sebaceous secretion). Laffont et al. (2003) demonstrated that after the topical administration of ivermectin to cattle, drug absorption through the gastrointes-

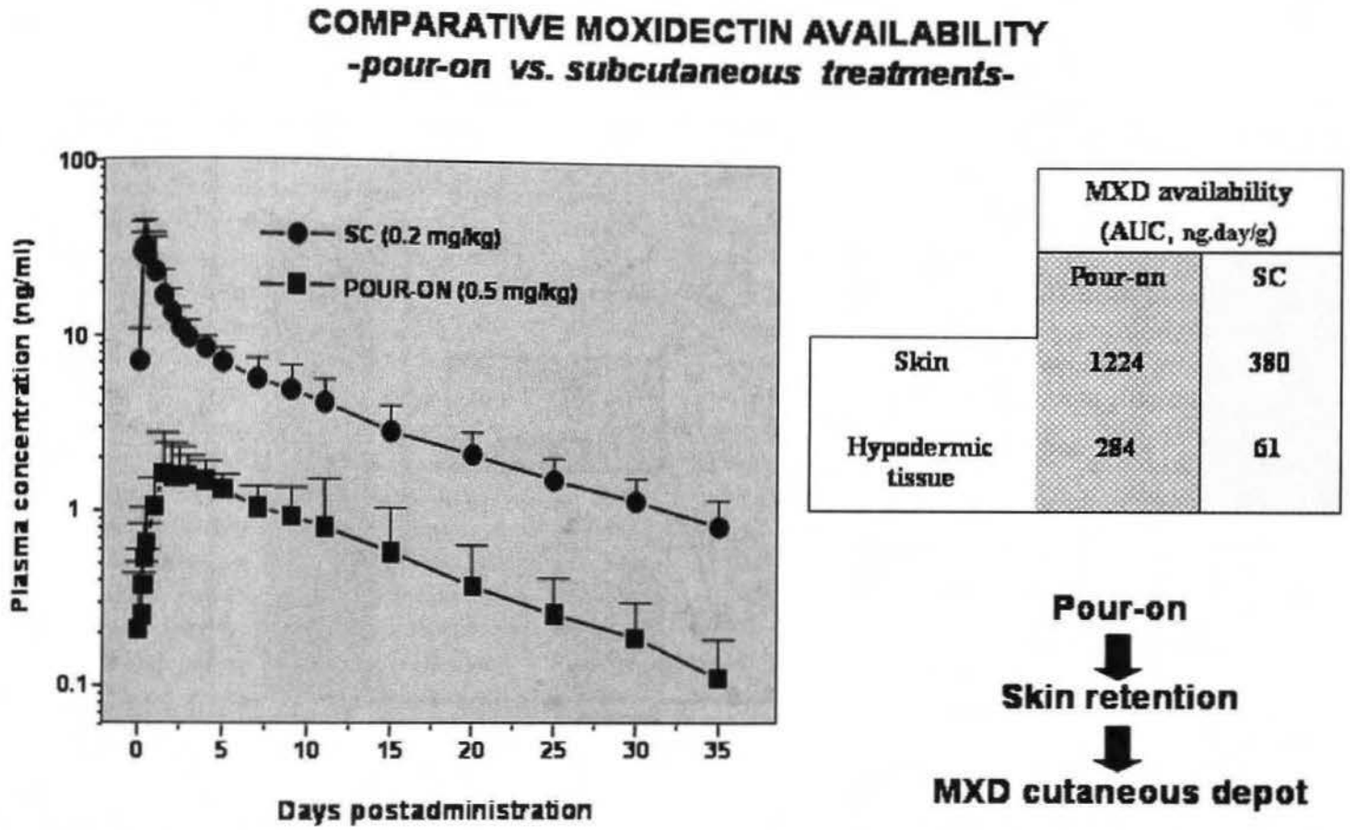

FIG. 42.8 Comparative plasma concentration profiles and total drug (expressed as AUC values) recovered in skin and hypodermic tissue after the subcutaneous (SC) and pour-on administrations of moxidectin (MXD) at recommended doses to cattle. The data illustrate the cutaneous depot of MXD after topical treatment. Data from Lifschitz et al. 1999a; Sallovitz et al. 2003.

tinal tract due to licking-induced oral ingestion is more important than the transdermal absorption in determining drug systemic concentrations. Thus, a more complete absorption of the MLs in the gastrointestinal tract following oral ingestion of the topically administered formulation, compared to the cutaneous permeation considered as the only absorption process in nonlicking animals, would explain the enhanced plasma profiles measured in calves allowed to lick freely.

Licking prevention during 10 days posttreatment permitted the identification of marked changes on the doramectin concentration profiles both systemically and, much more importantly, in the gastrointestinal tract. Doramectin concentrations in luminal contents from the intestine were markedly higher in free-licking cattle (see Fig. 42.9). Doramectin concentrations were higher in the fluid contents than in the mucosas in the licking group. Conversely, in licking-restricted calves, doramectin concentrations were higher in the mucosal tissue than in luminal content of the different gastrointestinal sections. These observations in nonlicking calves are in agreement with the data reported by Lifschitz et al. (2000) after the subcutaneous administration of doramectin, where after absorption into the systemic circulation, the drug can reach the gastrointestinal lumen by a distribution exchange between the bloodstream and the digestive compartment, which must occur through the mucosal layer of the intestine.

Considering the marked licking-induced changes observed in the concentrations of doramectin in the mucosal tissue and luminal contents from abomasum and intestine, the overall patterns of antiparasitic efficacy and persistence claimed for topically administered endectocides in cattle should be revised. On the face of the observed variations on antiparasitc response and with the threat of resistance development, the use of pour-on formulations to control endo- and ectoparasites should be carefully

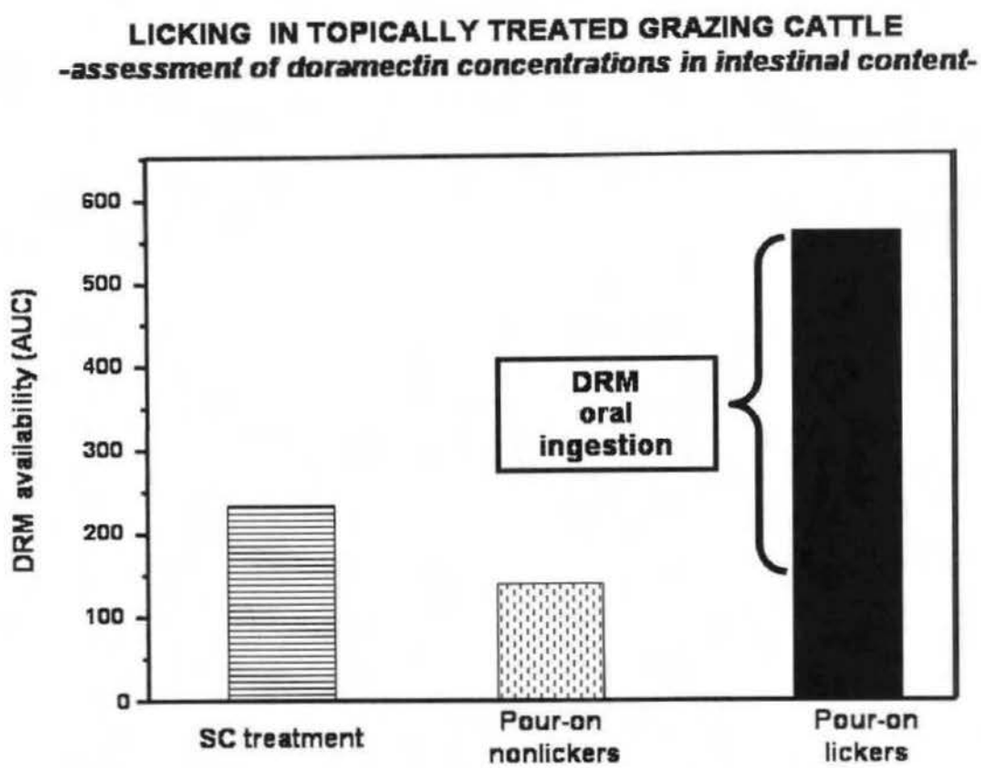

FIG. 42.9 Influence of animals' licking behavior on the intestinal availability of topically administered doramectin (DRM) in grazing cattle. The data show the AUC values obtained for DRM in the duodenal content after its topical administration (0.5 mg/kg) in both nonlicker (licking restricted over 10 days posttreatment) and free-licker calves. The comparison with the values obtained for the subcutaneous treatment (0.2 mg/kg) is included. DRM intestinal availability was significantly higher in licker calves due to licking-induced oral ingestion of the topical formulation. See the text for further explanation. AUC values are expressed in ng.day/ml. Data from Sallovitz et al. 2005.

considered. As recently pointed out by Bousquet-Málou et al. (2004), there are many therapeutic, practical, and regulatory issues to be discussed on the basis of the altered pharmacokinetic behavior induced by the natural licking in pour-on treated cattle. While the pharmacoparasitological implications of this animal behavior need to be further evaluated, the available data on the effect of licking prevention on ML concentrations in the gastrointestinal tract illustrate the magnitude of the pharmacokinetic modifications occurring after pour-on treatments in cattle.

TISSUE RESIDUES AND WITHDRAWAL TIMES

From mouse teratogenicity studies and from multigeneration studies in rats, the no-effect levels (NOEL) of 0.2 mg/kg/day have been established. Based on the relationship of these NOEL to residue levels in edible tissues from pharmacokinetic studies, the current withholding periods for sheep and cattle have been established. However, due to their high potency and elimination through milk, the classic injectable ML formulations are contraindicated for use in animals that produce milk for human consumption. The MLs are highly lipophilic substances extensively distributed to different tissues. The highest tissue residue concentrations in food-producing animals are recovered from the liver and fat. Regulatory agencies (U.S. Food and Drug Administration, European Agency for the Evaluation of Medicinal Products) have established the maximum residue levels (MRL) in target tissues (liver and fat) for some of the ML compounds in sheep and beef cattle. A 100 μg/kg MRL value for ivermectin in liver and fat tissue has been set. The MRL values established for

doramectin are 100 µg/kg (fat) and 150 µg/kg (liver). Higher MRL values were proposed for moxidectin in fat (500 µg/kg) and eprinomectin in fat (250 µg/kg) and liver (1500 µg/kg).

Posttreatment withdrawal periods have been established for the commercialized formulations in the different food-animal species. Although the established withdrawal times may vary according to the policies applied by the regulatory agencies in different countries, the classic 1% cattle injectable formulations of abamectin, ivermectin, doramectin, and moxidectin require withdrawal times ranging from 35 up to 50 days. A 120-day period is required to consume tissues from cattle treated with the 3.15% long-acting ivermectin formulation. An 84-day posttreatment period is required to deplete moxidectin below the established tolerance limits for different tissues after its administration as a long-acting preparation (10%) in cattle subcutaneously injected in the base of the ear. Withdrawal times between 10 and 15 days are required to consume meat from sheep treated with the ivermectin oral drench. In the U.S., a 45-day (35-day in Europe) withdrawal period is required for beef cattle treated with the available doramectin topical preparation. Required meat withdrawal times for doramectin in pigs parenterally treated are as follows: 24 (U.S.), 28–50 (Latin America), and 28–77 (European countries) days posttreatment. Detailed information on posttreatment withholding periods for the different ML formulations approved for use in food-producing animals in the U.S. can be found on the website for the U.S. Pharmacopeia (www.usp.org). There are no established withdrawal times for goats because MLs are not approved for use in this species. If ivermectin is administered to goats as a single extralabel oral dose of 0.2 to 0.4 mg/kg, evidence has been compiled by the Food Animal Residue Avoidance Databank (FARAD) that suggests a meat withdrawal time of 14 days and a milk withholding time of 9 days, which would be sufficient to avoid potentially harmful residues (Baynes et al. 2000).

All the ML injectable formulations are restricted for use in lactating dairy animals. However, a pour-on formulation of eprinomectin is approved for topical use in all cattle, including lactating dairy cows, without any milk withdrawal period. A moxidectin pour-on formulation is now available for use in dairy cattle with zero withdrawal time in milk. Additionally, generic ivermectin topical preparations are now approved for use in dairy cattle without milk withdrawal in some countries. Milk MRL values have been established for ivermectin (10 µg/kg), eprinomectin (20 µg/kg), and moxidectin (40 µg/kg).

SAFETY AND TOXICITY

The ML compounds given at recommended therapeutic doses are highly safe compounds in the majority of the target animal species. These large safety margins are based on the selectivity of their pharmacodynamic action. A GABA-mediated action in the mammalian central nervous system may be responsible for the neurotoxicity observed when large toxic doses of different MLs are administered (Lankas and Gordon 1989). In general, the avermectins have at least a tenfold safety margin in ruminants, horses, swine, and most dog breeds except collies and some Australian shepherds. The signs of acute toxicity include depression, ataxia, tremors, salivation, mydriasis, and in severe cases, coma and death. No effect on breeding performance, semen quality, or pregnancy was observed when bulls or cows were treated with ivermectin at 0.4 mg/kg (Campbell and Benz 1984). Avermectins are safe for use in cows during all stages of pregnancy. A twofold increase in dosage and multiple dosing have not adversely affected spermatogenesis, conception, longevity of gestation, or fetal development. Abamectin is slightly more toxic than ivermectin, with an oral LD_{50} in mice (14–24 mg/kg) higher than that of ivermectin (25–40 mg/kg). Signs of toxicosis were observed in cattle treated subcutaneously with abamectin at levels of 2–8 mg/kg. Abamectin is not recommended to be used in calves under 4 months of age (Pulliam and Preston 1989). No adverse effects were observed in different tolerance studies using up to 25-fold the therapeutic dose of doramectin injectable in cattle. Numerous field trials corroborate that eprinomectin is safe to use in cattle of all breeds and ages. Like the avermectins, milbemycin compounds have a wide therapeutic margin. No adverse effects have been observed in cattle subcutaneously treated with moxidectin up to 10 times the recommended dose (2 mg/kg). Moxidectin is safe in breeding animals. At three times the recommended dose (0.6 mg/kg), no adverse effects on reproductive performance of bulls and pregnant cows were observed.

As described, P-GP is a transport protein that acts as a multidrug efflux pump reducing intracellular concentration of different drugs, including the MLs. The activity of this transmembrane protein, located in brain capillary

endothelial cells, intestinal epithelial cells, biliary canalicular cells, renal proximal tubular epithelial cells, and placental and testicular cells is related to the toxicity of the MLs. Its presence in the blood-brain barrier limits the entry of these antiparasitic molecules into the central nervous system. The accumulation of ivermectin in the brain of genetically engineered P-GP–deficient mice was 87-fold higher compared to normal mice (Schinkel et al. 1994). Certain collie dogs are more sensitive to high doses of ivermectin than other dogs and develop signs of toxicity with single doses as low as 0.1 mg/kg (Fassler et al. 1991). The higher ivermectin brain concentrations reported in the avermectin-sensitive collies versus nonsensitive dogs may be related to a limited P-GP expression (Mealey et al. 2001; Roulet et al. 2003). A 4 base-pairs deletion in the *MDR1* (multidrug resistance) gene in sensitive collie dogs seems to account for altered P-GP synthesis. Dogs homozygous for a mutant allele of *MDR1* have a nonfunctional P-GP (Mealey et al. 2001). A sample population study of 40 collie dogs in the northwestern United States found 35% to be homozygous for the mutation and 42% to be heterozygous carriers of the mutant allele (Mealey et al. 2002). A gene study of subpopulations has shown that the mutation of the *MDR1* gene can be found in members of breeds other than collie dogs (Australian shepherds, English shepherds, Shetland sheepdogs, etc.), generally at a much lower frequency (Hadrick et al. 1995).

Animals deficient in P-GP expression in the intestine may also absorb more drug after oral treatment, which may result in higher blood concentrations and enhanced potential for neurotoxicity (Shoop and Soll 2002). Additionally, limited P-GP expression in the hepatobiliary tract may result in a decreased bile excretion of the ML compounds. Selametin was evaluated in dogs and cats at 10 times the recommended doses and no adverse reactions were observed (Novotny et al. 2000; Krautmann et al. 2000). Selamectin use is also safe in ivermectin-sensitive collie dogs. No abnormalities were observed in sensitive collies treated topically with selamectin at 40 mg/kg. Milbemycin oxime is well tolerated in dogs, including collies. Clinical signs are seen only after the administration of a tenfold overdose. Overall, as suggested by Shoop and Soll (2002), the wide safety margin is based on the low therapeutically used doses and on the fact that mammals do not have glutamate-gated chloride channels (specific site of action for the MLs in target parasites). Additionally, these drugs do not cross the blood-brain barrier. The presence of P-GP in the blood-brain barrier as well as in other tissues, serves as an important protective biological barrier to any adverse effects of the MLs.

ECOTOXICOLOGICAL IMPACT

The pattern of fecal elimination of different ML compounds administered by different routes to cattle has received special attention, due to the potential negative environmental impact caused by the effect of the drugs against dung-degrading insects. This has been evaluated under different conditions, initially for ivermectin (Lumaret et al. 1993; Herd 1995) and more recently for other MLs (Suarez et al. 2003). The prolonged presence of these molecules in the feces of treated cattle produces an adverse effect against invertebrate organisms that have a relevant role on dung degradation and nutrients recycling to the soil (Strong 1993). The residues of ivermectin and abamectin in feces not only affect the development and reproduction of adult *Coleoptera* but also are toxic against larval stages between 2 and 4 weeks after an injectable treatment (Strong and Wall 1994; Herd 1995). The consequences of this toxicity over the ecosystem are not fully understood. Moxidectin has been considered as a less harmful compound compared to the avermectin-type compounds following standard injectable treatments. The lower fecal concentrations measured after moxidectin treatment in cattle compared to those obtained after ivermectin and doramectin administration (Lifschitz et al. 1999a) with a possible higher rate of environmental degradation of moxidectin may determine its lower toxicity against dung fauna. Further research is required to evaluate potential adverse environmental impact of the ML compounds under a variety of conditions. Long-term investigations under different field production systems are particularly needed.

CONCLUDING REMARKS

The avermectins' discovery and the commercial launch of ivermectin as an ecto-endoparasiticidal agent in the early 80s were a great breakthrough within veterinary therapeutics, which was successfully followed by the development of other avermectin and milbemycin compounds. The MLs from both chemical families combine excellent spectrum with safety, potency, and persistence. They are highly efficacious antiparasitic agents for use in a variety of livestock and companion animal species. The observations highlighted in this chapter on the phamacokinetic/

pharmacodynamic relationship for MLs provide pharmacological knowledge required to improve their therapeutic use. Avoiding misuse of the MLs is critical to delay the development of resistance. The integrated assessment of the drug disposition kinetics in the host, the processes of drug diffusion into different target parasites, and the use of pharmaceutical technology to improve drug delivery at the site of infection are key research areas within the pharmacology of the antiparasitic drugs.

ANTIPROTOZOAN DRUGS

JENNIFER L. DAVIS AND JODY L. GOOKIN

Nitroimidazoles 1150
Metronidazole 1150
Tinidazole 1152
Ronidazole 1152
Benznidazole 1153
Pentavalent Antimonials 1153
Sodium Stibogluconate 1153
Meglumine Antimonate 1154
Arsenicals 1154
Benzimidazoles 1154
Albendazole 1155
Fenbendazole 1155
Febantel 1155
Aminoglycosides 1156
Paromomycin 1156
Nitrofurans 1157
Nifurtimox 1157
Tetracyclines 1158
Hydroxyquinolones and Naphthoquinones 1158
Decoquinate 1158
Atovaquone 1159
Parvaquone and Buparvaquone 1160
Pyridinols 1160
Clopidol 1160
Guanidine Derivatives 1160
Robenidine 1160
Thiamine Analogues 1161
Amprolium 1161
Nitrobenzamides 1162
Aklomide and Dinitolmide 1162
Nicarbazin 1162
Alkaloids 1163
Halofuginone 1163
Polyether Ionophores 1163
Lasalocid 1165
Maduramicin 1165
Monensin 1165
Narasin 1166
Semduramicin 1166
Salinomycin 1166
Triazine Derivatives 1166
Diclazuril 1167
Toltrazuril 1167
Ponazuril 1167
Sulfonamides 1169
Dihydrofolate Reductase/Thymidylate Synthase Inhibitors 1169
Trimethoprim 1169
Ormetoprim 1171
Pyrimethamine 1171
Lincosamides 1172
Clindamycin 1172
Azalides 1173
Azithromycin 1173
4-Aminoquinolines 1173
Chloroquine 1173
Diamidine Derivatives 1174
Diminazene Diaceturate 1174
Pentamidine Isethionate 1175
Phenamidine Isethionate 1175
Amicarbalide 1175
Imidocarb Dipropionate 1175
Nitrothiazole Derivatives 1176
Nitazoxanide 1176

Numerous chemotherapeutic agents are known to possess activity against parasitic protozoa (Tables 43.1 43.2). Although antiprotozoal activity is characteristic of many different chemical groups, most possess a rather narrow spectrum of activity. This is in contrast to antibacterial agents, which are effective against a wide variety of organisms. This chapter presents the clinically relevant antiprotozoan drugs used against the more important protozoal disease agents of domesticated animals.

TABLE 43.1 Summary of drugs used to treat selected protozoal diseases in animals

Protozoal Disease	Protozoa	Species	Drug Class	Drug and Dosing Regimen
Giardiasis	*Giardia duodenalis, G. intestinalis, G. lambia*	Dogs	Nitroimidazoles	Metronidazole: 12–15 mg/kg PO q12h for 8 days Tinidazole: 15 mg/kg PO q12h
			Benzimidazoles	Albendazole: 25 mg/kg q12h for 2 days Fenbendazole: 50 mg/kg q24h for 3 days Febantel, pyrantel, and praziquantal: febantel (26.8–35.2 mg/kg), pyrantel (26.8–35.2 mg/kg), praziquantel (5.4–7 mg/kg) PO q24h for 1–3 days
		Cats	Nitroimidazoles	Metronidazole: 22–25 mg/kg PO q12h for 5–7 days Tinidazole: 15 mg/kg PO q24h
			Benzimidazoles	Fenbendazole: 50 mg/kg q24h for 5 days Febantel, pyrantel, and praziquantal: febantel (56.5 mg/kg), pyrantel (11.3 mg/kg), and praziquantel (37.8 mg/kg) PO q24h for 5 days
		Horses	Nitroimidazoles	Metronidazole: 5 mg/kg PO q8h for 10 days
		Cattle	Benzimidazoles	Albendazole: 20 mg/kg PO q24h for 3 days Fenbendazole: 5–20 mg/kg PO q24h for 3 days
			Aminoglycosides	Paromomycin: 75 mg/kg PO q24h for 5 days
Trichomoniasis	*Tritrichomonas foetus, Pentatrichomonas hominis, Trichomonas gallinae*	Cats	Nitroimidazoles	Tinidazole: 30 mg/kg PO q24h for 14 days Ronidazole: 30 mg/kg PO q24h for 14 days
		Cattle	Nitroimidazoles	Metronidazole: 75 mg/kg IV q12h for 3 doses*
		Pigeons	Nitroimidazoles	Metronidazole: 40–60 mg/kg orally once a day for 5 days Ronidazole: 5 mg/kg orally once a day for 14 days Carnidazole: 20 mg/kg orally once
Trypanosomiasis	*Trypanosomas cruzi*	Dogs	Nitroimidazoles Nitrofurans	Benznidazole: 5–7 mg/kg PO q24h for 2 months Nifurtimox: 2–7 mg/kg PO q6h for 3–5 months
		Cattle	Diamidene derivatives	Diminazene diaceturate: 3.5–7 mg/kg IM
Babesiosis	*Babesia divergens, B. equi, B. caballi, B. bigemini, B. canis*	Dogs	Tetracyclines	Doxycycline: 10 mg/kg PO q12h for 11 days (*B. canis*)
			Hydroxyquinolones and naphthoquinones	Atovaquone: 13.3 mg/kg PO q8h combine with azithromycin 10 mg/kg PO q24h for 10 consecutive days (*B. gibsoni*)
			Diamidene derivatives	Diminazene diaceturate: 3.5–5 mg/kg BW IM (*B. canis*); 3.5 mg/kg q12h for 2 treatments (*B. gibsoni*) Pentamidine isethionate: 16.5 mg/kg IM on 2 consecutive days Phenamidine isethionate: 15–20 mg/kg SC q24h for 2 days (*B. gibsoni*); 8–13 mg/kg SC once (*B. canis*) Imidocarb dipropionate: 7.5 mg/kg SC (*B. canis*); 3.5 mg/kg diminazene followed by 6 mg/kg imidocarb on the following day (*B. canis*)

TABLE 43.1—*continued*

Protozoal Disease	Protozoa	Species	Drug Class	Drug and Dosing Regimen
		Horses	Tetracyclines	Chlortetracycline: 0.5–2.6 mg/kg IV q24h for 6 days (*B. equi*)
			Diamidene derivatives	Diminazene diaceturate: 3–5 mg/kg IM q12h for 2 treatments (*B. caballi*); 6–12 mg/kg IM (*B. equi*); 0.5 mg/kg IM (*B. bigemina*)
				Phenamidine isethionate: 8.8 mg/kg IM q12h for 2 treatments
				Amicarbalide: 8.8 mg/kg IM q12h for 2 treatments (*B. caballi*)
				Imidocarb dipropionate: 1–2 mg/kg IM q12h for 2 treatments (*B. caballi*); 4 mg/kg IM q72h for 4 treatments (*B. equi*)
		Cattle	Tetracyclines	Oxytetracycline: 20 mg/kg IM every 4 days for 3 weeks (*B. divergens*)
			Diamidene derivatives	Diminazene diaceturate: 3–5 mg/kg IM (*B. bigemina* and *B. bovis*)
				Pentamidine isethionate: 0.5–2 mg/kg SC
				Phenamidine isethionate: 8–13 mg/kg IM q12h for 2 treatments
				Amicarbalide: 5–10 mg/kg IM
				Imidocarb dipropionate: 1–3 mg/kg IM or SC
Cryptosporidiosis	*Cryptosporidium parvum*	Cats	Aminoglycosides	Paromomycin: 165 mg/kg PO q12h for 5 days**
			Nitrothiazole derivatives	Nitazoxanide: 75 mg/kg PO once
		Cattle	Aminoglycosides	Paromomycin: 12.5–50 mg/kg PO q24h for 12 days
			Azalides	Azithromycin: 1500–2000 mg/calf/day PO for 7 days
		Goats	Aminoglycosides	Paromomycin: 50 mg/kg PO q12h for 10 days
Leishmaniasis	*Leishmania donovani, L. infantum, L. chagasi*	Dogs	Pentavalent antimonials	Sodium stibogluconate: 30–50 mg/kg pentavalent antimony IV or SC q24h for 3–4 weeks
				Meglumine antimonate: 100 mg/kg IV or SC q24h for 3–6 weeks or 75 mg/kg SC q12h
				Liposomal meglumine antimonate: 9.8 mg/kg IM or SC q24h
Hepatozoonosis	*Hepatozoon americanum*	Dogs	Aminoglycosides	Paromomycin: 20–40 mg/kg IM q24h for 15–30 days
			Hydroxyquinolones and naphthoquinones	Decoquinate: feed additive (27.2 grams/pound of premix) added to moist dog food at 0.5–1.0 tablespoons per 10 kg BW twice a day
			Triazene derivatives	Toltrazuril: 5–10 mg/kg PO q12h for 5–10 days
			DHFR/TS*** inhibitors	Trimethoprim-sulfadiazine: 15 mg/kg PO q12h combined with clindamycin 10 mg/kg PO q8h and pyrimethamine 0.25 mg/kg PO q12h for 14 days****
			Diamidene derivatives	Imidocarb dipropionate: 5–6 mg/kg BW SQ or IM every 2 weeks until gamonts are no longer present in blood smears
Theileriosis	*Theileria parva*	Cattle	Hydroxyquinolones and naphthoquinones	Parvaquone: 20 mg/kg IM once
				Buparvaquone: 2.5 mg/kg IM 1–2 times
			Alkaloids	Halofuginone: 1–2 mg/kg PO once
Equine Protozoal Myelitis	*Sarcocystis neurona*	Horses	Triazene derivatives	Diclazuril: 5 mg/kg PO q24h for 30 days
				Toltrazuril: 5 mg/kg PO q24h for 28 days
				Ponazuril: 5 mg/kg PO q24h for 28 days
			DHFR/TS inhibitors	Pyrimethamine: 1 mg/kg PO q24h combined with sulfadiazine 20–30 mg/kg PO q12h for 30 days after clinical signs plateau
			Nitrothiazole derivatives	Nitazoxanide: 11.36 mg/lb PO q24h for the first 5 days, followed by 22.72 mg/lb PO q24h for 23 days

TABLE 43.1—*continued*

Protozoal Disease	Protozoa	Species	Drug Class	Drug and Dosing Regimen
Neosporosis	*Neospora caninum*	Dogs	DHFR/TS inhibitors	Pyrimethamine: 0.25–0.5 mg/kg PO q12h combined with sulfadiazine 30 mg/kg PO q12h for 2–4 weeks
			Lincosamides	Clindamycin: 12.5–18.5 mg/kg PO q12h for 2–4 weeks
		Cattle	Triazene derivatives	Ponazuril: 20 mg/kg PO q24h for 6 days
Toxoplasmosis	*Toxoplasma gondii*	Dogs	DHFR/TS inhibitors	Pyrimethamine: 0.25–0.5 mg/kg PO q12h combined with sulfadiazine 30 mg/kg PO q12h for 2–4 weeks
			Lincosamides	Clindamycin: 3–13 mg/kg PO or IM q8h for 2 weeks or 10–20 mg/kg PO or IM q12h for 2 weeks
		Cats	DHFR/TS inhibitors	Pyrimethamine: 0.25–0.5 mg/kg PO q12h combined with sulfadiazine 30 mg/kg PO q12h for 2–4 weeks
			Lincosamides	Clindamycin: 10–12 mg/kg PO q12h for 4 weeks or 12.5–25 mg/kg IM q12h for 4 weeks
Coccidiosis	*Eimeria sp.*, *Isospora sp.*	Dogs	DHFR/TS inhibitors	Ormetoprim/sulfadimethoxine: 11 mg/kg ormetoprim combined with 55 mg/kg sulfadimethoxine PO for up to 23 days
				Trimethoprim/sulfadiazine: 5–10 mg/kg trimethoprim combined with 25–50 mg/kg sulfadiazine PO q24h for 6 days to dogs over 4 kg; dogs under 4 kg BW are given half this dosage for 6 days
			Thiamidine derivatives	Amprolium: 100–200 mg total PO q24h for 7–12 days; in drinking water (sole source) at 30 ml (9.6% solution)/gal for up to 10 days; in food at 250–300 mg (20% powder) q24h for 7–10 days
			Sulfonamides	Sulfadimethoxine: 55 mg/kg PO q24h for 1 day, then 27.5 mg/kg PO q24h for 14–20 days
		Cats	Sulfonamides	Sulfadimethoxine: 55 mg/kg PO q24h for 1 day, then 27.5 mg/kg PO q24h for 14–20 days
			DHFR/TS inhibitors	Trimethoprim/sulfadiazine: 5–10 mg/kg trimethoprim combined with 25–50 mg/kg sulfadiazine PO q24h for 6 days to cats over 4 kg; cats under 4 kg BW are given half this dosage for 6 days.
			Thiamidine derivatives	Amprolium: 110–220 mg/kg PO q24h for 7–12 days; in drinking water (sole source) at 1.5 tsp (9.6% solution)/gal for up to 10–days; 150 mg/kg PO combined with sulfadimethoxine at 25 mg/kg PO q24h for 14 days.

*The use of nitroimidazoles in food-producing animals is strictly prohibited by the US FDA. Cattle receiving metronidazole should never enter the food chain.
**See text for discussion of toxicity.
***Dihydrofolate reductase/thyamidine synthase inhibitors.
****Regimen should be followed up with decoquinate therapy.

TABLE 43.2 Drugs licensed for the treatment of coccidiosis in food animals.*

Species	Drug	Trade name	Regulatory information
Chickens	Roxarsone	Ren-O-Sal®, Roxarsone 10% Type A Medicated Article, combination products available	Not for use in laying hens; 5-day slaughter withdrawal for noncombination products
	Decoquinate	Deccox® Type A Medicated Article, combination products available	Not for use in laying hens; no withdrawal necessary for noncombination products
	Clopidol	Cloyden 25®, combination products available	Not for use in laying hens; 5-day slaughter withdrawal for noncombination products
	Robenidine	Robenz®, combination products available	Not for use in laying hens; 5-day slaughter withdrawal for noncombination products
	Amprolium	Amprol 25%, CORID 25% Type A Medicated Article, combination products available	No withdrawal necessary for noncombination products

TABLE 43.2—*continued*

Species	Drug	Trade name	Regulatory information
	Dinitolmide	Zoamix®	Not for use in laying hens; no withdrawal necessary
	Nicarbazin	Nicarbazin, combination products available	Not for use in laying hens; 4-day slaughter withdrawal for noncombination products
	Halofuginone	Stenerol®, combination products available	Not for use in laying hens; 4-day slaughter withdrawal for noncombination products
	Lasalocid	Avatec®, combination products available	Not for use in laying hens; no withdrawal necessary for noncombination products
	Maduramicin	Cygro®	Not for use in laying hens; 5-day slaughter withdrawal for noncombination products
	Monensin	Coban®, combination products available	Not for use in laying hens; no withdrawal necessary
	Narasin	Monteban®, combination products available	Not for use in laying hens; no withdrawal necessary
	Semduramicin	Aviax®, combination products available	Not for use in laying hens; no withdrawal necessary for noncombination products
	Salinomycin	Bio–Cox®, Sacox®	Not for use in laying hens; no withdrawal necessary
	Diclazuril	Clinacox®, combination products available	Not for use in laying hens; no withdrawal necessary for noncombination products
	Ormetoprim/ sulfadimethoxine	Rofenaid®, combination products available	Not for use in laying hens; 5-day slaughter withdrawal for noncombination products
	Sulfamethazine	Sulmet® Drinking Water Solution	Not for use in laying hens; 10-day slaughter withdrawal for noncombination products
Turkeys	Roxarsone	Ren-O-Sal®, Roxarsone 10% Type A Medicated Article, combination products available	Not for use in laying animals; 5-day slaughter withdrawal for most products
	Clopidol	Cloyden 25®, combination products available	Not for use in laying animals; 5-day slaughter withdrawal for noncombination products
	Amprolium	Amprol 25%, CORID 25% Type A Medicated Article, combination products available	No withdrawal necessary for noncombination products
	Dinitolmide	Zoamix®	Not for use in laying animals; no withdrawal necessary
	Halofuginone	Stenerol®, combination products available	Not for use in laying animals; 7-day slaughter withdrawal for noncombination products
	Lasalocid	Avatec®, combination products available	Not for use in laying animals; no withdrawal necessary for noncombination products
	Monensin	Coban®, combination products available	Not for use in laying animals; no withdrawal necessary for noncombination products
	Diclazuril	Clinacox®, combination products available	Not for use in laying hens; no withdrawal necessary
	Ormetoprim/ sulfadimethoxine	Rofenaid®, combination products available	Not for use in laying animals; 5-day slaughter withdrawal for noncombination products
	Sulfamethazine	Sulmet® Drinking Water Solution	Not for use in laying hens; 10-day slaughter withdrawal for noncombination products
Cattle	Decoquinate	Deccox® Type A Medicated Article, combination products available	Not for use in lactating dairy cattle; approved for preruminating calves; no withdrawal necessary for noncombination products
	Amprolium	Amprol 25%, CORID 25% Type A Medicated Article, combination products available	Not for use in preruminating calves; 1-day slaughter withdrawal
	Sulfamethazine	Sulmet® Oblets, Sulfamethazine sustained release bolus	Not for use in lactating dairy cattle; 8–10-day slaughter withdrawal for individual products
	Sulfaquinoxaline	Sulfa-nox Liquid	Not for use in lactating dairy cattle; 10-day slaughter withdrawal for noncombination products

TABLE 43.2—*continued*

Species	Drug	Trade name	Regulatory information
Sheep	Decoquinate	Deccox® Type A Medicated Article, combination products available	Not for use in lactating sheep; no withdrawal necessary for noncombination products
	Lasalocid	Bovatec®, numerous others and combination products available	Not for use in breeding animals; no withdrawal necessary for noncombination products
Goats	Decoquinate	Deccox® Type A Medicated Article, combination products available	Not for use in lactating sheep; no withdrawal necessary for noncombination products
	Monensin	Rumensin®	Not for use in lactating sheep; no withdrawal necessary
Swine	Toltrazuril	Baycox®	Extralabel drug use, contact regulatory agencies for withdrawal times
Rabbits	Diclazuril	Clinicox®	Extralabel drug use, contact regulatory agencies for withdrawal times
	Lasalocid	Avatec/Bovatec®, numerous others and combination products available	No withdrawal necessary for noncombination products
	Sulfaquinoxaline	SQ 40% Medicated feed	10-day withdrawal
Pheasants	Amprolium	Amprol 25%, CORID 25% Type A Medicated Article, numerous others and combination products available	No withdrawal necessary for noncombination products
Chukar partridges	Lasalocid	Avatec/Bovatec®	No withdrawal up to 8 weeks of age
	Ormetoprim/ sulfadimethoxine	Rofenaid®	Not released into wild before 18 weeks and can be used only up to 8 weeks of age
Bobwhite quail	Monensin	Coban®, combination products available	Not for use in laying hens; no withdrawal necessary
	Salinomycin	Bio-Cox®, Sacox®	No withdrawal necessary
Ducks	Ormetoprim/ sulfadimethoxine	Rofenaid®	Not for use in breeding animals or animals producing eggs for human consumption; 5-day slaughter withdrawal

Please see text for further explanation of dosing and toxicities. Regulatory information is applicable to drugs used in the United States, and is current only as of the writing of this chapter. Please consult the label directions on all products prior to administration because extralabel use of feed additives is prohibited by the US FDA.

NITROIMIDAZOLES

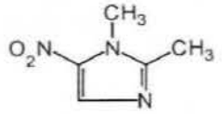
Spectrum: *Giardia, Balantidium, Entamoeba histolytica, Tritrichomonas foetus, Pentatrichomonas hominis, Trichomonas gallinae, Histomonas maleagridis, Trypanosomas sp.*

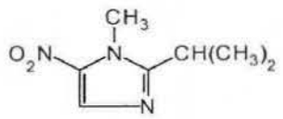
Drugs included: metronidazole, tinidazole, ronidazole, dimetridazole, ornidazole, carnidazole, benznidazole, and ipronidazole (Fig. 43.1).

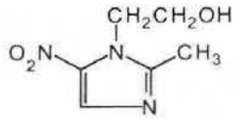
Many of these important agents were used in the treatment of poultry flagellates, and all except metronidazole and tinidazole have been removed from the market in the United States. Nitroimidazoles are suspected mutagens and carcinogens; therefore their use in food-producing animals has been strictly prohibited by the US FDA. (Legal control of veterinary drugs is discussed in more detail in Chapter 56.) For companion animals, metronidazole is the most commonly used agent in this group and the most studied.

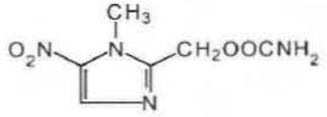
It is convenient to think of the mode of action of nitroimidazoles as occurring in four successive steps (Finegold and Mathisen 1990). First is entry into the protozoan cell, second is reductive activation, third is toxic effect of reduced intermediates, and fourth is release of inactive end products. The protozoal toxicity is due to short-lived intermediates or free radicals that produce damage by interacting with DNA and possibly other molecules. The cytotoxic intermediates decompose to nontoxic and inactive compounds.

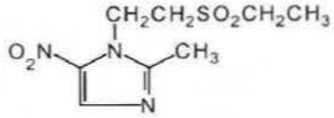
METRONIDAZOLE. Metronidazole (Flagyl® and generic) is a weak base that is moderately lipophilic. It has a low molecular weight compared to other drugs (MW 171), which facilitates penetration across membranes. The oral absorption in most animals is almost complete and it











Name	Chemical name (Empirical formula) [Molecular weight]	Chemical structure
Dimetridazole	1,2-dimethyl-5-nitro-1*H*-imidazole ($C_5H_7N_3O_2$) [141.13]	
Ipronidazole	1-methyl-2-(1-methylethyl)-5-nitro-1*H*-imidazole ($C_7H_{11}N_3O_2$) [169.18]	
Metronidazole	1-(2-hydroxyethyl)-2-methyl-5-nitroimidazole ($C_6H_9N_3O_3$) [171.16]	
Ronidazole	1-methyl-2-[(carbamoyloxy)methyl]-5-nitroimidazole ($C_6H_8N_4O_4$) [200.16]	
Tinidazole	1-[2-(ethylsufonyl)ethyl]-2-methyl-5-nitro-1*H*-imidazole ($C_8H_{13}N_3O_4S$) [247.26]	

FIG. 43.1 Nitroimidazoles.

reaches high concentrations in the tissues; therefore it is active against both luminal and extraluminal protozoa (Finch and Snyder 1986). Bioavailability of metronidazole is good in most species. In the horse, the bioavailability ranges from 75–85% (Steinman et al. 2000; Sweeney et al. 1986), and in the dog, it is reported to be 60–100% (Neff-Davis et al. 1981). It has a half-life of about 6–8 hours, and less than 20% binds to plasma proteins. It is metabolized in the liver by oxidation and glucuronide formation and is excreted primarily by the kidneys. Small amounts may be found in saliva and breast milk (Finch and Snyder 1986).

Metronidazole is usually well tolerated, but potential adverse reactions include glossitis, stomatitis, and nausea.

The most important adverse effect vomiting, neurotoxicosis, and neurotoxicity (Longhofer 1988). The reactions observed appear to be caused by inhibition of the gamma-aminobutyric acid (GABA) neurotransmitter. At high doses (67–129 mg/kg/day) metronidazole has caused ataxia, lethargy, proprioceptive deficits, nystagmus, and seizurelike signs in dogs. Dogs have recovered if drug administration was discontinued, but it may require 1 to 2 weeks (Dow 1988, 1989). However, when diazepam was administered as a treatment, recovery was much faster (Evans et al. 2003). Neurotoxicosis also has been observed in cats with high doses.

Metronidazole is notoriously unpalatable. This may create difficulty for administering to difficult-to-medicate pets (cats), may be challenging to administer to horses, and the aftertaste may be accompanied by a loss of appetite.

Metronidazole Benzoate. In an attempt to provide a more palatable formulation, compounding pharmacists

have provided metronidazole as an ester of benzoic acid-metronidazole benzoate, also known as *benzoylmetronidazole*. This formulation, although not registered by the FDA, is available from compounding pharmacists and has been popular for use in cats. The oral absorption is 65% and it has a half-life in cats of approximately 5 hours (Sekis et al. 2009). Metronidazole base is soluble (10 mg/ml), and has moderate lipophilicity (logP −0.02 and log D −0.27 at pH 5 and above). By contrast, the benzoate form, which is an ester, is much less soluble but more lipophilic (log P value of 2.19; log D value of 2.19 at pH 5.0 and above). The lower solubility results in less drug dissolved in the saliva of cats and therefore does not produce the degree of unpleasant taste compared to the base. The lipophilicity allows for good oral absorption from the GI tract. At a dose of 20 mg/kg of metronidazole benzoate, which is equivalent to 12.4 mg/kg of metronidazole, concentrations following the oral dose in cats were above the MIC_{90} for most anaerobic bacteria for at least 12 hours and above 1 µg/ml (for more susceptible organisms) for at least 24 hours (Sekis et al. 2009). Although cats are sensitive to benzoic acid toxicity, at these dosages it is unlikely that administration of metronidazole benzoate will produce toxicosis in cats.

Clinical Use. Metronidazole is not registered for animal use, but is available as the base in capsules (375 mg), tablets (250 and 500 mg), or for injection as metronidazole hydrochloride in 500 mg vials

Cats. Metronidazole at a dose of 25 mg/kg orally, twice daily for 7 days has been shown to completely eliminate *Giardia* cyst shedding in cats known to be chronic shedders of a human isolate of *Giardia* (Scorza and Lappin 2004). Metronidazole was also effective in eliminating cyst shedding as well as diarrhea associated with naturally occurring *Giardia* infections at a dose of 22 mg/kg orally, twice daily for 5 days (Zimmer 1987).

Dogs. Metronidazole at a dose of 12–15 mg/kg orally, twice a day for 8 days is commonly prescribed for treatment of infections caused by *Giardia*, *Balantidium*, *Entamoeba*, and *P. hominis*.

Horses. Giardia infections in horses are rarely reported to cause disease; however, successful treatment has been accomplished with 5 mg/kg of metronidazole orally, three times a day for 10 days (Kirkpatrick and Skand 1985).

Cattle. Metronidazole has been used to treat trichomoniasis in bulls at a dose of 75 mg/kg IV q12h for up to three doses. Metronidazole (and related drugs) are strictly forbidden for use in food-producing animals. Due to regulatory issues, animals treated in this manner must never enter the food chain in the United States.

TINIDAZOLE. Tinidazole (Tindamax™, Simplotan®, or Fasigyn®) is a second-generation 5-nitroimidazole that is FDA approved for use in treating *T. vaginalis*, *Giardia* spp., and *Entamoeba histolytica* infections in people. Tinidazole is completely absorbed after oral administration in cats and dogs (Sarkiala et al. 1991), and has been shown to penetrate well into various tissues where drug concentrations are found to be similar to that in plasma (Wood et al. 1973). The apparent total plasma clearance of the drug is about twofold higher in dogs than in cats, resulting in an elimination half-life that is twice as long in cats (8.4 hours) than in dogs (4.4 hours) (Sarkiala et al. 1991). It is metabolized in the liver by hydroxylation and glucuronide conjugation and is excreted into both urine and feces. Tinidazole has been administered to dogs at doses up to 150 mg/kg body weight for 24 weeks without toxic or adverse reactions. Dosages of 450 mg/kg body weight may result in liver enzyme elevations in dogs. Toxicity data in cats has not been reported.

Clinical Use

Dogs and Cats. Tinidazole at a dose of 30 mg/kg orally once a day for 14 days has been shown to suppress shedding of *T. foetus* in experimentally infected cats (Gookin 2007). Based on studies in people, tinidazole is also likely to be effective for treatment of most infections amenable to metronidazole including *Giardia* infections in dogs and cats. Pharmacokinetic studies suggest that doses of 15 mg/kg orally twice a day for dogs or once a day for cats will produce concentrations at a level that is thought to be therapeutic.

RONIDAZOLE. Ronidazole is not registered for human or veterinary use in the United States; however, it is considered an effective treatment for *T. gallinae*, *Histomonas meleagridis*, and *T. foetus* infections. It has a tenfold higher in vivo activity against trichomonal infections compared to metronidazole (Miwa et al. 1986). The susceptibility of *Tritrichomonas foetus* has been reported in two studies

(Kather et al. 2007; Gookin et al. 2006). In the study by Gookin et al. (2006) ronidazole was the most active compound tested for in vitro activity.

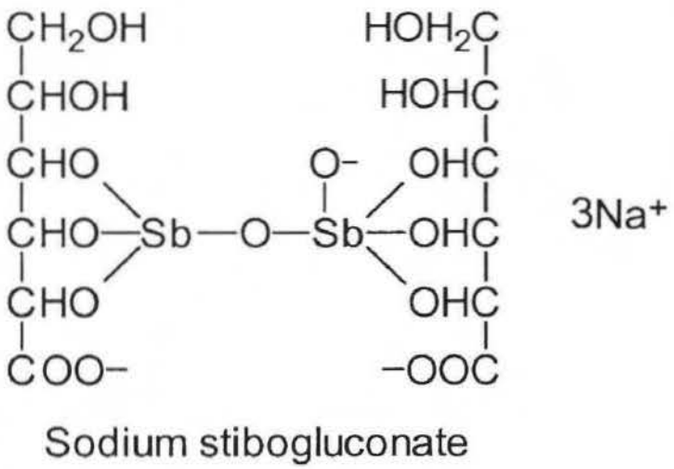
Clinical Use

Cats. Ronidazole at a dose of 30 mg/kg orally twice a day for 14 days has been shown to eliminate shedding of *T. foetus* in experimentally infected cats (Gookin et al. 2006). The pharmacokinetics of ronidazole has been examined in cats after IV and oral administration (LeVine et al. 2008). It was rapidly absorbed after oral administration in cats with a long terminal half-life. Although neurotoxicity has been reported from administration to cats (Rosado et al. 2007), these reactions were associated with high doses. Current recommendation are to not exceed 30 mg/kg once daily in cats. However, based on the pharmacokinetic results cited above, once-daily administration should be considered in cats at risk of neurotoxicity. In a pharmacokinetic study in which ronidazole was administered intravenously (prepared from an aqueous compounded formulation) and orally, no adverse reactions in healthy cats were observed.

Pigeons. *T. gallinae* (pigeon canker) is generally treated with ronidazole (5 mg/kg orally once a day for 14 days), carnidazole (20 mg/kg orally once) or metronidazole (40–60 mg/kg orally once a day for 5 days).

BENZNIDAZOLE. Benznidazole has been shown to produce cures of acute trypanosomiasis in dogs with fewer side effects than nifurtimox.

Clinical Use



Dogs. Dogs are treated with 5–7 mg/kg BW benznidazole orally at 24-hour intervals for 2 months (Barr 2006).

PENTAVALENT ANTIMONIALS

Spectrum: *Leishmania* spp.

Drugs included: Sodium stibogluconate, meglumine antimonate (Fig. 43.2)

Pentavalent antimonials have been shown to inhibit topoisomerase in vitro (Lucumi et al. 1998) and thereby interfere with parasite replication. They also inhibit enzymes involved in the synthesis of nucleotides and inhibit phosphofructokinases, enzymes necessary for glycolytic and fatty acid oxidation (Baneth and Shaw 2002). The in vivo mode of action of the pentavalent antimonials is still unclear. The pharmacodynamics of these drugs are still debated, and it is not known whether a better clinical response would be achieved with higher peak plasma concentrations versus prolonged time above the minimum inhibitory concentration of the protozoa (Valladares et al. 1998). Increasing resistance to pentavalent antimony compounds has been documented in recent years, and their effectiveness appears to be decreasing. In general, canine visceral leishmaniasis is more difficult to treat than the human form of the disease. The use of pentavalent antimonials is contraindicated in patients with myocarditis, hepatitis, or nephritis. Both sodium stibogluconate and meglumine antimonate are administered on the basis of their antimony content.

Sodium stibogluconate

FIG. 43.2

SODIUM STIBOGLUCONATE. Sodium Stibogluconate (Pentostam®) was made available in the United States from the Centers for Disease Control in 1968 for treatment of leishmaniasis in human beings (Fig. 43.2). It is in aqueous solution at a concentration of 330 mg/ml of agent, which is equivalent to 100 mg/ml pentavalent antimony. Clinical formulations consist of multiple uncharacterized molecular forms, some of which have higher molecular weights than the active compound. In human beings, most of a single dose of sodium stibogluconate is excreted by the kidneys in the urine within 24 hours regardless of whether it is given IV or IM. Antimony compounds are eliminated faster if given IM than SC or IV in dogs, and it is important to maintain serum levels

of the compound to treat leishmaniasis. Pentavalent antimonials are relatively well tolerated. Adverse reactions include pain at the injection site, GI symptoms, delayed muscle pain, and joint stiffness.

Clinical Use

Dogs. Canine leishmaniasis is treated with sodium stibogluconate to deliver 30–50 mg/kg BW pentavalent antimony by either IV or SC administration at daily intervals for 3–4 weeks (Slappendel and Teske 1997). Relapses may occur a few months to a year after treatment and should be treated with another round of pentavalent antimony.

MEGLUMINE ANTIMONATE. Meglumine antimonate (Glucantime®) may be less likely to cause adverse effects than sodium stibogluconate. Adverse effects noted include lethargy, gastrointestinal disturbance, and injection site reactions, including muscle fibrosis and abscess formation with IM injection (Noli and Auxilia 2005). It is available in a solution that contains 300 mg/ml antimony. Bioavailability is approximately 92% after IM or SC administration, and 80% of the drug is excreted in the urine within the first 9 hours (Valladares et al. 1997).

Liposomal encapsulated formulations of meglumine antimonite (LMA) have also been tested in dogs. They reach higher plasma concentrations, have slower clearance, and have a higher volume of distribution than regular formulations (Valladares et al. 1997). They also reach good concentrations in the bone marrow of affected dogs. Compared to conventional formulations, a positive effect on plasma total protein and gammaglobulin concentrations was seen with the LMA formulation, with no relapses noted at 12 months after treatment. Although good results have been seen with this formulation, complete eradication of the parasite is unlikely to be achieved and the product may not be cost effective when compared to conventional formulations.

Clinical Use

Dogs. Canine leishmaniasis has been treated with meglumine antimonate given IV or SC at 100 mg/kg BW once daily for 3–6 weeks (Slappendel and Teske 1997). No advantage is provided by IV administration. Relapses will occur in long-term survivors and require retreatment. Alternatively, a dosing regimen of 75 mg/kg SC twice daily achieves higher peak concentrations and maintains detectable plasma concentrations for the entire dosing interval (Valladares et al. 1998). For liposomal encapsulated meglumine antimonite, a dose of 9.8 mg/kg q24h is recommended (Valladares et al. 2001).

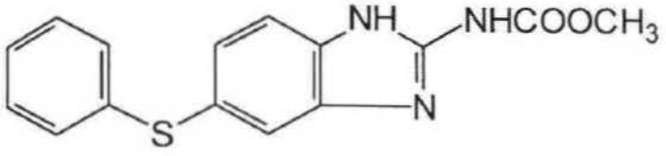
ARSENICALS

Spectrum: Histomoniasis, coccidiosis

Drugs included: Arsenicals, carbarsone, nitarsone, and roxarsone

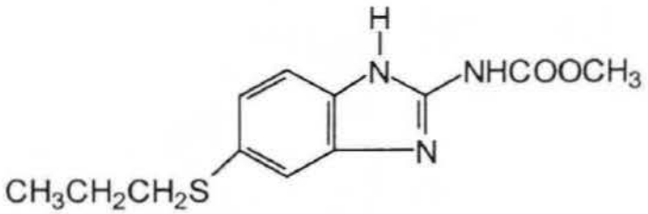
The exact antiprotozoal mechanism of action of arsenicals is not known, however these drugs are known to nonspecifically bind to disulphide moieties in proteins, thereby inhibiting many enzyme systems that use biological ligands containing available sulfhydral groups (Blum and Burri 2002). This mechanism is also thought to be related to the toxic effects of arsenic compounds on the host. These drugs continue to be administered to humans for treatment of African trypanosomiasis. These compounds were used at one time for the prevention and treatment of histomoniasis and coccidiosis in turkeys.

Clinical Use



Chickens and Turkeys. Nitarsone (Histostat-50®) is used as a feed additive for the prevention of histomoniasis in turkeys and chickens. It is not active if birds have been infected for more than 4 days. A 5-day withdrawal is required for nitarsone. Overdosing or lack of adequate water may result in leg weakness and paralysis in birds. Nitarsone is dangerous for ducks, geese, and dogs. Roxarsone is fed as a growth promotant and as a preventative for coccidiosis. A 5-day withdrawal is required for roxarsone. Like nitarsone, overdosing or lack of adequate water may result in leg weakness and paralysis in birds.

BENZIMIDAZOLES



Spectrum: Giardiasis

Drugs included: Albendazole, fenbendazole, febantel (Fig. 43.3).

The benzimidazoles are a group of agents that are widely used in the treatment of helminth parasites of large and small animals (Antihelmintics are discussed in detail in Chapters 40–42.) Some compounds in this group have excellent activity against *Giardia* spp. This group lacks or has little antibacterial activity and unlike other antigiardial agents is unlikely to interfere with intestinal microflora during treatment. The benzimidazoles are known to bind

Fenbendazole
$(C_{15}H_{13}N_3O_2S)$
[299.35]

Albendazole
$(C_{12}H_{15}N_3O_2S)$
[265.33]

FIG. 43.3

to β-tubulin subunits of microtubules and interfere with microtubule polymerization (Gardner and Hill 2001). This causes structural changes in *Giardia* trophozoites consistent with microtubule damage to the adhesive disk and internal microtubule cytoskeleton but not the external flagella.

ALBENDAZOLE. Albendazole (Valbazan®) is available in liquid and paste formulations. It is effective against *Giardia* sp. in human beings, mice, and dogs. Albendazole is poorly absorbed from the intestinal tract. Albendazole is potentially toxic, causing dose-dependent and idiosyncratic myelosuppression in dogs and cats respectively (Stokol et al. 1997). It is potentially teratogenic so it should not be given to pregnant animals. Its use in cats is not recommended.

Clinical Use

Dogs. Dogs treated orally with albendazole at 25 mg/kg BW every 12 hours for 2 days cleared *Giardia* cysts from their feces (Barr et al. 1993). A single oral 25 mg/kg BW treatment was not effective in clearing cysts from the feces of dogs. None of 32 dogs treated for giardiasis with albendazole developed adverse reactions (Barr et al. 1993).

Cattle. Albendazole given at 20 mg/kg BW orally for 3 days reduced *Giardia* cyst production by >90% in naturally infected calves (Xiao et al. 1996).

FENBENDAZOLE. Fenbendazole (Panacur®, Safeguard®, Axilur®) is available in numerous preparations as a paste, suspension, or granules. Side effects with this drug are rare; however, vomiting and diarrhea may occur in small animals. Pancytopenia has been reported in a dog following fenbendazole administration (Gary et al. 2004). The changes were reversible with discontinuation of therapy.

Clinical Use

Dogs. Fenbendazole is effective against *Giardia* organisms in dogs if given at 50 mg/kg BW every 24 hours for 3 days (Zajac et al. 1998). More frequent dosing at 50 mg/kg BW orally every 8 hours was as effective as every 24 hours, and no adverse effects were noted (Barr et al. 1994a).

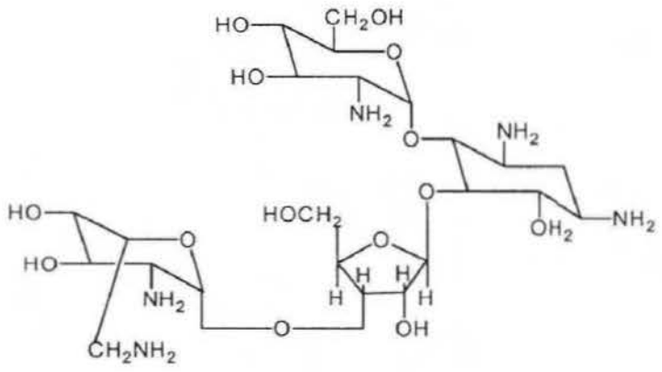
Cats. Fenbendazole at 50 mg/kg BW every 24 hours for 5 days was effective in eliminating the shedding of *Giardia* cysts in 4/8 cats coinfected with *Cryptosporidium* (Keith et al. 2003).

Cattle. Fenbendazole is also effective against *Giardia* organisms in calves when given orally at 5–20 mg/kg BW every 24 hours for 3 days (O'Handley et al. 1997; Xiao et al. 1996).

FEBANTEL. Febantel (Drontal-Plus®) is a benzimidazole available in a combination product with pyrantel pamoate and praziquantel for the treatment of intestinal nematodes and cestodes in dogs and cats. Febantel is metabolized by the liver to fenbendazole and oxfendazole.

Clinical Use

Dogs. This combination has been shown to be effective against canine giardiasis when given orally, once daily for 1–3 days to provide praziquantel (5.4 to 7 mg/kg), pyrantel pamoate (26.8 to 35.2 mg/kg), and febantel (26.8 to 35.2 mg/kg) (Barr et al. 1998; Giangaspero et al. 2002). Strict hygiene to prevent reinfection is imperative to maximize treatment success (Payne et al. 2002).



Cats. The combination product of febantel, pyrantel, and praziquantal was shown to be effective at decreasing *Giardia* cyst shedding in naturally infected kittens at doses of 56.5 mg/kg, 11.3 mg/kg, and 37.8 mg/kg, respectively, orally once a day for 5 days (Scorza et al. 2006). In addition, kittens treated at these doses were resistant to recrudescent shedding of oocysts following administration of methylprednisolone.

AMINOGLYCOSIDES

Spectrum: Giardiasis, luminal amoebiasis, leishmaniasis, cryptosporidiosis

Drugs included: Paromomycin (Fig. 43.4).

PAROMOMYCIN. Paromomycin (Aminosidine®) is an aminoglycoside antibiotic that is produced by *Streptomyces rimosus*. Paromomycin interferes with bacterial protein synthesis by binding to 16S rRNA at the amino-acyl-tRNA binding site, which causes a conformational change and subsequent misreading of the mRNA and inhibition of translocation (Fourmy et al. 1998). Its anti-*Leishmania* mode of action is not known, but it has been suggested that it interferes with parasite mitochondrial activity (Maarouf et al. 1997).

Paromomycin
$(C_{23}H_{45}N_5O_{14})$
[615.65]

FIG. 43.4

Paromomycin is used in the treatment of luminal amoebiasis, leishmaniasis, and cryptosporidiosis. It has also been used in humans for the treatment of resistant giardiasis. It is poorly absorbed following oral administration, which leads to high intestinal luminal concentrations of the drug. Paromomycin has little activity against intestinal bacteria. Side effects include nausea, vomiting, abdominal cramps, and diarrhea. Although little is absorbed from the intestinal tract, it is eliminated via the kidneys, so its use is contraindicated in patients with renal disease. It is possible that in animals with intestinal disease, the mucosal barrier may be breached to produce more systemic absorption and potential for systemic toxicity. This may have contributed to toxicity in four cats in one clinical study (Gookin et al. 1999). It also has the potential to cause reversible and irreversible vestibular, cochlear, and renal toxicity when given parenterally. Paromomycin levels peak in the serum of dogs at 30 μg/ml about 60 minutes after IM or SC administration of a 15 mg/kg BW dose (Belloli et al. 1996). About 4% is bound to serum proteins.

Clinical Use

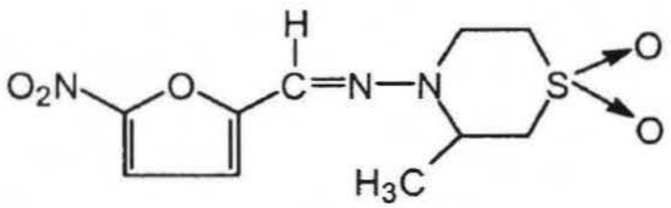
Dogs. Paromomycin given IM at 20 mg/kg BW daily for 15 days will greatly improve clinical signs of visceral leishmaniasis in dogs (Vexenat et al. 1998). However, relapses may occur within 50–100 days. Treatment with 40 mg/kg IM once daily for 30 days may enhance the cure rate of dogs (Vexenat et al. 1998). If paromomycin is administered SC with antimony, there is no effect on the pharmacokinetics of paromomycin but there is a marked effect on the pharmacokinetics of antimony (Belloli et al. 1995). Serum levels of antimony remain higher, and the dose should be adjusted to prevent toxic levels of the metal from appearing in the blood.

Cats. A naturally infected cat with cryptosporidial diarrhea was successfully treated with oral paromomycin given at 165 mg/kg BW orally every 12 hours for 5 days (Barr et al. 1994b). As mentioned previously, it can be toxic in cats if systemic absorption occurs owing to intestinal barrier disruption. It resulted in acute renal failure, deaf-

ness, and hypermature cataract formation when given orally to four cats with *T. foetus* infection at doses as low as 70 mg/kg BW every 12 hours for 4 days (Gookin et al. 1999).

Cattle. For cryptosporidiosis, when administered at 12.5–25 mg/kg PO to calves, it delayed the onset of shedding and decreased the number of oocysts shed, while a dose of 50 mg/kg prevented oocyst shedding. Treatment of calves with oral paromomycin at 50, 25, or 12.5 mg/kg BW twice daily was effective in preventing oocyst production (50 mg/kg dose) or in delaying the onset of oocyst production and in greatly reducing the numbers of oocysts excreted (12.5–25 mg/kg BW doses) when started 1 day before inoculation and continued for 10 days after inoculation (Fayer and Ellis 1993). For giardiasis, a dose of 75 mg/kg orally, once daily for 5 days caused a 100% reduction in cyst shedding at 9 days after initiation of treatment (Geurden et al. 2006).

Goats. Treatment of 2- to 4-day-old goat kids with oral paromomycin at 50 mg/kg BW twice daily for 10 days was effective in preventing cryptosporidiosis (Mancassola et al. 1995).



Paromomycin may also have a role in treating or preventing the spread of cryptosporidiosis outbreaks in calves and goats. The anticryptosporidial activity of paromomycin apparently does not involve trafficking through the host cell cytoplasm but involves movement of the agent through altered apical membranes that surround the developing parasites (Griffiths et al. 1998). Paromomycin does not exert its effects on extracellular stages of *C. parvum* (Griffiths et al. 1998). There are no products containing paromomycin approved for use in food-producing animals in the United States; therefore, all use would be considered extralabel.

NITROFURANS

Spectrum: *Trypanosomas cruzi*

Drugs included: Nifurtimox (Fig. 43.5).

NIFURTIMOX. Nifurtimox (Lampit®) is a nitrofuran derivative that is the most widely used agent for the treatment of human *Trypanosoma cruzi* infections (Van Reken and Pearson 1990) and is effective against natural and experimental disease in dogs (Barr 2006). It is marketed

Nifurtimox
($C_{10}H_{13}N_3O_5S$)
[287.29]

FIG. 43.5

as 100 mg tablets, but in the United States, must be obtained from the Centers for Disease Control. Mutagenicity and carcinogenicity of these compounds have been documented in laboratory animals; therefore, their use in food-producing animals, including the use of topical products, is strictly prohibited by the US FDA. (Legal control of veterinary drugs is discussed in Chapter 56.)

Its likely mode of action is through the production of activated forms of oxygen. It is reduced to the nitro anion radical in the presence of pyridine nucleotides. The anion then reacts with oxygen to produce superoxide and regeneration of nifurtimox (Finch and Snyder 1986). This cycle continues, and the activated oxygen molecules exert their toxic effects on the parasites. This cycle is thought to be initiated by the enzyme trypanothione reductase. It has activity against amastigote and trypomastigote stages.

In human beings, nifurtimox is well absorbed after oral administration, but only low concentrations of the parent compound are found in the plasma and little is found in the tissues or urine (Webster 1990). It is excreted in the urine in the form of metabolites. Adverse side effects occur in up to 50% of human beings treated and are associated with GI and central nervous system signs.

Clinical Use

Dogs. Canine *T. cruzi* infections are treated with 2–7 mg/kg BW nifurtimox orally at 6-hour intervals for 3–5 months (Barr 2006). This is effective in preventing death from acute disease and extending life, but most dogs will still develop chronic cardiac disease, which is usually fatal (Barr 2006). Improved survival has been shown in dogs

concurrently treated with antiinflammatory doses of glucocorticoids (Andrade et al. 1980).

TETRACYCLINES

Spectrum: Amoebae, flagellates, piroplasms, ciliates

Drugs included: Oxytetracycline, chlortetracycline, doxycycline

Tetracyclines represent a broad group of antiprotozoal agents, some of which have activity against amoebae, mucosal flagellates, piroplasms, and ciliates. (Chapter 35 of this book has more detailed description of the pharmacology of tetracyclines.)

Clinical Use

Cattle. A long-acting formulation of oxytetracycline (LA/200) is useful in prophylaxis of bovine *Babesia divergens* infection if 20 mg/kg BW is given IM every 4 days for 3 weeks after exposure; 10–15 mg/kg BW given IM every 4 days causes moderation in the clinical signs (Kuttler 1988). Tetracyclines can also be used to treat *Theileria* infections in cattle but are less effective and must be given in large doses early in the infection and used for longer periods of treatment. Product label for chlortracycline medicated feed includes control if active infection is caused by *Anaplasma marginale*. Oxytetracycline has been used in cattle for treatment of *Anaplasma marginale* infections. However, efficacy has been questionable. One study compared enrofloxacin (5 mg/kg IV q24h for 5 days), imidocarb (5 mg/kg IM twice, 7 days apart), or oxytetracycline (22 mg/kg IV q24h for 5 days) for elimination of persistent *Anaplasma marginale* infections in cattle. None of the tested treatments reliably eliminated persistent *A. marginale* infections in all cattle (Coetzee et al. 2006).

Horses. Chlortetracycline may be effective against *Babesia equi* infection in horses if 0.5–2.6 mg/kg BW is given IV daily for 6 days early in the infection (Kuttler 1988).

Dogs. Doxycycline is effective at preventing clinical manifestations of *Babesia canis* infection if given at 10 mg/kg BW twice daily for 11 days (Vercammen et al. 1996).

HYDROXYQUINOLONES AND NAPHTHOQUINONES

Spectrum: *Coccidia*, *Babesia* sp., *Hepatozoon americanum*, *Theileria* sp., *Cytauxzoon* sp., *T. gondii*, *Eimeria* sp., malaria, *Pneumocystis carnii*.

Drugs included: Decoquinate, atovaquone, parvaquone, buparvaquone (Fig. 43.6).

The quinolone anticoccidials inhibit coccidial respiration by interfering with cytochrome-mediated electron transport in the parasites' mitochondria. The site of action of quinolone anticoccidials is probably within the bc1 complex, where the electrons are transferred from ubiquinone to cytochrome c. These compounds are coccidiostatic and allow penetration of sporozoites, but not development. These inhibited sporozoites have the ability to resume development after the agents are removed. Little anticoccidial immunity develops in chickens on these medications.

DECOQUINATE. Decoquinate (Deccox®) is one of the quinolone (4-hydroxyquinolones) anticoccidials. It is poorly absorbed from the intestinal tract, and what is absorbed is rapidly cleared from the blood and tissues. Recent evidence indicates that decoquinate can have an anticoccidial effect on first-generation schizonts of *E. tenella*, adversely affect sporulation, and permit the development of immunity if fed at levels that are lower than its coccidiostatic levels (Williams 1997). Activity against cryptosporidium has also been demonstrated in cattle and sheep.

Clinical Use

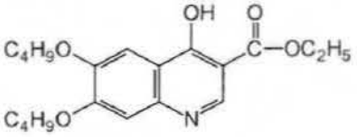
Chickens. Decoquinate is used for prevention of coccidiosis in broilers. It should be fed for at least 28 days when development of coccidiosis is likely. Do not feed to laying chickens. No withdrawal is required.

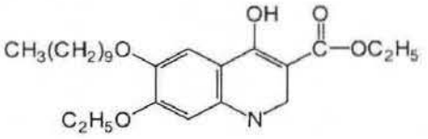
Cattle. In cattle, decoquinate is used to prevent coccidiosis when fed for at least 28 days, but it is prohibited to feed to lactating dairy cows. In beef cattle, no withdrawal time is required.

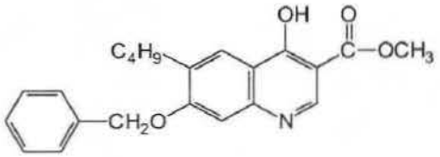
For treatment of cryptosporidiosis, doses of 2 mg/kg were not effective at decreasing oocyst shedding or clinical signs in experimentally challenged calves (Moore et al. 2003). However, treatment of pregnant cows with 1.25 mg/kg/day in the feed for 30 days prior to and for 8 days after parturition prevented clinical signs in the calves

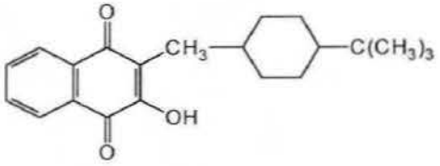
Sheep. Decoquinate is fed to sheep to provide 0.5 mg/kg BW for at least 28 days to prevent coccidiosis. Do not feed to sheep producing milk for human consumption. No withdrawal is required.

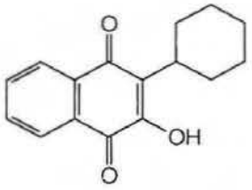
Goats. Decoquinate is fed to goats to provide 0.5 mg/kg BW for at least 28 days to prevent coccidiosis. Do not feed

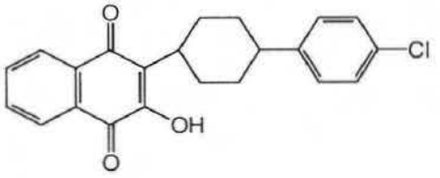












Name	Chemical name (Empirical formula) [Molecular weight]	Chemical structure
Buquinolate	4-hydroxy-6,7-diisobutoxy-3-quinolinecarboxylic acid ethyl ester ($C_{26}H_{37}NO_5$) [361.42]	
Decoquinate	6-declyoxy-ethoxy-4-hydroxy-3-quinolinecarboxylic acid ethyl ester ($C_{24}H_{35}NO_5$) [417.53]	
Nequinate	7-(benzyloxy)-6-*n*-butyl-1,4-dihydro-4-oxo-3-quinoline-carboxylic acid methyl ester ($C_{22}H_{23}NO_4$) [365.43]	
Buparvaquone	2-*trans*(4-*t*-butylcyclohexyl)methyl-3-hydroxy-1,4-naphthoquinone ($C_{21}H_{26}O_3$) [326.44]	
Parvaquone	2-cyclohexyl-3-hydroxy-1,4-naphthoquinone ($C_{16}H_{16}O_3$) [256.30]	
Atovaquone	2-[*trans*-4-(4-chlorophenyl)cyclohexyl]-3-hydroxy-1,4-naphthoquinone ($C_{22}H_{19}ClO_3$) [366.69]	

FIG. 43.6 Hydroxyquinolones and naphthoquinones.

to goats producing milk for human consumption. No withdrawal is required.

Dogs. For preventing clinical relapses of *Hepatozoon americanum* infection, decoquinate feed additive (27.2 grams decoquinate per pound of premix) can be added to moist dog food at a rate of 0.5–1.0 tablespoons per 10 kg BW twice a day (Macintire et al. 2001).

ATOVAQUONE. Atovaquone (Mepron® suspension) is a hydroxyquinolone that has broad-spectrum antiprotozoal activity. It is a yellow crystalline solid that is practically insoluble in water. Atovaquone is supplied as a bright yellow suspension of microfine particles at a concentration of 150 mg atovaquone/ml. It is highly lipophilic and administering it with food increases its absorption twofold. It was originally developed for human use to treat drug-

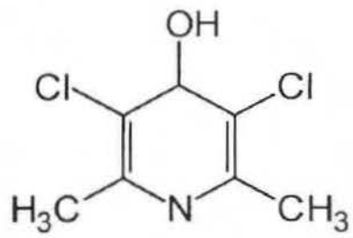
resistant strains of malaria and *Pneumocystis carinii* pneumonia. It is discussed here because it was also found to have excellent activity against *T. gondii* and *Babesia* sp. It also has activity against *Eimeria* spp. Atovaquone is thought also to work via inhibition of electron transport at the mitochondrial bc1 complex because cross-resistance often develops between atovaquone and decoquinate (Pfefferkorn et al. 1993).

Clinical Use

Dogs. Atovaquone (13.3 mg/kg PO q8h) administered concurrently with azithromycin (10 mg/kg PO q24h) for 10 consecutive days was shown to completely eliminate *Babesia gibsoni* infection from 8 of 10 dogs treated (Birkenheuer et al. 2004). The dogs in that study had previously been treated unsuccessfully with imidocarb or diminazene.

PARVAQUONE AND BUPARVAQUONE. Parvaquone (Clexon®) and buparvaquone (Butalex®) are naphthoquinones that are used for the treatment of theileriosis. They act on the macroschizonts and intraerythrocytic piroplasms.

Theileriosis is a severe disease of cattle in Africa and is caused by *Theileria parva*, a piroplasm. Several *Theileria* spp. infect wild ruminants in the United States, but none of these causes serious illness.



Clinical Use

Cattle. Parvaquone is administered IM at 20 mg/kg BW as a single treatment for theileriosis. Buparvaquone is given IM at 2.5 mg/kg BW for 1–2 treatments. Both drugs are considered curative for *Theileria* infections in cattle.

Cats. Parvaquone and buparvaquone have been used to treat *Cytauxzoon felis* infections in cats, although their efficacy is questionable (Kier 1990).

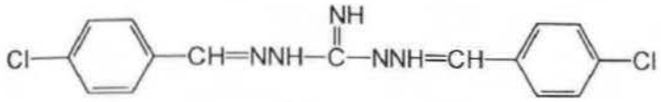
PYRIDINOLS

Spectrum: Coccidiosis, *Leucocytozoon* sp.
Drugs included: Clopidol (Fig. 43.7)

Clopidol
($C_7H_7Cl_2NO$)
[192.06]

FIG. 43.7

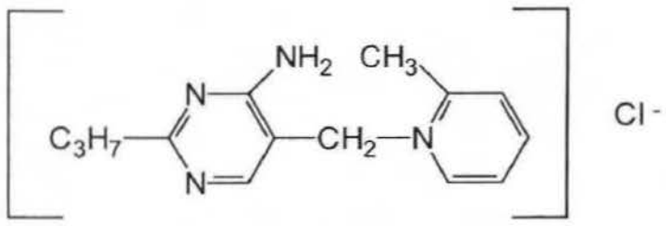
CLOPIDOL. Clopidol (Coyden 25®) is the only pyridinol to be used as an anticoccidial. It is practically insoluble in water. It is active against the sporozoite stage, allowing host cell penetration but not parasite development. It also has activity against second-generation schizogony, gametogony, and sporulation. Sporozoites can resume development after the medication is removed. Little anticoccidial immunity develops in chickens receiving this agent. Long (1993) suggested that the mode of action of clopidol was similar to that of the quinolone anticoccidials because of similar structure and biological activity of the agents. However, cross-resistance between clopidol and quinolone anticoccidials does not occur (Long 1993).



Clinical Use

Chickens and Turkeys. Clopidol is fed at 0.0125–0.0250% for prevention of coccidiosis. A 5-day withdrawal is required if the 0.0250% level is used. This level may be lowered to 0.0125% 5 days before withdrawal and fed. Clopidol is transmitted to the eggs of hens that are fed clopidol-containing diets (Long 1971). Clopidol is used for prevention of coccidiosis in turkeys and fed at 0.0125–0.0250%. A 5-day withdrawal is required. Clopidol is also approved for the prevention of *Leucocytozoon smithi* infections in turkeys when fed at its anticoccidial levels.

GUANIDINE DERIVATIVES



Spectrum: Coccidiosis.
Drugs included: Robenidine (Fig. 43.8).

ROBENIDINE. Robenidine (Cycostat®, Robenz®) is a synthetic anticoccidial derivative of guanidine. It is active

Robenidine
($C_{15}H_{13}Cl_2N_5$)
[334.21]

FIG. 43.8

Amprolium
($C_{14}H_{19}ClN_4$)
[278.78]

FIG. 43.9

against the first-generation schizont of *E. tenella* by preventing formation of merozoites. Feeds with robenidine should not be fed to laying hens, as studies have shown that robenidine is transmitted to the eggs (Long et al. 1981), and these eggs may have an unpleasant taste even though the ability of humans to taste robenidine is apparently under genetic control. It does not have any other adverse effects on egg production or quality.

Clinical Use

Chickens. Robenidine is used for the prevention of coccidiosis in chickens. Finish feeds must be fed within 50 days of manufacture. Do not feed with bentonite clays. A 5-day withdrawal is required. If robenidine is not withdrawn 5 days before slaughter, the flesh of medicated birds will have an unpleasant taste.

THIAMINE ANALOGUES

Spectrum: Coccidiosis.

Drugs included: Amprolium (Fig. 43.9).

AMPROLIUM. Amprolium (Corid®, Amprol®) is labeled for use in the United States as a preventative and treatment of *Eimeria* infections in chickens, turkeys, pheasants, and calves. It is one of the most commonly administered anticoccidia agents in veterinary medicine. It is structurally related to the vitamin thiamine and the antiparasitic activity of the drug is thought to be related to competitive inhibition of active thiamine transport into the parasite. There is a fiftyfold greater sensitivity of the parasite system compared with the host system.

Amprolium is freely soluble in water. Because amprolium lacks the hydroxyethyl function of thiamine it is not phosphorylated to a pyrophosphate analog (Looker et al. 1986). Amprolium acts on the first-generation schizont to prevent merozoite production and has some activity against sexual stages and the sporulating oocyst. Amprolium-resistant strains of chicken and turkey *Eimeria* spp. are prevalent. Amprolium is often combined with other agents to increase activity.

Clinical Use

Chickens and Turkeys. Amprolium is used for the prevention of coccidiosis in chickens as a feed additive or in the drinking water. No withdrawal is required. Amprolium is used for the treatment and prevention of coccidiosis in turkeys when fed continuously.

Pheasants. Amprolium is approved for use in the prevention of coccidiosis in pheasants and is fed continuously. It must not be used in feeds containing bentonite.

Cattle. Amprolium is given to calves in the feed, drinking water, or orally at 5 mg/kg BW for 21 days to prevent coccidiosis or at 10 mg/kg BW for 21 days to treat coccidiosis.

Dogs. In dogs, amprolium can be used for the treatment of coccidiosis at 100–200 mg total dose (20% powder) orally once a day for 7–12 days. Amprolium is also used in the drinking water (sole source) at 30 ml (9.6% solution)/gal for up to 10 days or in the food at 250–300 mg (20% powder) once a day for 7–12 days.

Cats. Amprolium can be used for the treatment of coccidiosis at 110–220 mg/kg orally once a day for 7–12 days. Amprolium is also used in the drinking water (sole source) at 1.5 teaspoons (9.6% solution)/gal for up to 10 days.

Amprolium can be combined with sulfadimethoxine and used for the treatment of coccidiosis at 150 mg/kg BW amprolium and 25 mg/kg BW sulfadimethoxine once a day for 14 days.

NITROBENZAMIDES

Spectrum: Coccidiosis.

Drugs included: Aklomide, dinitolmide. (Fig. 43.10)

AKLOMIDE AND DINITOLMIDE. Aklomide and dinitolmide (Zoamix®) are nitrobenzamide anticoccidial agents. These agents act primarily on the first-generation schizonts, and dinitolmide inhibits sporulation of oocysts (Mathis and McDougald 1981). Dinitolmide is coccidiostatic if given for 6 days but is coccidiocidal if given for longer periods (Long 1993). Nitrobenzamide-resistant strains of coccidia are common. The anticoccidial mode of action of nitrobenzamides is not known.

Aklomide is not currently marketed as a single agent or combined with other anticoccidial drugs in the United States.

Clinical Use

Chickens and Turkeys. Dinitolmide is fed as a single agent to prevent coccidiosis in chickens. Do not feed to layers or birds over 14 weeks of age. Dinitolmide is also approved for use in nonlaying turkeys in feed in birds up to 14–16 weeks of age. Combination products are also available.

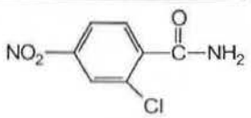
NICARBAZIN

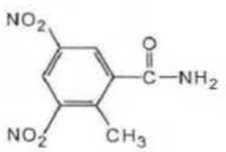
Spectrum: Coccidiosis.

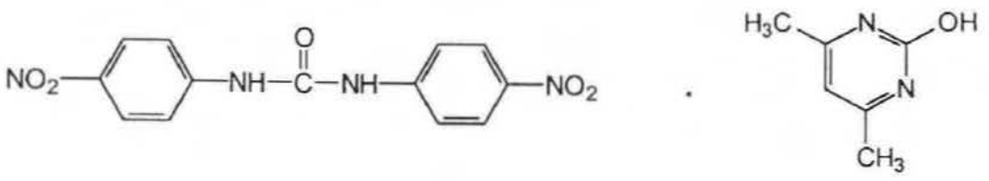
Nicarbazin (Nicarb®, Cycarb®) is an equimolecular complex of 4,4′-dinitrocarbanilide and 2-hydroxy-4,6-dimethylpyrimidine (Fig. 43.11). The agents are absorbed separately from the digestive tract, and both are needed for anticoccidial activity. Dry crystals are strongly electrostatic and present some dry-mixing problems. The precise mode of action of nicarbazin is not known. Nicarbazin causes reduced egg production, depressed egg weight, and reduced eggshell thickness and egg-yolk mottling when fed to white leghorn layers at 125 ppm (Jones et al. 1990). It also causes poor hatchability and depigmentation of brown-shelled eggs. Nicarbazin is usually restricted in use to the starting period because of potential growth-suppressing effects and to cooler months of the year because of its potential to enhance the effects of heat distress (McDougald 1993).

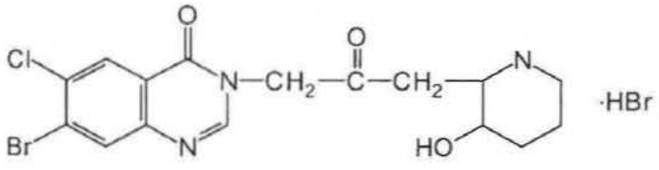
Clinical Use

Chickens. Nicarbazin is fed for the prevention of coccidiosis. Do not feed to laying hens. Do not use for treatment of coccidiosis. A combination of narasin and nicarbazin (Maxiban®) is available for prevention of coccidiosis in broilers. It is for broilers only and should not be fed to other types of chickens. The use of this combination has been associated with increased mortality of broilers in times of heat distress. Feed containing this combination may cause fatalities in horses that ingest it, and it should not be fed to adult turkeys.









Name	Chemical name (Empirical formula) [Molecular weight]	Chemical structure
Aklomide	2-chloro-4-nitrobenzamide ($C_7H_5ClN_2O_3$) [200.60]	
Dinitolmide	2-methyl-3,5-dinitrobenzamide ($C_8H_7N_3O_5$) [225.16]

Halofuginone
$(C_{16}H_{18}Br_2ClN_3O_3)$
[495.50]

FIG. 43.12

ALKALOIDS

Spectrum: Coccidiosis, theileriosis.

Drugs included: Halofuginone (Figure 43.12).

HALOFUGINONE. Halofuginone (Stenerol®) is an alkaloid originally isolated from the plant *Dichroa febrifuga*. Halofuginone is active against the asexual stages of coccidia. Its anticoccidial mode of action is not known. Halofuginone is transmitted to eggs from hens that have been fed halofuginone for 1 week (Long et al. 1981), but no adverse effects on egg production or egg quality have been associated with administration (Jones et al. 1990). Halofuginone has been associated with skin tears in chickens, and it has been shown to be an inhibitor of collagen type I synthesis in avian and mammalian cells (Granot et al. 1993). Halofuginone is toxic to fish and other aquatic life and must not be fed to waterfowl. Halofuginone is a skin and eye irritant and appropriate precautions (such as protective clothing) should be taken when handling this agent.

Clinical Use

Chickens and Turkeys. Halofuginone is used for the prevention of coccidiosis in chickens when administered in feed. Do not feed to layers. Halofuginone is also approved for the prevention of coccidiosis in growing turkeys.

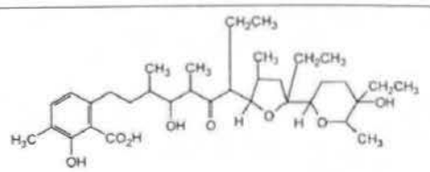
Cattle. In cattle, halofuginone is given orally at 1–2 mg/kg BW for a single treatment and is curative for *Theileria* infections. At 2 mg/kg BW transient diarrhea may occur.

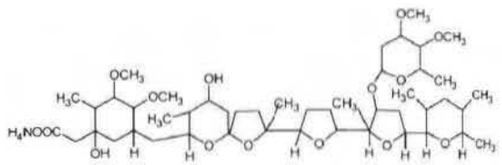
POLYETHER IONOPHORES

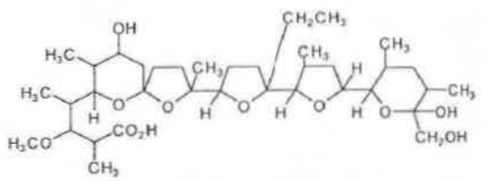
Spectrum: Coccidiosis.

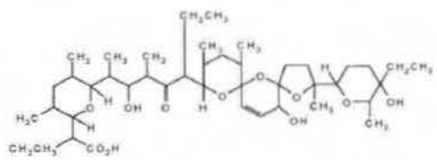
Drugs included: Lasalocid, maduramicin, monensin, narasin, semduramicin, salinomycin (Fig. 43.13).

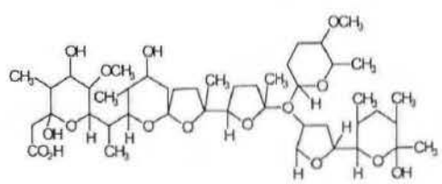
The polyether ionophore antibiotics were first discovered in the early 1950s, and their anticoccidial activities were recognized in the late 1960s. Because of their broad spectrum of activity and the development of drug resistance to other agents, the ionophores gained widespread usage in the poultry industry soon after their introduction. Polyether ionophores fall into one of five classes: monovalent, monovalent glycosides, divalent, divalent glycosides,











Name	Chemical name (Empirical formula) [Molecular weight]	Chemical structure
Lasalocid	6-[7*R*-[5*S*-Ethyl-5-(5*R*-ethyltetra-hydro-5-hydroxy-6 *S*-methyl-2*H*-pyran-2*R*-yl) tetrahydro-3*S*-methyl-2*S*-furanyl]-4*S*-hydroxy-3*R*,5*S*-dimethyl-6-oxonon-yl]-2-hydroxy-3-methylbenzoic acid ($C_{34}H_{54}O_8$) [590.80]	
Maduramicin	(3*R*,4*S*,5*S*,6*R*,7*S*,22*S*)-23,27-Didemethoxy-2,6,22-tridemethyl-11-*O*-demethyl-22-[(2,6-dideoxy-3,4-di-*O*-methyl-β-Larabino-hexopyranosyl)oxy]-6-methyloxylonomycin A monoammonium salt ($C_{47}H_{83}NO_{17}$) [934.17]	
Monensin	2-[5-Ethyltetrahydro-5-[tetrahydro-3-methyl-5-[tetrahydro-6-hydroxy-6-(hydromethyl)-3,5-dimethyl-2*H* -pyran-2-yl]-2-furyl]-2-furyl]-9-hydroxy-β-methoxy-α, γ, 2,8-tetramethyl-1,6-dioxaspiro [4.5] decane-7-butyric acid ($C_{36}H_{62}O_{11}$) [670.90]	
Narasin	(αβ,2β,3α,5α,6α)-α-ethyl-6-[5-[5-(5α-ethyltetrahydro-5β-hydroxy-6α-methyl-2*H*-pyran-2β-yl)-3″α,4,4″,5,5″α,6″-hexahydro-3′β-hydroxy-3″β,5α,5″β-trimethylspiro] furan-2(3*H*),2′-[2*H*]pyran-6′(3′*H*),2″-[2*H*]pyran]6″α-yl]2α-hydroxy-1α,3β-dimethyl-4-oxoheptyl]-tetrahydro-3,5-dimethyl-2*H*-pyran-2-acetic acid ($C_{43}H_{72}O_{11}$) [765.05]	
Semduramicin	(2*R*,3*S*,4*S*,5*R*,6*S*)-tetrahydro-2,4-dihydroxy-6-[(1*R*)-1-[(2*S*,5*R*,7*S*,8*R*,9*S*)-9-hydroxy-2,8-dimethyl-2-[(2*R*,6*S*)-tetrahydro-5-methyl-5-[(2*R*,3*S*,5*R*)-tetrahydro-5[(2*S*,3*S*,5*R*,6*S*)-tetrahydro-6-hydroxy-3,5,6-trimethyl-2*H*-pyran-2-yl]-3-[[(2*S*,5*S*,6*R*)-tetrahydro-5-methoxy-6-methyl-2*H*-pyran-2-yl]oxy]-2-furyl]-2-furyl]-1,6-dioxaspirol [4.5]dec-7-yl]ethyl]-5-methoxy-3-methyl-2*H*-pyran-2-acetic acid ($C_{44}H_{77}O_{16}$) [748.47]	

FIG. 43.13 Ionophores antibiotics.

or divalent pyrole ethers. The mode of action of ionophores is related to their ability to form lipophilic complexes with alkali metal cations and to transport these cations across biological membranes. Different ionophores may produce varying affinities for different cations. Ionophores that have anticoccidial activity are thought to act against extracellular sporozoites and merozoites. Extracellular stages develop membrane blebs indicating alterations in membrane integrity and in internal osmolality. Because coccidia have no osmoregulatory organelles, this change in internal osmotic conditions damages the parasites.

Because of the unique mode of action of ionophores, development of anticoccidial resistance to ionophores was difficult to produce under experimental conditions and slow to develop after clinical use in the field. In the mid- to late 1980s ionophore-resistant strains of chicken *Eimeria* spp. were documented in the United States, and ionophore resistance is now common. Cross-resistance between ionophores is common, although strain differences in coccidial response to specific ionophores have been demonstrated. In general, resistance to a monovalent polyether ionophore confers some cross-resistance to other monovalent polyether ionophores, but susceptibility to monovalent monoglycoside and divalent polyether ionophores may be retained.

Ionophores are potentially toxic for highly susceptible species, such as horses and other equines, and guinea fowl. Clinical signs occur from acute myocardial and muscle degeneration. Sweating, colic, and ataxia with hindlimb paresis/paralysis are also noted. Pathologically, focal degenerative cardiomyopathy, skeletal muscle necrosis, and congestive heart failure may be noted. Ionophore toxicosis can be potentiated with concurrent administration of tiamulin, chloramphenicol, macrolides, sulfonamides, and cardiac glycosides (Novilla 1992; Mitema et al. 1988). Exposure to horses is usually accidental, or resulting from horses gaining access to medicated feed. Care should always be taken to prevent highly susceptible animals from gaining access to feeds containing these products.

LASALOCID. Lasalocid (Avatec®, Bovatec®) is a divalent polyether ionophore that is a fermentation product of *Streptomyces lasaliensis* and was the second ionophore marketed in the United States. Lasalocid is well tolerated when fed with tiamulin (Meingasser et al. 1979). Lasalocid is transmitted to eggs of hens that have been fed this medication for 1 week.

Clinical Use

Chickens and Turkeys. Lasalocid is fed for the prevention of coccidiosis in chickens. Lasalocid is also approved for the prevention of coccidiosis in growing turkeys.

Chukar Partridges. Lasalocid is approved for the prevention of coccidiosis in chukar partridges and is fed until the birds are 8 weeks old.

Cattle. In cattle, lasalocid is used to prevent coccidiosis and is fed at 1 mg/kg BW, with a maximum of 360 mg/animal/day. Do not use in breeding animals.

Sheep. Lasalocid is fed in the ration to sheep to provide 15–70 mg/animal/day and is used in the prevention of coccidiosis. Do not administer to breeding animals.

Rabbits. Lasalocid is approved for use in the prevention of hepatic coccidiosis in rabbits and is fed until the rabbits are 6.5 weeks old.

MADURAMICIN. Maduramicin (Cygro®) is a monovalent monoglycoside polyether ionophore that is a fermentation product of *Actinomadura yumaense*. Maduramicin does not adversely affect egg production or egg quality (Jones et al. 1990). Maduramicin is well tolerated when fed with tiamulin (Meingasser et al. 1979). At higher doses (≥6 ppm), an adverse effect on growth and feathering may occur.

Clinical Use

Chickens. Maduramicin is used for the prevention of coccidiosis in broilers and fed at 5 ppm. It is for broilers only and should not be fed to other types of chickens.

MONENSIN. Monensin (Coban®, Rumensin®) is a monovalent polyether ionophore that is a fermentation product of *Streptomyces cinnamonensis*. Tiamulin may interfere with the metabolism of monensin in chickens and cause weight suppression (Meingasser et al. 1979). Monensin is apparently not transmitted to eggs of hens fed monensin for 1 week, nor does it adversely affect egg production or quality. Mature turkeys and guinea fowl should not have access to monensin-containing diets. Monensin will cause deaths in horses and guinea fowl that ingest feeds containing it.

Clinical Use

Chickens and Turkeys. Monensin is fed for prevention of coccidiosis in broilers. Do not feed to layers or chickens over 16 weeks of age. Monensin is used for prevention of coccidiosis in turkeys. Do not feed to turkeys over 10 weeks old.

Bobwhite Quail. Monensin is approved for use in bobwhite quail for prevention of coccidiosis and is fed at 73 g/ton from 1 day to 10 weeks old.

Cattle. In cattle, monensin is used to prevent coccidiosis and is fed to provide 100–360 mg/animal/day. It has recently been approved for use in dairy cattle as well, with a zero meat and milk withdrawal time.

Goats. Monensin is fed at 20 g/ton for the prevention of coccidiosis in confinement-reared goats. Do not feed to goats producing milk for human consumption.

NARASIN. Narasin (Monteban®) is a monovalent polyether ionophore that is a fermentation product of *Streptomyces aureofaciens*. It is structurally similar to salinomycin, differing only in the presence of a methyl group in narasin that is not present in salinomycin. It does not adversely affect egg production or egg quality. Narasin may cause fatalities in horses that ingest it, and it should not be fed to adult turkeys. Tiamulin may interfere with the metabolism of narasin in chickens and cause weight suppression (Meingasser et al. 1979).

Clinical Use

Chickens. Narasin is a feed additive for the prevention of coccidiosis in broilers. It is for broilers only and should not be fed to other types of chickens.

SEMDURAMICIN. Semduramicin (Aviax®) is a monovalent monoglycoside polyether ionophore that is a fermentation product of a mutant of *Actinomadura roseorufa* (Ricketts et al. 1992). The parent produced a diglycoside form of semduramicin that had to be semisynthetically modified. Both forms of the monoglycoside agent have identical activity. It is well tolerated when coadministered with tiamulin (Ricketts et al. 1992).

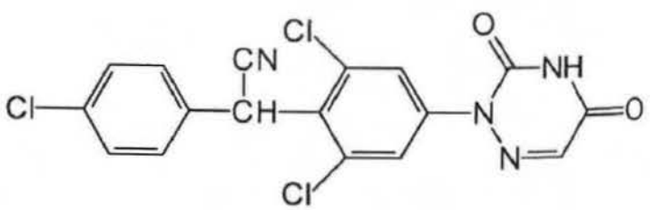
Clinical Use

Chickens. Semduramicin is used as a feed additive for prevention of coccidiosis in broiler chickens.

SALINOMYCIN. Salinomycin (Bio-Cox®) is a monovalent polyether ionophore that is a fermentation product of *Streptomyces albus* and was the third ionophore marketed in the United States. Salinomycin is active against sporozoites and early and late asexual stages of chicken coccidia (Conway et al. 1993). Salinomycin does not adversely affect egg production or egg quality. Tiamulin may interfere with the metabolism of salinomycin in chickens and cause weight suppression (Meingasser et al. 1979). It is not for use with pellet binders such as bentonite clays. Salinomycin will cause deaths in horses and adult turkeys that ingest feeds containing it.

Clinical Use

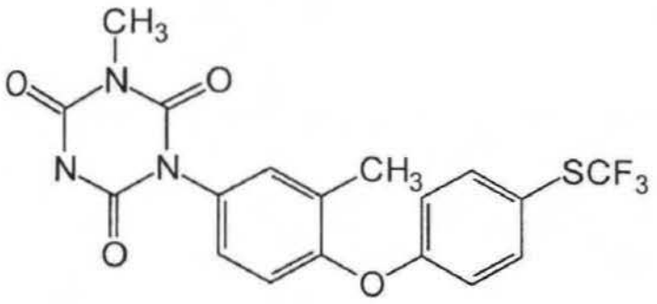
Chickens. Salinomycin is fed for prevention of coccidiosis in broilers. Do not feed to layers.



Bobwhite Quail. Salinomycin is approved for prevention of coccidiosis in bobwhite quail when administered in feed.

TRIAZINE DERIVATIVES

Spectrum: *Sarcocystis neurona*, coccidiosis, toxoplasmosis, *Neospora caninum*.



Drugs included: Diclazuril, toltrazuril, ponazuril (Figs. 43.14, 43.15).

The triazine antiprotozoal drugs act on the apicoplast, a plastid obtained by endosymbiosis that is present in apicomplexan parasites, but is not present in the vertebrate host. The exact function of the apicoplast is not known; however, it may play a vital role in biosynthesis of amino acids and fatty acids, assimilation of nitrate and sulfate, and starch storage, as has been demonstrated for other plastid organelles (Kühler et al. 1997; Fichera and Roos 1997).

Diclazuril
($C_{17}H_9Cl_3N_4O_2$)

FIG. 43.14

Toltrazuril
$(C_{18}H_{14}F_3N_3O_4S)$
[425.38]

FIG. 43.15

DICLAZURIL. Diclazuril (Clinicox®) is a benzeneacetonitrile that has potent anticoccidial activity when fed at low levels in the feed.

Clinical Use

Horses. Diclazuril has been used as a treatment for equine protozoal myelitis (EPM). Doses of 5 mg/kg (equivalent to 500 gm Clinicox®/horse) have been successful in improving clinical signs of EPM using a shorter duration of treatment (30 days) compared to standard therapy with combinations of sulfonamides and pyrimethamine (90–120 days). Due to the large volume of drug to be administered, some horses have to be given the drug via a nasogastric tube, which makes treatment inconvenient and difficult. A recent study examined the pharmacokinetics of a sodium salt of diclazuril administered orally to horses (Dirikolu et al. 2006). This formulation had a higher oral bioavailability compared to the conventional powder or the conventional powder mixed with DMSO. This product was also able to be administered as a feed additive.

Chickens. Diclazuril is approved for use in broilers as a preventative for coccidiosis. There are several other combination products available as well. The withdrawal times can vary, depending on the product. This drug is not approved for use in laying hens.

Turkeys. Diclazuril is approved for use in the prevention of coccidiosis in turkeys. It is also available combined with bacitracin. These products should not be fed to breeding turkeys or layers.

Rabbits. When fed at 1–2 ppm continuously in pelleted feed, diclazuril was effective in controlling the clinical signs of intestinal coccidiosis in experimentally infected rabbits (Vanparijs et al. 1989).

TOLTRAZURIL. Toltrazuril (Baycox®) is a triazinon drug that has broad-spectrum anticoccidial and antiprotozoal activity. It is not commercially available in the United States. It is active against both asexual and sexual stages of coccidia by inhibiting nuclear division of schizonts and microgamonts and the wall-forming bodies of macrogamonts. It may also be useful in the treatment of neonatal porcine coccidiosis, EPM, and canine hepatozoonosis.

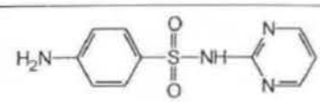
Clinical Use

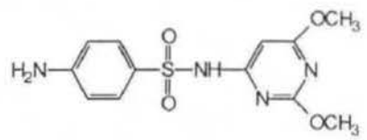
Swine. Toltrazuril has been shown to reduce the signs of coccidiosis in naturally infected nursing pigs when a single oral 20–30 mg/kg BW dose is given to 3- to 6-day-old pigs (Driesen et al. 1995). Clinical signs were reduced from 71 to 22% of nursing pigs, and diarrhea and oocyst excretion were also decreased by the single oral treatment.

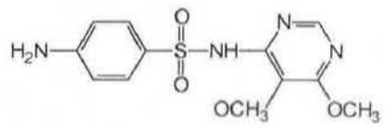
Dogs. For hepatozoonosis, toltrazuril given orally at 5 mg/kg BW every 12 hours for 5 days or given orally at 10 mg/kg BW every 12 hours for 10 days caused remission of clinical signs in naturally infected dogs in 2–3 days (Macintire et al. 2001). Unfortunately, most treated dogs relapsed and eventually died from hepatozoonosis.

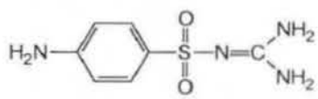
Horses. Toltrazuril has also been used for the treatment of EPM. It has a better bioavailability and is easier to use when compared to diclazuril. This drug is safe, even at high doses. Current recommended treatments are 5–10 mg/kg orally for 28 days. Despite the favorable efficacy with toltrazuril, its use has diminished in horses because of better availability of other effective drugs (see Ponazuril below).

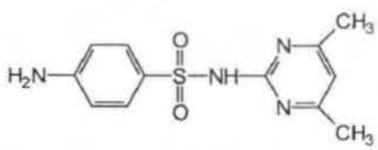
PONAZURIL. Ponazuril (Marquis®) also known as toltrazuril sulfone, is an active metabolite of toltrazuril; therefore, its mechanism of action is identical to that of toltrazuril. It is available in a paste formulation for horses.

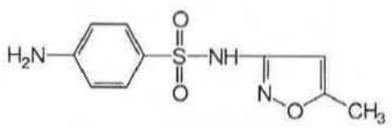


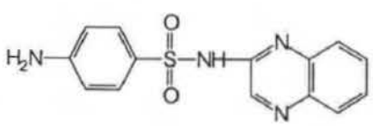


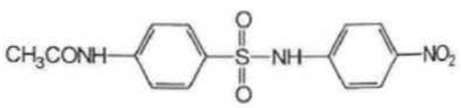












Name	Chemical name (Empirical formula) [Molecular weight]	Chemical structure

FIG. 43.16 Sulfonamides.

Clinical Use

Horses. Ponazuril is approved for use in horses as a treatment for EPM at a dose of 5 mg/kg orally for 28 days. Treatment can be extended for another 28 days if no improvement is seen. No side effects have been noted.

Cattle. Ponazuril has been shown to be effective at a dose of 20 mg/kg orally once a day for 6 days in calves experimentally infected with *Neospora caninum.*

SULFONAMIDES

Spectrum: Coccidiosis.

Drugs included: Sulfaguanidine, sulfadiazine, sulfadimethoxine, sulfadoxine, sulfamethazine (syn. sulfadimidine), sulfamethoxazole, sulfanitran, and sulfaquinoxaline (Fig. 43.16).

Sulfonamides were the first effective anticoccidials used. Sulfonamides can be either coccidiostatic or coccidiocidal. The pharmacology of sulfonamides is also discussed in Chapter 33 of this book. The structure of sulfonamides is similar to para-aminobenzoate (para-aminobenzoic acid, PABA), which is required by bacteria in the synthesis of folate (folic acid). Sulfonamides interfere in the early phases of folate synthesis. Mammalian and avian cells use preformed folate and are therefore not affected by the sulfonamide treatments. Sulfonamides are often used in combination with dihydrofolate reductase/thymidylate synthase (DHFR/TS) inhibitors because of the observed synergistic effects due to activity at two places in folate biosynthesis. Sulfonamides have most activity against the asexual stages and lesser activity against the sexual stages of coccidia.

Sulfonamides used in veterinary medicine for the treatment or prevention of coccidia and coccidialike parasites include sulfaguanidine, sulfadiazine, sulfadimethoxine, sulfadoxine, sulfamethazine (in some countries called *sulfadimidine*), sulfamethoxazole, sulfanitran, and sulfaquinoxaline. Many are used in combination with other products that have antibacterial or growth-promoting properties. Combinations with trimethoprim or ormetoprim are discussed in the next section.

Clinical Use

Chickens and Turkeys. Sulfamethazine is approved for use in chickens and turkeys for the treatment of coccidiosis when administered in drinking water. Sulfamethazine should not be administered to animals producing eggs for human consumption.

Cattle. Sulfamethazine is used to treat coccidiosis in calves by oral administration of a single dose of 100 milligrams of sulfamethazine per pound of body weight the first day and 50 milligrams per pound of body weight on each following day, not to exceed 5 days. Other formulations are also available. Do not feed to preruminating calves or lactating dairy cattle. Sulfaquinoxaline can be administered in the drinking water for 3 to 5 days. Treated animals must actually consume enough medicated water to provide 6 mg per pound body weight per day. Do not feed to calves to be slaughtered under 1 month old or use in lactating dairy cattle.

Dogs and Cats. Several agents have been used for the treatment of intestinal coccidiosis in dogs and cats (Lindsay et al. 1997a), but only sulfadimethoxine is approved by the FDA for this usage. Sulfadimethoxine is used for treatment of coccidiosis in dogs and cats at 55 mg/kg BW for 1 day, and then 27.5 mg/kg BW once a day for 14–20 days.

Rabbits. Sulfaquinoxaline is used in the feed of rabbits for 30 days for treatment of coccidiosis.

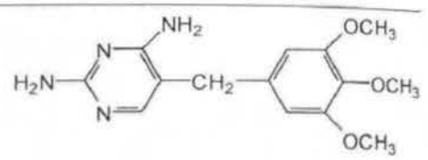
DIHYDROFOLATE REDUCTASE/ THYMIDYLATE SYNTHASE INHIBITORS

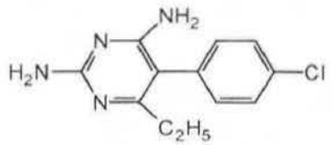
Spectrum: Coccidiosis, *Toxoplasma* sp., *Neospora* sp., *S. neurona*, leucocytozoon, *Hepatozoon americanum.*

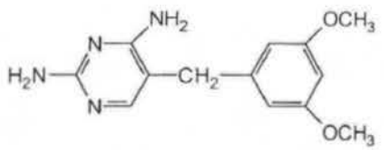
Drugs included: trimethoprim, ormetoprim, pyrimethamine (Daraprim). (Fig. 43.17)

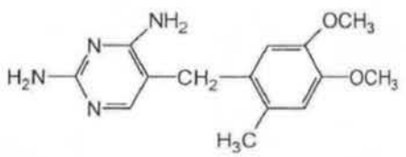
In protozoa, unlike other eukaryotic cells, the dihydrofolate reductase and thymidylate synthase enzymes do not exist as separate molecular entities, but instead these enzymes are part of a bifunctional DHFR/TS complex that has both DHFR and TS activity (Roos 1993). The best-known and most often used members of this group are trimethoprim, ormetoprim, and pyrimethamine.

TRIMETHOPRIM. Trimethoprim is available in several formulations, as well as in trimethoprim combinations for oral or parenteral administration. Examples include trimethoprim + sulfadiazine (Tribrissen®, Di-Trim®) and trimethoprim + sulfamethoxazole (Bactrim®, Septra®, human









Name	Chemical name (Empirical formula) [Molecular weight]	Chemical structure
Trimethoprim	2,4-diamino-5-(3,4,5-trimethoxybenzyl)pyrimidine ($C_{14}H_{18}N_4O_3$) [290.32]	
Pyrimethamine	2,4-diamino-5-(*p*-chlorophenyl)-6-ethylpyrimidine ($C_{12}H_{13}ClN_4$) [248.71]	
Diaveridine	2,4-diamino-5-veratrylpyrimidine ($C_{13}H_{16}N_4O_2$) [260.29]	
Ormetoprim	2,4-diamino-5-(4,5-dimethoxy-2-methylbenzyl)-pyrimidine ($C_{13}H_{15}N_4O_2$) [259.17]	

FIG. 43.17 Dihydrofolate reductase/thymidylate synthase inhibitors.

drugs). Trimethoprim also is available as a single drug (Proloprim). Pharmacology of trimethoprim is discussed in more detail in Chapter 33.

Trimethoprim is readily absorbed from the digestive tract after oral administration, and peak serum levels occur 1–4 hours later. The half-life is 3.8 hours in the horse, 3.0 hours in the dog, and 10.6 hours in human beings. Concurrent administration of sulfonamide does not affect the rate of absorption of trimethoprim. Trimethoprim is widely distributed in tissues. Levels of trimethoprim in cerebral spinal fluid are about 40% of those in the serum (Zinner and Mayer 1990). Trimethoprim is almost completely (60–80%) excreted by the kidneys within 24 hours, and some is also excreted in the bile. The remainder is excreted as metabolites by the kidneys. Use of trimethoprim and other DHFR/TS inhibitors is associated with adverse effects on bone marrow. Administration of folinic acid usually will counteract these adverse effects.

Trimethoprim is available in several tablet, liquid, and paste formulations in combination with sulfamethoxazole (Cotrimethoxazole®, Bactrim®, Septra®) or sulfadiazine (Di-Trim®) that are usually in the ratio of 1 part trimethoprim to 5 parts sulfonamide. In addition to their antibacterial use (Chapter 33), these agents are used in treatment of coccidiosis, toxoplasmosis, neosporosis, EPM, and malaria. Adverse reactions to these agents are similar to those of the individual constituents. These combinations should not be used in animals with liver disease, blood dyscrasias, or a history of sulfonamide sensitivity. Precautions normally observed when animals are taking sulfonamides should be observed. The safety of ormetoprim-sulfadimethoxine has not been established in pregnant dogs, but studies indicate that the use of trimethoprim-sulfadiazine is safe in pregnant dogs. Trimethoprim is not absorbed following oral administration in ruminating animals.

Clinical Use

Dogs. Sulfadiazine combined with trimethoprim is used as a treatment for coccidiosis at 5–10 mg/kg BW trimethoprim combined with 25–50 mg/kg BW of sulfadiazine, given for 6 days to dogs over 4 kg BW. Dogs under 4 kg BW are given half this dosage for 6 days. Remission of clinical signs of hepatozoonosis can be obtained by oral administration of a combination of trimethoprim-sulfadiazine (15 mg/kg BW every 12 hours), clindamycin (10 mg/kg every 8 hours), and pyrimethamine (0.25 mg/kg every 12 hours) for 14 days (MacIntire et al. 2001). As the therapy is ineffective in eliminating the tissue stages of the organism, clinical response is short-lived. Clinical relapses may be prevented by subsequent therapy with decoquinate (MacIntire et al. 2001).

Cats. Agents and dosages used for the treatment of canine coccidiosis are also used for the treatment of feline coccidiosis.

ORMETOPRIM. Ormetoprim combined with sulfadimethoxine (Rofenaid 40®) is the only combination DHFR/TS-sulfonamide presently available in the United States for poultry. Other combinations are intended for use in human beings, equines, and small animals. Ormetoprim is also available in combination with sulfadimethoxine in the ratio of 1 part ormetoprim plus 5 parts sulfadimethoxine (Primor®) in various size tablets.

Clinical Use

Chickens and Turkeys. Combinations are fed to chickens at 0.0075% ormetoprim and 0.0125% sulfadimethoxine to prevent coccidiosis in broiler chickens. Do not feed to birds producing eggs for food. Ormetoprim combined with sulfadimethoxine is fed to turkeys at 0.00375% ormetoprim and 0.00625% sulfadimethoxine to prevent coccidiosis. Do not feed to birds producing eggs for food.

Dogs. Sulfadimethoxine combined with ormetoprim is used as a treatment for coccidiosis in dogs at 11 mg/kg BW ormetoprim plus 55 mg/kg BW sulfadimethoxine for up to 23 days.

PYRIMETHAMINE. Pyrimethamine is available in 25 mg tablets. Pyrimethamine is well absorbed after oral administration and is slowly but extensively metabolized. Less than 3% is excreted in the urine in the first 24 hours, and the half-life is 4–6 days in human beings (Van Reken and Pearson 1990). It accumulates in the kidneys, lungs, liver, and spleen. It is excreted in urine as metabolites, but some pyrimethamine can be found in the milk. Very high doses of pyrimethamine are teratogenic in laboratory animals. Pyrimethamine is available in tablets that contain 25 mg pyrimethamine and 500 mg sulfadoxine (Fansidar®), and in tablets that contain 12.5 mg pyrimethamine and 100 mg dapsone (Maloprim®). The equine formulation is a suspension (ReBalance®) that contains pyrimethamine (12.5 mg/ml) + sulfadiazine (250 mg/ml).

Clinical Use

Avian. Pyrimethamine (1 ppm) combined with sulfadimethoxine (10 ppm) will prevent but not cure *Leu. caulleryi* infections in birds.

Dogs and Cats. For toxoplasmosis, cats and dogs are treated orally with 0.25–0.5 mg/kg BW pyrimethamine and 30 mg/kg BW sulfonamide (preferably, sulfadiazine) every 12 hours for 2–4 weeks. Canine neosporosis will also respond to the above regimens of DHFR/TS inhibitors and sulfonamides used to treat canine toxoplasmosis. Bone marrow suppression can occur with the synergistic use of pyrimethamine and sulfonamides and can be corrected by the addition of folinic acid (5 mg/day) or by the addition of yeast (100 mg/kg BW daily) to the animal's diet.

Horses. Treatment recommendations for equine protozoal myelitis include sulfadiazine at 20–30 mg/kg BW orally twice daily combined with oral pyrimethamine at 1 mg/kg BW once daily for 30 days after clinical signs have stopped improving. Twelve weeks is the average length of treatment time. Relapse is possible if horses are not treated long enough, and reactivation of the infection may occur during periods of unusual stress. It has fallen out of favor, due to the length of treatment required. The presence of food may adversely affect the absorption of DHFR/TS inhibitors, and food should be withheld 1–2 hours before and after treatment. Cell culture studies have shown that pyrimethamine kills developing *S. neurona* at 1.0 μg/ml and trimethoprim kills it at 5.0 μg/ml (Lindsay and Dubey 1999). These levels of agent probably are not reached in the treated horses. It has been suggested that intermittent (every 2 or 4 weeks) single EPM treatment may help prevent clinical relapse in

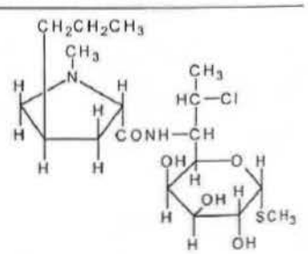
horses recovering from EPM (MacKay et al. 1992). If relapse does occur, the entire treatment regimen should be repeated. A recent study of 12 horses with EPM on a farm with an EPM outbreak indicated that combination treatment with trimethoprim-sulfonamides and pyrimethamine resulted in transient fever, anorexia, and depression in 2; acute worsening of ataxia in 2; mild anemia in 4; and abortions in 3 (Fenger et al. 1997). Prolonged use of DHFR/TS inhibitors has long been known to result in bone marrow suppression. Therefore, horses should be examined periodically (about every 2 weeks) for anemia and leukopenia. If the neutrophil counts drop below 3000 cells/μL, treatment should be discontinued until the counts recover (MacKay et al. 1992). Supplementation with 40 mg/day of folinic acid is recommended in horses with bone marrow suppression. Pregnant mares should be supplemented routinely with folinic acid while on EPM treatment, and the dose of pyrimethamine should be dropped to 0.5 mg/kg BW to reduce the risks to the fetus.

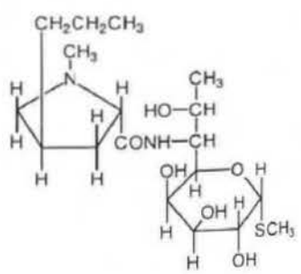
LINCOSAMIDES

Spectrum: Toxoplasmosis, *Neospora* sp, hepatozoonosis.

Drugs included: Clindamycin, Lincomycin (Fig. 43.18).

CLINDAMYCIN. Clindamycin (Antirobe®, Cleocin®) has been used for treatment of disseminated toxoplasmosis in cats and dogs (Lindsay et al. 1997b). The pharmacology of lincosamides, including clindamycin, is discussed in more detail in Chapter 37 of this book. It is a semisynthetic compound produced by alteration of the parent molecule lincomycin, which is produced by *Streptomyces lincolnensis*. It differs from lincomycin in having a chlorine group at C-7 rather than a hydroxyl group. The dosages used against *T. gondii* are higher than for the treatment of the anaerobic infections for which it is marketed. Clindamycin is active against tachyzoites of *Toxoplasma gondii* and is initially coccidiostatic but becomes coccidiocidal after a few days of treatment. Oral and parenteral formulations of clindamycin have similar activity. The drug is almost completely absorbed after oral administration in both dogs and cats, and peak serum concentrations occur within 75 minutes (Harari and Lincoln 1989). The half-life is about 5 hours after oral or IV administration. Clindamycin is widely distributed in many tissues and





Name	Chemical name (Empirical formula) [Molecular weight]	Chemical structure
Clindamycin	(2*S-trans*)-methyl-7-chloro-6,7,8-trideoxy-6-[[(1-methyl-4-propyl-2-pyrrolidinyl)carbonyl]-amino]-1-thio-L-threo-α-D-galacto-octopyranoside ($C_{18}H_{33}ClN_2O_5S$) [424.98]	
Lincomycin methyl	6,8-dideoxy-6-[[(-1-methyl-4-propyl-2-pyrrolidinyl) carbonyl]amino]-1-thio-D-erythro-α-D-galacto-octopyranoside ($C_{18}H_{34}N_2O_6S$) [406.56]	

FIG. 43.18 Lincosamides.

fluids and crosses the placenta and blood-brain barrier. It is metabolized in the liver and excreted in the bile and urine as parent agent and metabolites.

Clinical Use

Dogs and Cats. For toxoplasmosis, cats are treated with clindamycin at 10–12 mg/kg BW orally every 12 hours for 4 weeks or treated with 12.5–25 mg/kg BW clindamycin IM every 12 hours for 4 weeks. Dogs are treated with 3–13 mg/kg BW orally or IM every 8 hours for 2 weeks or with 10–20 mg/kg BW orally or IM every 12 hours for 2 weeks. Clindamycin is also combined with pyrimethamine and used for the treatment of toxoplasmic encephalitis in human beings; such combinations might have applications in veterinary medicine. Neonatal canine neosporosis is treated with 12.5–18.5 mg/kg BW clindamycin orally twice daily for 2–4 weeks (Dubey and Lindsay 1998). Death may be prevented in pups with severe hindlimb involvement, but hindlimb function usually does not return to normal. The amount of clinical improvement will depend on the degree of paralysis that has occurred.

The response of *H. americanum*–infected dogs to treatment with a combination of trimethoprim plus sulfadiazine (orally 15 mg/kg BW every 12 hours) plus clindamycin (orally 10 mg/kg BW every 8 hours) plus pyrimethamine (orally 0.25 mg/kg BW daily) (TCP therapy) for 14 days demonstrated that remission of clinical signs in naturally infected dogs occurred in 2–3 days, but most treated dogs relapsed and eventually died from hepatozoonosis (Macintire et al. 2001). The best results have been seen in dogs that have undergone TCP therapy and then been placed on a daily oral treatment program with 10–20 mg/kg BW decoquinate. The decoquinate treatment must be continued because once it is stopped, relapse and clinical disease occur (Macintire et al. 2001). Dogs have tolerated this treatment and survived for over 18 months.

AZALIDES

Spectrum: Cryptosporidiosis, toxoplasmosis, babesiosis

Drugs included: Azithromycin (Zithromax®).

The azalide antimicrobials are derivatives of the macrolides. The pharmacology of the macrolides is discussed in more detail in Chapter 37 of this book. They have activity against bacteria, as well as mycoplasma. Recently, they have been investigated for the treatment of cryptosporidiosis in human patients with HIV infection, with some success (Kadappu et al. 2002). In vitro activity against *Toxoplasma gondii* has also been demonstrated. Azalides exhibit their antibacterial activity through inhibition of protein synthesis by binding to the 50S ribosomal unit of susceptible bacteria. The antiprotozoal mechanism of action is unknown.

AZITHROMYCIN. Azithromycin differs from other azalides and the macrolides by having a much higher volume of distribution and by its ability to accumulate within phagocytic cells. Concentrations are 100–200 times higher in neutrophils than in the plasma (Davis et al. 2002).

Clinical Use

Cattle. Azithromycin dihydrate given to calves naturally infected with cryptosporidiosis under field conditions, at doses of 1500 or 2000 mg per day had a lower incidence of diarrhea, decreased oocyst shedding, and increased weight gains (Elitok et al. 2005). The recommended treatment regimen is 1500 mg/calf/day for 7 days.

Dogs. Azithromycin (10 mg/kg PO q24h) administered concurrently with atovaquone (13.3 mg/kg PO q8h) for 10 consecutive days was shown to completely eliminate *Babesia gibsoni* infection from 8 of 10 dogs treated (Birkenheuer et al. 2004). The dogs in that study had previously been treated unsuccessfully with imidocarb or diminazene.

4-AMINOQUINOLINES

Spectrum: *Plasmodium* sp.

Drugs included: Chloroquine.

CHLOROQUINE. Chloroquine has been used in the treatment of avian malaria. The mechanism of action against malarial organisms involves concentration of the drug, which is a weak base, within the acidic food vacuoles of the parasites. Once inside the cell, chloroquine causes rapid clumping of heme pigments by inhibiting plasmodial heme polymerase activity (Slater and Cerami 1992). Heme then accumulates to toxic levels, causing cell death.

Clinical Use

Penguins. Clinical malaria in penguins that are kept in zoos or aquariums is caused by *Plasmodium relictum.* It is treated with an oral loading dose of 10 mg/kg BW chloroquine, followed by oral doses of 5 mg/kg BW given 6, 18, and 24 hours later (Clubb 1986).

DIAMIDINE DERIVATIVES

Spectrum: Piroplasmosis, *Hepatozoon canis.*

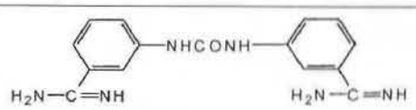
Drugs included: *Aromatic derivatives:* diminazene diaceturate, pentamidine isethionate, phenamidine isethionate. *Carbanilide derivatives:* amicarbalide, imidocarb dipropionate (Fig. 43.19).

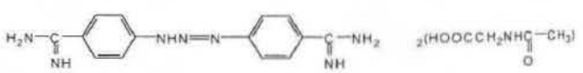
These diamidine derivatives bind to DNA and interfere with parasite replication (Pilch et al. 1995; Patrick et al. 1997). This class of drugs has a tendency to accumulate in tissues; therefore, half-lives are very long, which may lead to residue problems in food-producing animals. Imidocarb was still detectable in liver samples from treated cattle 224 days after drug administration (Coldham et al. 1994). Specific drugs have been shown to cross the placenta, as well as the blood brain barrier. Toxicity may involve renal disease, hepatic disease, or pulmonary congestion and edema, and is dose-dependent. Treatment of babesiosis may produce clinical cures in some animals, but the infection is not completely cleared, leading to a carrier state in affected individuals. This depends on the susceptibility of the organism being treated.

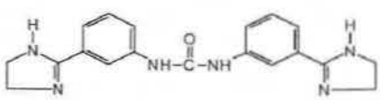
DIMINAZENE DIACETURATE. Diminazene diaceturate (Berenil®, Ganaseg®) has a very long half-life, which is reported to be up to 29 days in the plasma of cattle, with the highest concentrations in tissues being found in the kidneys (Mdachi et al. 1995). Diminazene is excreted into the milk, with residues being reported for up to 6 days in sheep and goats (el Banna et al. 1999), and up to 21 days in cattle (Mdachi et al. 1995). Parasitic infections can alter the pharmacokinetics of this drug.

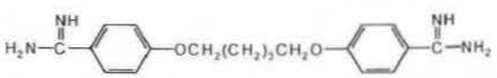
Clinical Use

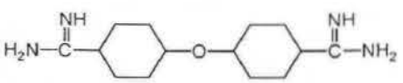
Horses. *Babesia caballi* infections can be treated with 3–5 mg/kg BW IM, but 6–12 mg/kg BW is required for *B. equi* in horses. Doses as low as 0.5 mg/kg BW can be effective against *B. bigemina.* Diminazene at 5.0 mg/kg BW











Name	Chemical name (Empirical formula) [Molecular weight]	Chemical structure
Amicarbalide	3,3′-(Carbonyldiimino)*bis*-benzenecarboximidamide ($C_{15}H_{16}N_6O$) [296.34]	
Diminazene	*N*-acetylglycine compounded with 4,4′-(1-triazene-1,3-diyl) *bis*-(benzenecarboximidamide) ($C_{22}H_{29}N_9O_6$) [515.54]	
Imidocarb	3,3′-di-2-imidazolin-2-yl-carbanilide ($C_{19}H_{20}N_6O$) [348.41]	
Pentamidine	4,4′-[1,5-pentanediylbis(oxy)]*bis*benzenecarboximidamide ($C_{19}H_{24}N_4O_2$) [340.43]	
Phenamidine	4,4′-oxybisbenzenecarboximidamide ($C_{14}H_{14}N_4O$) [254.29]	

FIG. 43.19 Diamidine derivatives.

will eliminate *B. caballi* from horses if given twice during a 24-hour period (Kuttler 1988).

Cattle. Diminazene at a dose of 3–5 mg/kg IM is effective against *B. bigemina* and *B. bovis* infections (Vial and Gorenflot 2006). Doses of 3.5–7 mg/kg IM have been used for treatment of trypanosomiasis.

Dogs. A single 3.5–5 mg/kg BW IM treatment with diminazene is effective against canine babesiosis caused by *Babesia canis*, but 3.5 mg/kg BW given twice over 24 hrs is required for *B. gibsoni*. The drug may enable survival against acute hemolytic crises and clinical improvement, but is inconsistent in clearing infection. Higher cumulative doses may produce central nervous system signs.

Cats. For treatment of *Cytauxzoon* infection, two injections are given intramuscularly at 2 mg/kg BW within a 1-week interval (Greene et al. 1999). Diminazene is not effective against *B. felis* but is effective against *B. herpailuri* in cats.

PENTAMIDINE ISETHIONATE. Pentamidine isethionate (Lomidine®, Pentam 300®) is useful in programs that are attempting to produce immunity in cattle by abbreviating infections.

Clinical Use

Cattle. When given SC during the acute phase at 0.5–2 mg/kg BW, pentamidine usually produces a clinical cure, but as much as 5 mg/kg BW will not completely eradicate the parasite from cattle.

Dogs. Pentamidine is effective against canine babesiosis when given IM at 16.5 mg/kg BW on 2 consecutive days but may cause adverse reactions, including pain at the injection site, hypotension, tachycardia, and vomiting. It has also been used in the treatment of leishmaniais at a dose of 4 mg/kg BW IM twice weekly for 4 weeks. This regimen was repeated again 3 weeks later. Clinical remission was obtained in all dogs treated, and signs did not appear during a 6-month follow-up period (Noli and Auxilia 2005).

PHENAMIDINE ISETHIONATE. Phenamidine isethionate (Lomadine®) can be used to treat bovine and equine *Babesia* infections with 8–13 mg/kg BW IM. Phenamidine at 8.8 mg/kg BW will eliminate *B. caballi* from horses if given twice during a 24-hour period (Kuttler 1988).

Dogs. Phenamidine isethionate given SC at 15–20 mg/kg BW once a day for 2 days, is effective against canine babesiosis caused by *B. gibsoni*; a single dose of 8–13 mg/kg is effective against *Babesia canis*.

AMICARBALIDE. Amicarbalide (Diampron®) is effective against bovine babesiosis when given IM at 5–10 mg/kg BW. Amicarbalide at 8.8 mg/kg BW will eliminate *B. caballi* from horses if given twice during a 24-hour period but will not eliminate *B. equi* when used at levels of 22 mg/kg BW, which approaches toxic levels (Kuttler 1988).

IMIDOCARB DIPROPIONATE. Imidocarb dipropionate (Imizol®) is one of the treatments of choice for babesial infections. Also, administration of imidocarb may interfere with the efficacy of some babesial vaccines in certain species (Combrink et al. 2002). In cattle, the elimination half-life of imidocarb in liver was 48.5 days and 120 days in muscle (Coldham et al. 1995). A dose-dependent hepatic toxicity has been noted.

Clinical Use

Cattle. Imidocarb is effective against bovine babesiosis when given at 1–3 mg/kg BW IM or SC.

Horses. Imidocarb given at 1–2 mg/kg BW will eliminate *B. caballi* from horses if given twice during a 24-hour period (Kuttler 1988). When given at 4 mg/kg IM every 72 hours for a total of 4 doses, imidocarb produced a significant increase in the urine GGT:creatinine ratio, as well as mild azotemia in normal horses (Meyer et al. 2005). Liver function was not affected. This dose has been shown to be ineffective in eliminating the carrier state in *B. equi*–infected animals (Kuttler et al. 1987). At higher doses (16 and 32 mg/kg BW), renal failure, hepatic failure, and pulmonary edema were noted (Adams 1981). When administered to pregnant mares, imidocarb was detectable in fetal blood at levels similar to those found in the dam's blood (Lewis et al. 1999).

Dogs. A single 7.5 mg/kg BW SC imidocarb treatment will completely clear *Babesia canis* infections in dogs (Penzhorn et al. 1995). A single dose of 3.5 mg/kg BW SC diminazene, followed the next day by a single dose of 6 mg/kg BW SC imidocarb, will completely clear *Babesia canis* infections in dogs (Penzhorn et al. 1995). *Hepatozoon canis* infections are treated with 5–6 mg/kg BW SQ or IM every 2 weeks until gamonts are no longer present in blood smears (Baneth and Weigler 1997).

Cats. For treatment of *Cytauxzoon* infection, two injections are given intramuscularly at 5 mg/kg BW within a 1–2 week interval (Greene et al. 1999). Control of parasympathetic side effects is recommended by pretreating cats with atropine or glycopyrrolate. Feline babesiosis is refractory to treatment with imidocarb.

NITROTHIAZOLE DERIVATIVES

Spectrum: *Giardia, Coccidia,* cryptosporidiosis, *S. neurona*

Drugs included: Nitazoxanide.

The antiprotozoal action of the nitrothiazole derivatives is thought to be via interference with the pyruvate-ferredoxin oxidoreductase enzyme dependent electron transfer reaction, which is essential for anaerobic energy metabolism of the parasites (Parashar and Arya 2005). It is specific for parasites capable of intracellular reduction of the nitro group on the drug to a toxic-free radical. Nitazoxanide (NTZ) is rapidly converted to an active metabolite, deacetylnitazoxanide (also known as tizoxanide), in the horse (Navigator Paste, package insert), as well as in humans (Parashar and Arya 2005).

NITAZOXANIDE. Nitazoxanide (Navigator®) is available as a 32% paste and is registered for use in horses to treat equine protozoal myeloencephalitis (EPM). The side effects in horses are numerous and can be severe, including a fatal enterocolitis at recommended doses; therefore, its use is typically reserved for horses that have not responded to other therapies. In vitro and in vivo efficacy against *Cryptosporidium* organisms has also been demonstrated (Jenkins 2004). It is approved by the FDA as a treatment for cryptosporidial infection in children.

Clinical Use

Horses. Field trials with NTZ have shown a success rate, defined by an improvement in neurologic signs and/or conversion to a negative result on western blot of the CSF, of 57–81%. This included a 78% success rate for horses that had previously been treated with other drugs for EPM. Horses are treated for 28 days. For the first 5 days, the dose is 11.36 mg/lb orally once daily. The dose is then increased to 22.72 mg/lb orally once daily for the remaining 23 days. This drug should not be used in horses less than 1 year of age or in those horses that have concurrent disease.

Cats. Sustained inhibition of *Cryptosporidium* oocyst shedding in the feces of four naturally infected cats after a single oral dose of 75 mg/kg BW has been reported. However, reshedding of oocysts was prompted by administration of corticosteroids. NTZ is not well tolerated by cats and results in vomiting and dark, foul-smelling diarrhea (Gookin et al. 2001).

INTRODUCTION

The focus of this chapter is to describe the pharmacology of veterinary drugs and pesticides currently approved to control important ectoparasites that adversely affect domestic animal health and production. These ectoparasites are primarily insects (fleas, flies, lice) and ascarines (ticks and mites, flies). Effective control of these ectoparasites is not only critically important for the veterinary patients, but also from a public health perspective as several of the animal ectoparasites not only transmit disease between animals but they can also transmit major diseases to humans. Fleas are known vectors for tapeworms, *Dipilidium caninum* and humans can develop cat scratch disease when *Bartonella henselae* is transmitted from cats to humans via cat fleas. Flea allergy dermatitis (FAD) is a major concern for companion animals. These are among the most important reasons why flea control in companion

animals is critical, and it explains why annual expenditures to control fleas have totaled in excess of $2 billion in the U.S. and Western Europe (Kramer and Mencke 2001). Ticks can transmit Lyme disease, Rocky Mountain spotted fever, babesia in dogs and cattle, and heartwater in ruminants to mention only a few. Mosquitoes can transmit West Nile virus to humans; heartworm diseases to pets; and malaria to birds, rodents, and primates; they also serve as biological vectors of viral encephalitides in horses. Flies not only transmit disease and cause damage to hides and coats of pets, their nuisance can result in decreased feed intake in livestock and thus reduced timely weight gain and economic loss to livestock farmers. Face flies are known to transmit the causative agent (*Moraxella bovis*) of pinkeye or infectious bovine keratoconjunctivitis in cattle. Control of myiasis-causing flies can be significantly reduced with effective ectoparasiticides.

The *feeding behaviors* of ectoparasites differ and this may be critical if the drug of choice is strictly a repellent or adulticide. Adult fleas usually engorge themselves with a blood meal from the host with 5 minutes to 1 hour of infestation of the animal, with female fleas feeding for about 25 minutes and males feeding for 11 minutes (Cadiergues et al. 2000). In order to prevent FAD, an effective ectoparasiticide should be able to prevent this feeding behavior. Comparative efficacy studies suggest that organophosphates (OPs) and/or pyrethroids, more so than the newer ectoparasiticides, may be more effective in preventing the flea from taking the first blood meal (Franc and Cadiergues 1998). Ticks feed on a blood meal for a longer period (days) before it is completed. Under these conditions pathogens such as *Borrelia burgdorferi*, which causes Lyme disease, become well adapted to this long feeding period. However, with other tickborne pathogens such as *Ehrlichia* and *Rickettsia*, transmission can occur within the first hours. For these reasons, the use of combination drugs (insecticide and repellent) will prevent ticks from attaching and feeding (Young et al. 2003). A good example of this desired combined efficacy is a drug formulation containing the repellent permethrin and the acaricide imidacloprid.

The ideal ectoparasiticide should not only be an effective repellent and adulticide, it must also be *persistent* in the blood or skin surface at therapeutic concentrations for a significantly long time, such as 1–3 months, so that there is adequate client compliance. Another challenge is the formulation of an insecticide that is *stable* to sunlight and also water/shampooing. An excellent example of this is imidacloprid, which is photostable and persistent after shampooing compared to the early generation pyrethroids that were not very stable in sunlight. Some formulations, such as Frontline Plus, contain the adulticide (fipronil) as well as an insect growth inhibitor (methoprene) because by the time pets are observed to be infested with fleas, the fleas would already have laid eggs. A final consideration in choice of therapy is whether to *treat the environment* as well as the animal. There appears to be a new paradigm within the last 10 years of treating the pet and not the environment (Rust 2005).

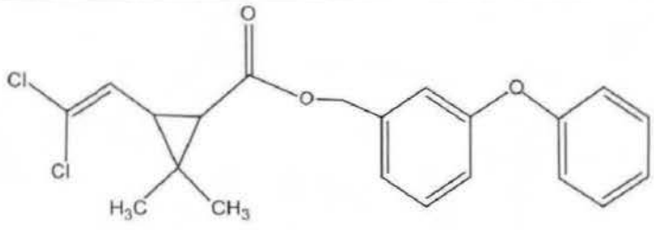
PHARMACEUTICS OF TOPICAL FORMULATIONS

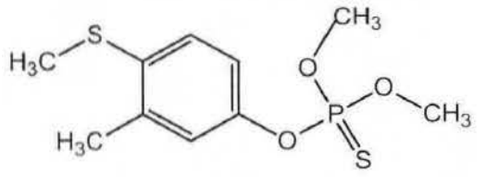
Many of the commercial topical ectoparasiticides used to treat domestic animals are formulated to be released from 1) liquid organic/aqueous formulations and/or 2) synthetic polymers such as collars and ear tags. The rate of penetration through the skin or translocation across the skin surface is dependent on several critical pharmaceutical properties. Liquid formulations include pour-ons, topical sprays, and dips, which consist of the active ingredient and other (formerly called *inert*) ingredients that can modulate dermal pharmacokinetics. These other ingredients include mostly alcohols, oils, and spreading agents (Magnusson et al. 2001). The ear tags are composed of a solid organic polymeric macromolecule (e.g., polyvinyl chloride) and an active ingredient that are mixed with the tag being formed by injection molding. These devices are designed to slowly release the insecticide over a defined time period (e.g., Cutter Gold® lasts 5 months) as the animal moves its head, but it should be removed at the end of the fly season or before slaughter.

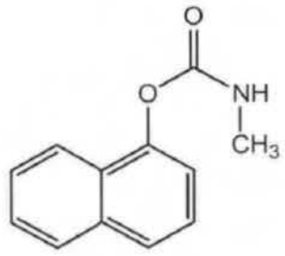
TRANSDERMAL DELIVERY

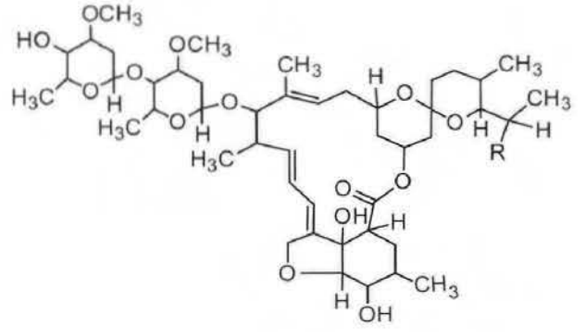
Topical application is more common for administration of ectoparasiticides. An understanding of the dermal pharmacokinetics of these drug and pesticide formulations will further the understanding of drug efficacy and safety. Many of these drugs and pesticides are lipophilic with large molecular weights (Table 44.1), and therefore it's not surprising that there is slow dermal absorption, low systemic *bioavailability*, large volume of distribution, and long plasma and tissue half-lives. All of these are important factors when considering repeat

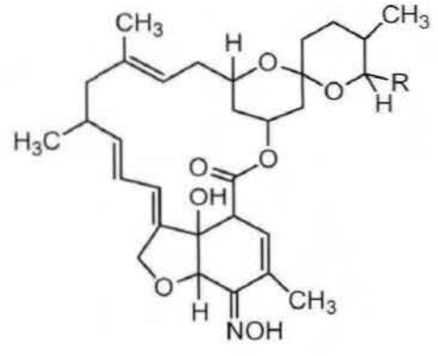
TABLE 44.1 Chemical structures and physicochemical properties of common ectoparasiticides

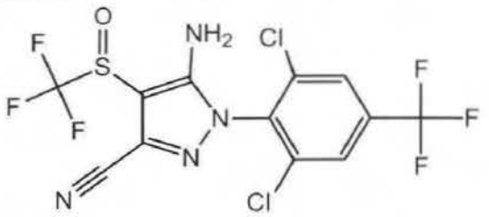


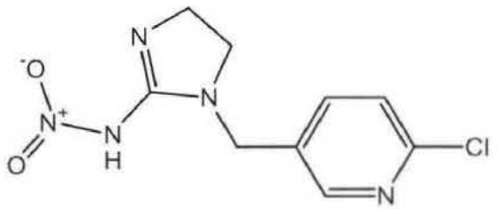












Name	Chemical Name (Empirical Formula) [Molecular Weight] Log P	Chemical Structure
Permethrin	3-(2,2-dichloroethenyl)-2,2-dimethyl-cyclopropane-carboxylic acid (3-phenoxyphenylmethyl) ester ($C_{21}H_{20}Cl_2O_3$) [391.29] Log P = 6.10	
Fenthion	Phosphorothioic acid O,O-dimethyl O-[3-methyl-4-(methylthio)phenyl] ester ($C_{10}H_{15}O_3PS_2$) [278.34] Log P = 4.84	
Carbaryl	1-naphthalenol methylcarbamate ($C_{12}H_{11}NO_2$) [201.22] Log P = 1.85	
Ivermectin	22,23-dihydroavermectin B_1 ($C_{48}H_{74}O_{14}$) [875.10] Log P = 5.31	
Milbemycin Oxime	5-didehydromilbemycin (oxime derivative) 80% A_4, 20% A_3 ($C_{31}H_{43}NO_7$) A_3 [541.68] ($C_{32}H_{45}NO_7$) A_4 [555.71] Log P = 5.29	

TABLE 44.1—*continued*

Name	Chemical Name (Empirical Formula) [Molecular Weight] Log P	Chemical Structure
Fipronil	5-amino-1-[2,6-dichloro-4-(trifluoromethyl)phenyl]-4-[(trifluoromethyl)sulfinyl]-1H-pyrazole-3-carbonitrile ($C_{12}H_4Cl_2F_6N_4OS$) [437.15] Log P = 4.0	
Imidacloprid	1-[(6-chloro-3-pyridinyl)methyl]-4,5-dihydro-N-nitro-1H-imidazol-2-amine ($C_9H_{10}ClN_5O_2$) [255.66] Log P = 0.57	

applications and strategies to minimize the emergence of pest resistance, whether it's in a house, kennel, or pasture, and also to minimize drug residues in food-producing animals.

The advantages of transdermal delivery include ease of application to the animal's coat and avoidance of the problems of first pass metabolism and gastrointestinal degradation often associated with oral administration. Some of the major disadvantages associated with this route of administration are that pet owners sometimes overdose the animal with topical sprays or pour-on formulations, which often result in toxicoses in sensitive populations such as feline species and juveniles. Licking is part of the natural grooming and social behavior of many animal species; this can result in significant oral absorption and subsequently increased systemic exposure in the treated and also untreated animals that are part of a large livestock herd (Laffont et al. 2003). Application of pour-on products to food animals can result in significantly longer withdrawal times when compared to administration by oral or injection. This is most evident with ivermectin pour-on products, which cause significant retention of ivermectin in the skin layers and thus prolong release of the drug. For example, this results in a 45-day withdrawal time for the pour-on product versus 35 days for the subcutaneous route (KuKanich et al. 2005).

ROUTES OF DERMAL ABSORPTION

There are five possible routes (Fig. 44.1) for a drug or pesticide to diffuse as it partitions from the formulation on the skin surface through the stratum corneum and viable epidermis before entering the microcapillaries at the epidermal-dermal juncture. Many if not all of the ectoparasiticides diffuse through the intercellular matrix (intercellular route) in the stratum corneum and viable epidermis. This matrix may vary biochemically between animal species, but in all species this matrix consists of varying proportions of fatty acids, ceramides, and cholesterol. The reader should also be aware that apparent epidermal thickness (Monteiro-Riviere et al. 1990) varies across animal species in the following order, thereby influencing the intercellular path length for the diffusing pesticide:

Porcine > Cattle > Canine > Feline

(52 μm) (37 μm) (21 μm) (13 μm)

The intracellular route and the sweat pores are less likely routes for these lipophilic chemicals because they have more hydrophilic properties than the intercellular matrix.

Even though light microscopy examination of skin suggests that the hair follicle extends into the dermis and

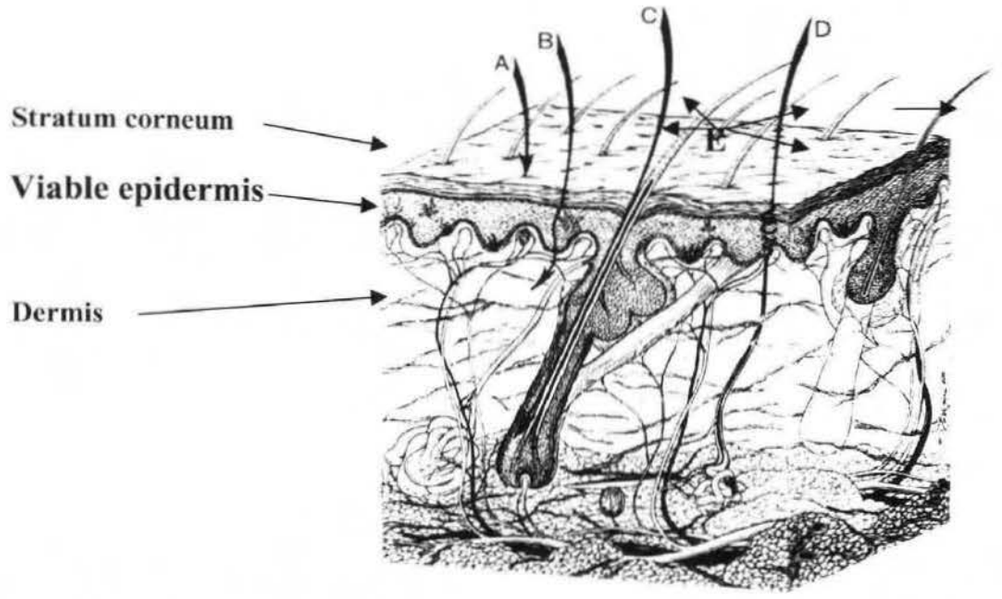


FIG 44.1 Pathways for drug and insecticide transport in mammalian skin. A = transcellular; B = intercellular; C = transfollicluar; D = sweat pore; E = lateral diffusion.

hypodermis, this is not really true. The hair follicle is really a deep invagination of the epidermis, and therefore if a drug travels down the hair follicle, it still has to cross the epidermis in order to gain access to the circulatory system. However, the presence of many hair follicles significantly increases the effective epidermal surface area and thus increased flux, although the apparent surface area may be the same. This in part explains why care must be taken when administering pour-on ectoparasiticides in an extra-label manner across species. In essence, hair follicles are arranged and distributed differently across animal species, and these differences can dictate transdermal delivery into the systemic circulation for pour-on products as well as translocation across the skin surface for topicals. The coat may contain primary and or secondary hair follicles. The former are large-diameter and deep-rooted into the dermis and associated with sebaceous and sweat glands. The secondary follicles are smaller in diameter, they are near the surface, and they have sebaceous glands but no sweat gland erector pili muscle. Horses and cattle have single hair follicles distributed evenly; pigs have single follicles grouped in clusters of 4 follicles. Dogs have primary and secondary follicles with as many as 15 hairs emerging from a single opening in the skin. Goats will have primary follicles occurring in groups of 3 with 3–6 secondary follicles associated with each group. Sheep are bit more complex. They have hair-growing regions with mostly single follicles on face, distal leg region, and ears and they have wool-growing regions over most of their body, which can be defined as mostly compound follicles. A cluster will have 3 primary follicles and several secondary follicles.

MECHANISMS OF ACTION

Ectoparasiticides can have the following broad mechanisms of action that can affect the biology of the ectoparasite. More specific examples are summarized in Table 44.2.

- Ectoparasite nervous system
  - AChE inhibitors
  - Na^+ channel blockers
  - nAChR inhibitors
  - GABA and Cl^- channel inhibitors
- Ectoparasite repellant
- Insect growth and development.

A good ectoparasiticide has a high efficacy against the ectoparasite and is not toxic to the host. Many of the organophosphate and organochlorine pesticides are very effective and have broad spectrum activity. However, because of their toxicity to mammals (Table 44.2) and the fact that there are safer pesticides available for veterinary

TABLE 44.2 Mechanisms of action of ectoparasiticides against the parasite and signs of mammalian toxicity

Drug	Mechanism of Action	Signs of Toxicity
Fipronil	Noncompetitively blocks passage of Cl ions through GABA- and glutamate-gated channels	Hyperactivity and convulsions related to GABA antagonism
Imidacloprid	Competitive inhibition at postsynaptic nicotinic acetylcholine receptors (nAChR) leads to influx of Na ions	Nicotinic effects (tremors)
Avermectins	Targets glutamate-gated chloride channels Targets GABA- and glycine-gated chloride ion channels	CNS depression and ataxia
Pyrethrins and Pyrethroids	Targets voltage-gated Na ion channels in axonal membrane	Type 1 Syndrome (tremors, hyperexcitability) Type 2 Syndrome (salivation, weakness)
Organophosphates and Carbamates	Inhibits acetylcholinesterase (AChE)	Muscarinic and nicotinic effects (miosis, tremors, depression)
Amitraz	Inhibits monamine oxidase	Activates α2-adrenergic receptors (CNS depression)
Insect Growth Regulators	Falsely signals insect to remain in immature stage Inhibits of chitin synthesis	No known toxic signs
Synergists	Inhibits cytochrome P450	Can potentiate drugs and pesticides

use, fewer chemicals from these two classes are being used in veterinary medicine. For this reason, this chapter will not discuss the organochlorines especially as they are no longer approved for veterinary use. The newer ectoparasiticides such as the neonicotinoids (e.g., imidacloprid) are more selective for certain insects such as fleas, and very few other insects. However, the term "broad spectrum" may be misleading. Recall that ivermectin which is often regarded as a broad spectrum antiparasitic drug is indeed highly effective against many nematodes and ectoparasites, but is without effect on cestodes and trematodes.

RESISTANCE TO ECTOPARASITICIDES

Resistance has been widely reported for many popular ectoparasiticides, such as the avermectins, pyrethroids, and organophosphates. Resistance also tends to occur where there is intensive use of antiparasitic drugs; even on "well managed" farms. There is some concern that as the newer insecticides, such as the neonicotinoids, become more frequently and inappropriately used, resistance can potentially emerge. However, there is little or no evidence of fleas developing resistance to the increasing use of imidacloprid (Schroeder et al. 2003). Mechanisms of resistance may be related to decreased penetration, increased detoxification enzyme activity, and decreased sensitivity of the target site. These mechanisms have been more recently elucidated from a molecular basis using annotated insect genomes and recognizing that insect resistance is mediated by complex multigene enzyme systems. Pyrethroid resistance among insects has been associated with mutations in the sodium channel genes reducing the ability of the insecticide to bind to the sodium channel. Although resistance to imidacloprid has not been demonstrated in cat fleas, mutations in nicotinic acetylcholine receptors have been associated with some agronomic insects being resistant to this new class of insecticides (Liu et al. 2005).

Cross-resistance for a specific target site is indeed very common within individual insecticide classes. However, cross-resistance across different target sites has more severe consequence and limits insect management. Detoxification mechanisms are often the source of cross-resistance between insecticides that differ in their mechanisms of action. These detoxification enzymes include the carboxylesterases, cytochrome P450 s, and glutathione-s-transferases that are often implicated in pyrethroid and OP resistance. In a more recent observation, point mutations in the *Rdl* gene in a field population of cat fleas confers cyclodiene resistance and cross-resistance to fipronil, which is one of the few new chemicals on the commercial market (Daborn et al. 2004).

Strategies that can prevent or delay resistance include 1) appropriate selection of insecticides, 2) insecticide rota-

tions and mixtures, 3) limited interactions with agricultural pesticides, and 4) resistance monitoring. The latter is a major issue when it comes to treating fleas because there are no universally susceptible strains of cat flea known (Russ 2005). However the use of various genetic tools such as TaqMan-allele specific amplification provides a promising method for assaying large populations of insects for insecticide resistance to the newer chemistries on the commercial market. With this in mind the reader is encouraged to read recent reviews (ffrench-Constant et al. 2004) on how the new genetic tools are addressing insecticide resistance.

FIPRONIL

Fipronil was first approved in 1996 for use in dogs and cats to treat for fleas and ticks. This chemical has been marketed as Frontline® TopSpot and Frontline® Plus for dogs, puppies, cats, and kittens and Frontline® Spray Treatments for cats and dogs. The Plus product indicates that fipronil was formulated with methoprene which is an insect growth regulator (IGR), which will be discussed in more detail under IGRs. The TopSpot product contains 9.7% fipronil, and the Spray contains 0.29%.

CHEMISTRY. This insecticide is classified as phenylpyrazole with the molecular formula: $C_{12}H_4Cl_2F_6N_4OS$. Fipronil has a molecular weight of 437.15 and log P (n-octanol/water) of 4.0, and solubility of 2 mg/l in water and >10,000 mg/l in corn oil. (Merck 1996). This high affinity for oils in the skin partly explains why dermal absorption is limited.

PHARMACOKINETICS. Topical application of the fipronil formulation between the shoulder blades is believed to result in surface translocation of the chemical over the entire body with significant deposition in sebum, sebaceous glands, and hair follicles. In effect, the sebaceous glands act as a reservoir that continuously secretes fipronil out of the hair follicle forming a layer on and in the stratum corneum and fur of the animal. Recognizing that 95% effective flea control requires 0.7 µg fipronil/g fur, as much as 4.5 µg/g and 1.6 µg/g have been detected in cats at 42 days and dogs at 56 days, respectively. Dermal absorption of ^{14}C-fipronil was less than 1% of the applied dose for all doses tested (0.88–48 mg/rat) and up to 24 hours exposure (Cheng 1995).

MECHANISM OF ACTION. Fipronil acts on the central nervous system where it appears to be primarily effective in noncompetitively blocking the passage of chloride ions through GABA-gated and glutamate-gated chloride channels in ectoparasites. The latter mechanism exists in ectoparasites, but not mammals, suggesting that there are multiple insect target sites for this drug. Recent work has demonstrated that fipronil and its metabolite, fipronil sulfone, are potent inhibitors at these sites (Zhoa et al. 2005). In mammals, fipronil binding to the GABA receptor is also less effective, which also accounts for its wide margin of safety. Fipronil sulfone has a higher potency than fipronil in mammalian GABA receptors, and simultaneous exposure to other drugs that potentiate formation of the metabolite could potentially be toxic to mammals in these scenarios. However, data from the literature is conflicting as to whether metabolic conversion to the sulfone derivative represents detoxification. For example, pretreatment of mice with a cytochrome P450 oxidase inhibitor, piperonyl butoxide, increased the toxicity of fipronil by as much as sevenfold (Hainzl and Casida 1996). Prior to its veterinary approval, fipronil was and is still approved for use in plant agriculture; however, photochemical conversion can result in a desulfinylated photoproduct that is tenfold more potent than Fipronil at the mammalian chloride channel. Whether this will be a concern for livestock that forage on exposed pastures is still to be determined.

EFFICACY. Fipronil as a topical spray is effective against adult fleas, all stages of brown dog ticks, American dog tick, lone star ticks, and deer ticks. This product is approved for dogs, cats, puppies, and kittens (>8 weeks), and can provide protection for up to 30 days. The manufacturers claim that although the Topical Spot On product can be effective against fleas for as long as 3 months, they still recommend that it be applied every month. Fipronil formulated with s-methoprene (Fipronil Plus), an insect growth regulator, is not only an effective adulticide, it also kills flea eggs and flea larvae. While excellent ectoparasiticidal efficacy against fleas and ticks has been proven, there has been some concern about its repellent effects against ticks and also ticks already on the animal (Denny 2001;

Young et al. 2003). Compared to some pyrethroids and some OPs, fipronil is also not effective in preventing fleas from biting and feeding within the first hour of infestation and prior to being killed (Franc and Cadiergues 1998). Fipronil is also effective for the treatment and control of biting lice (*Trichodectes canis*) in canine infestations (Pollmeier et al. 2002, 2004), although its use to treat lice infestations is extralabel.

SAFETY/TOXICITY. Fipronil appears to have a wide margin of safety (rat dermal LD50 = 2000 mg/kg), and thus is regarded as a lower order of toxicity when used in veterinary applications. No adverse effects have been observed at five times the maximum dose rate in dogs and cats. However, slight skin or eye irritation has been observed after skin and eye exposure, respectively (Technical Information Sheet 1997). The oral and dermal LD50 in rats is 100 mg/kg and >2000 mg/kg, respectively (Merck 1996). Like the avermectins and organochlorines, fipronil's mechanism of action involves GABA receptor antagonism. At toxic doses, it can cause hyperactivity, hyperexcitability, and convulsions, which are correlated with increased spontaneous nerve activity and generation of prolonged high-frequency discharges with nerve stimulation. These symptoms are associated with blockage of the neuronal inhibition or membrane hyperpolarization because these antagonists are also blocking chloride uptake. This in effect results in stabilization of the GABA-bound form of the chloride channel (Bloomquist 2003).

There appear to be no reported interactions between fipronil and approved companion animal drugs and ectoparasiticides. Animals exposed to large doses of fipronil via accidental oral absorption are expected to display seizures, and neurological and hepatic function should be monitored (Hovda and Hooser 2002). Extralabel use in young or small rabbits can cause seizures and death. Multigenerational rat studies have concluded that this drug is not mutagenic or teratogenic.

NEONICOTINOIDS

IMIDACLOPRID. Imidacloprid has been approved for use in crop agriculture as a systemic insecticide as well as treating fleas on dogs and cats. It is available as 9.1% w/v in Advantage™ specifically to target fleas and also formulated at 8.8% w/v with permethrin (44% w/v) in K9 Advantix™ to treat for fleas as well as ticks.

Chemistry. Imidacloprid belongs to a relatively new class of synthetic insecticides known as the *neonicotinoids*. Imidacloprid (chloronicotinyl nitroguanidine) more specifically belongs to the chloronicotinyls that were first synthesized in 1985. This chemical was found to have 62-fold to greater than 3000-fold more insecticidal activity than the nicotinoids (e.g., nicotine), and was introduced into the commercial market in 1991. These chemicals are photostable, which ensures prolonged residual efficacy, and they are moderately soluble in water (0.51 gm/l). The log octanol water partition coefficient of imidacloprid is 0.57 and it has a molecular weight of 255.7. Unlike the nicotinoids, the neonicotinoids are not ionized at physiological pH. Neonicotnoids therefore more readily penetrate the CNS of insects than nicotinoids because the former has a greater hydrophobicity. This physicochemical difference in physiological conditions partly explains why the neonicotinoids have greater insecticidal activity than the nicotine-based insecticides.

Pharmacokinetics. Topical application of imidacloprid to the skin does not result in significant dermal absorption into the bloodstream, but rather surface translocation aided by body movement resulting in whole body coverage. Its efficacy is dependent on contact with the flea at the surface of the animal's skin. Results from metabolism and toxicokinetics studies in other vertebrates suggest that if this chemical becomes systemic, it is widely distributed to organs, but not to fatty tissues or the central nervous system (Sheets 2001).

Mechanism of Action. At the nicotinic cholinergic synapse, acetylcholine (ACh) is normally released from the presynaptic membrane and binding to the postsynaptic membrane results in a conformational change in the receptor molecule that leads to activation and opening of the ion channel and subsequent influx of extracellular Na^+ and efflux of K^+. This results in change in membrane potential, and propagation of nerve impulse. Imidacloprid essentially mimics the effects of ACh by competitive inhibition at the postsynaptic nicotinic acetylcholine receptors (nAChR) and it has little or no effect on muscarinic acetylcholine receptors (Buckingham et al. 1997; Tomizawa and Casida 2003). The former are widely and predominantly distributed in the neuropil regions of the CNS in insects,

and imidacloprid is highly specific for nicotinic receptor subtypes unique to insects. However, instead of a depolarization of the postsynaptic neuron and transmission of the nerve impulse, as normally seen with acetylcholine, imidacloprid causes a biphasic response. This consists of increased frequency of spontaneous discharge followed by a block in nerve pulse propagation along the neurons and then insect death (Schroeder and Flattum 1984). Muscarinic receptors and other types of nicotinic receptors in mammals do not bind imidacloprid effectively, which accounts for its selectivity for insects (Kagabu 1997). There is therefore no surprise that no adverse effects are observed when dogs were topically exposed to greater than the recommended dosage. Readers should be aware that although the neonicotinoids are selective, the nicotinoids are less selective and therefore more toxic to vertebrates than the neonicotinoids.

Efficacy. Compared to fipronil and selemectin, imidacloprid appears to be more readily taken up by the flea via body contact (Mehlhorn et al. 2001). Mehlhorn and colleagues demonstrated that imidacloprid killed larvae and adult fleas within 1 hour of exposure, while similar efficacy was achieved with the other two chemicals within 24 hours. It should be noted that none of these three chemicals had any repellent activity against fleas. Imidacloprid can kill 98–100% of adult fleas for at least 4 weeks on dogs and cats. This chemical has limited activity against ticks. Imidacloprid also stops fleas from biting within 3–5 minutes after application, although the fleas do not die within this short time frame. This clearly is useful for preventing FAD. Earlier studies demonstrated that shampooing or water exposure does not significantly reduce the efficacy of imidacloprid for up to 28 days (Cunningham et al. 1997).

In Fall 2002, Bayer Corp. received registration from EPA for a topical ectoparasite K9 Advantix™, which is topical insecticide formulated with imidacloprid and permethrin to repel and kill mosquitoes, ticks, and fleas on adult dogs and puppies 7 weeks of age and older for up to 4 weeks. The product's efficacy is not affected by swimming or bathing activities. Imidacloprid acts on the postsynaptic nicotinic receptor by "locking" it in the open position, thus hyperstimulating the neuron, and permethrin keeps open the Na^+ ion exchange channels causing constant nerve impulses. Recall that these would normally close after transmitting an impulse. There is therefore a synergistic interaction on the nervous system that is associated with an overwhelmed parasite nervous system followed by rapid paralysis and death of the parasite. Due to their unique physiology and inability to metabolize certain compounds such as the pyrethroid (reduced glucuronidation activity in cats), this product must *NOT* be given to cats.

Safety/Toxicity. Clinical signs of toxicity are usually associated with nicotinic effects (e.g., tremors) and hepatic effects when dogs are exposed to 41 mg/kg in the diet high dose (Hovda and Hooser 2002). However, except for one single reported case in cats (Godfrey 1999), there are no published reports of imidacloprid causing toxicity in domestic animal species following dermal exposure. The chemical does not cause dermal irritation nor does it appear to cause dermal sensitization. Imidacloprid does not appear to be a teratogen, reproductive toxicant, mutagen, or carcinogen (Sheets 2001). The available products should not be given to puppies or kittens younger than 4 months.

NITENPYRAM. Nitenpyram (Capstar™) is in the same class as imidacloprid (i.e., chloronicotinyl), and therefore has the same mechanism of action. This is, however, not a topical application but an *oral adulticide* that is used against fleas in dogs and cats.

Chemistry. Nitenpyram, like imidacloprid, belongs to the new class of synthetic insecticides known as the *neonicotinoids*. Nitenpyram has a molecular weight of 270.72, a log octanol water partition coefficient of −0.64, and water solubility of 840 gm/l.

Pharmacokinetics. Nitenpyram is readily absorbed (bioavailability = 100%) in the gastrointestinal tract; the time to maximum blood concentration is 1.21 hours in dogs and 0.63 hours in cats. The Cmax is about 4.3 to 4.8 ppm in both dogs and cats, which is significantly greater than the blood concentration of 0.5–1.0 ppm nitenpyram required to kill 100% of the fleas. The half-life in dogs and cats is 2.8 hours and 7.7 hours, respectively, and it is primarily excreted in the urine.

Efficacy. The recommended minimum oral daily dosage is 1 mg/kg in tablet form with or without food and as often as once per day when fleas are seen on the animal. One dosage form (11 mg) is for cats and dogs up to 11 kg,

and the other dosage form (57 mg) is for dogs between 11 and 57 kg. This chemical is also very effective against fleas that have become resistant to fipronil (Schenker et al. 2001). Based on the above pharmacokinetics, it is no surprise that fleas begin falling off of the coat of dogs and cats within 0.5 hours of administration of this drug (Rust et al. 2003; Rust 2005). Efficacy reaches 98.6% in dogs and 98.4% in cats within 6 hours.

Safety/Toxicity. The acute oral LD50 in male rats is 1680 mg/kg., which suggests that this chemical is very safe. Dogs and cats given 10 times the recommended dose do not appear to experience adverse health effects (7–8-month-old cats and 7-month-old dogs, Witte and Luempert 2001). In the same study, administration of one, three, or five times the recommended daily dose for 6 months resulted in no adverse health effects in dogs and cats that were initially 8 weeks old. The drug is well tolerated for daily doses in puppies and kittens that are >4 weeks. No adverse reactions were observed when used with most other drugs or ectoparasiticides such as topical carbaryl, fipronil, pyrethin, or even imidacloprid, which has a similar mechanism of action (Witte and Luempert 2001). A transient itching period observed in dogs and cats within 1–2 hours after treatment with this product appears not to be associated with the chemical irritation, but attributed to fleas displaying increased trembling activity before dying and falling off the animal (Mahoney et al. 2001).

MACROCYCLIC LACTONES

These macrolides consist of two major groups, avermectins and milbemycins, that are effective against many ectoparasites, as summarized in Table 44.3. The avermectins include ivermectin, eprinomectin, doramectin, and selamectin, and the milbemycins include moxidectin and milbemycin oxime.

CHEMISTRY. Both avermectin and milbemycin groups are 16-membered macrocyclic lactones. The avermectins are products of *Streptomyces avermitilis* that have the 16-membered macrocycle replaced by a spiroketal unit at C-17 to C-28, a hexahydrobenzofuran at C-2 to C-8a, and a bisoleadrosyloxy disaccharide at C-13. The milbemycins are also products of *Streptomyces* and are structurally similar to the avermectins, but *lack the sugars at C-13*. The latter group is believed to enhance antiectoparasite activity. The nemadectins are classified as milbemycins, but differ from the milbemycins proper because they have a distributed double bond at C-26. An important nemadectin is moxidectin (e.g., Cydectin). Eprinomectin (4″-epi-acetylamino-4″-deoxy-avermectin B1) is a true second-generation macrocyclic lactone synthesized from avermectin. Doramectin differs from ivermectin in that a six-carbon ring replaces a three- or four-carbon chain at the C-25 position of the basic ivermectin. Compared to ivermectin, these molecular differences result in a more lipophilic and persistent doramectin molecule.

TABLE 44.3 US FDA approved* ectoparasiticides

Drug Class	Approved Species	Approved Indications
Avermectins/Milbemycins		
Ivermectin	Cats	Ear mites
	Beef cattle	Ticks, lice, mites
	Pigs	Mites
Doramectin	Beef cattle	Lice, mites, ticks, grubs
	Pigs	Lice, mites
Eprinomectin	Dairy and beef cattle	Lice, mites, flies
Selamectin	Dogs	Fleas, mites, ticks
	Cats	Fleas, mites
Moxidectin	Dairy and beef cattle	Lice, mites, flies, grubs
Milbemycin	Cats	Ear mites
Organophosphates		
Fenthion	Beef cattle	Grubs, lice, flies
Famphur	Beef cattle	Grubs, lice, flies, ticks
Amitraz	Dogs	Mites
Nitenpyram	Dogs and cats	Fleas
Lufenuron	Dogs and cats	Fleas

*Approved as of June 2006.

PHARMACOKINETICS. The oral, IV, and subQ pharmacokinetics have been described elsewhere in this book. The focus here will be to compare the dermatopharmacokinetics of topically applied avermectins. It should be first noted that eprinomectin and moxidectin pour-ons are formulated in >80% oil content. This encourages more drug depot formation on skin surface and stratum corneum, and thus *reduced bioavailability* compared to pour-on products with ivermectin and doramectin. The latter are formulated with isopropyl alcohol, which is more likely than oil to promote epidermal flux. Because of the high

oil content of the eprinomectin and moxidectin formulations, there is evidence that it is rain-fast and thus impervious to rain and other forms of weather precipitation (Gogolewski et al. 1997)

The dermal bioavailability of doramectin is about 40% greater than ivermectin in cattle (Gayrard et al. 1999). The dermal bioavailability for doramectin pour-on is approximately 16% when compared to the subcutaneous route of administration. Following topical application of selamectin, this drug is slowly absorbed (flip-flop kinetics) into the bloodstream and redistributed to form reservoirs in sebaceous glands as well as the hair follicle and basal cells of the epidermis (Sarasola et al. 2002). Dermal bioavailability appears to be significantly greater in cats (74%) than in dogs (4.4%), although this may be attributed to greater self-grooming in cats than in dogs. However, selamectin flux is three times greater in cat skin (0.1 $\mu g/cm^2$/hr) than in dog skin (0.03 $\mu g/cm^2$/hr). The half-life of this drug is greater in cats (69 hours) than in dogs (14 hours), and in general, selamectin half-life is greater in cats and dogs following dermal > oral > IV administration. This demonstrates its persistence in the stratum corneum and upper epidermis. As with many of the avermectins, the dermal absorption process is the rate-limiting step, and the increased persistence in the body after dermal application should reduce reinfection rates by ectoparasites. There is also conflicting evidence of differences in selamectin disposition between male and female dogs (Sarasola et al. 2002; Dupuy et al. 2004).

MECHANISM OF ACTION. In invertebrates, the avermectins primarily target the glutamate-gated chloride channels that are close in proximity to GABA-gated sites. It is possible that these endectocides may also potentiate GABA-gated sites as well. Chloride influx lowers cell membrane resistance and causes hyperpolarization of the resting potential of postsynaptic cells. Transmission to muscles is therefore prevented. The ectoparasite therefore displays ataxia, paralysis, and death. In contrast to GABA antagonists (e.g., lindane and fipronil) that lead to convulsions, the avermectins cause a different neurological syndrome that is characterized at first by a coarse tremor followed by ataxia and comalike sedation. It should be noted that the avermectins can block GABA at low concentrations, but at high concentrations cause irreversible channel activation or enhancement of GABA effect, which is associated with the classical signs of ataxia and sedation. These endectocides have a wide margin of safety because they are very selective for the glutamate-gated channels in nematodes and arthropods but are lacking in mammals. In mammals, the avermectins primarily target the GABA- and possibly the glycine-gated chloride channels (Bloomquist 2003). Furthermore, in mammals, GABA-mediated neurotransmission occurs in the CNS, and where the blood-brain barrier (BBB) prevents uptake of the endectocides. These endectocides are also thought to interfere with parasite reproduction. It should be noted that unlike the macrolide antibiotics, these endectocides lack antibacterial and antifungal activity.

EFFICACY

Ivermectin. Injectable formulations are used to control lice (*Haematopinus suis*) and mange mites (*Sarcoptes scabiei var suis*) in *swine* and horn flies (*Haematobia irritans*); and grubs (*Hypoderma bovis*), biting and sucking lice (*Lignathus vituli, Haemaotopinus eurystemus*), and mites (*Sarcoptes scabei var bovis*) in *cattle*. Pour-on and oral formulations are also available for cattle. There is NO immediate death to ticks in cattle, but reduced reproductive potential. As these drugs are eliminated in the feces, they are effective against dung breeding flies. Not all commercial formulations of ivermectin are approved for the treatment of the most common type of cattle mange caused by chorioptic mite. In dogs, SC doses can be effective against otodectic, sarcoptic, and notoedric mange and control of demodectic mange. A relatively new topical product (Acarexx®) is approved for treating adult ear mites (*Otodectis cynotis*) in cats and kittens 4 weeks of age and older. There is evidence that the ears do not necessarily need to be cleaned before treatment.

Eprinomectin. This is available only as a pour-on formulation (Eprinex®) and is approved only for dairy and beef cattle. It is an oil-based formulation that makes the drug "waterproof" to some extent. This broad spectrum antiparasiticide is effective against lice, horn flies, and mites. Because of its unique molecular structure, eprinomectin does not readily partition into milk and therefore is one of the two endectocides that requires NO milk withholding time. The meat withdrawal time is also zero.

Doramectin. Doramectin is available as an injectable for beef cattle (0.2 mg/kg SC and IM) and swine (0.3 mg/

kg IM) and pour-on (0.5 mg/kg) for beef cattle only. It is believed to be more efficacious than other endectocides against biting and sucking lice. This drug is not approved for dairy cattle because of the concern for significant residues in milk.

Cattle: The spectrum of activity is similar to that of ivermectin. Doramectin has activity against important sucking lice, grubs, ticks, mites, and screwworms in cattle. The latter is unique among the macrolide endectocides. Application of the pour-on can prevent reinfestation of lice for as long as 16 weeks.

Swine: Doramectin is approved for use against sucking lice and mange mites.

Moxidectin. Moxidectin products (Cydectin®, Equest®) are a new generation of milbemycins that have a broad spectrum of activity against nematode and arthropod parasites in cattle. Unlike the previously discussed endectocides, this is a single compound, and not a mixture of two compounds. The approved dose of Cydectin® pour-on is 0.5 mg/kg in cattle, and the drug has a spectrum of activity similar to ivermectin. Cydectin® *is the only pour-on endectocide labeled for control of common scab mite* (*Psoroptes ovis*), a reportable disease requiring quarantine.

Selamectin. Revolution® is a topical monthly application approved for treating dogs and cats for ear mites and adult fleas, and prevents flea eggs from hatching. In dogs, it is used in the treatment and control of sarcoptic mange (*Sarcoptes scabiei*) and control of the tick (*Dermacentor variabilis*). Selamectin is the only spot-on product approved for control of canine sarcoptic mange. There are anecdotal reports of delayed responses to this drug and a few treatment failures (Curtis 2004). However, in lieu of these situations, some veterinary dermatologists recommend that this drug be reapplied every 2–3 weeks with owner's consent as this is extralabel use of the drug.

Milbemycin Oxime. Milbemycin oxime is well known as a heartworm preventative, but it also has significant ectoparasiticidal effects. The only approved use of this chemical as an ectoparasiticide, MILBEMITE® OTIC Solution, at 0.1% is used as a treatment for ear mite (*Otodectes cynotis*) infestations in cats and kittens 4 weeks of age and older. Milbemycin oxime may also be effective in cases of amitraz-resistant demodicosis, but this is not an approved use thus far.

TABLE 44.4 Withdrawal times of pour-on macrolide endectocides

Generic Drug	Example	Approved Species	Withdrawal Times
Ivermectin	Ivomec®	Beef cattle	48 days for meat
Eprinomectin	Eprinex®	Beef and dairy cattle	0 days for meat and milk
Doramectin	Dectomax®	Beef cattle	45 days for meat
Moxidectin	Cydectin®	Beef and dairy cattle	0 days for meat and milk

SAFETY/TOXICITY. Ivermectin has a tenfold safety margin in ruminants, horses, swine, and dogs, except collies. Due to a mutation within the gene that codes for the MDR1 pump protein that normally disallows entry of ivermectin into the central nervous system, collies should not be treated with ivermectin or any other avermectin. Acute toxic signs include CNS depression, ataxia, and possible death. The principal clinical pathologic change is a decrease in serum iron values in dogs.

The meat and milk withdrawal times for this class of drugs vary across avermectins, and Table 44.4 provides clear evidence of this and why label instructions should be carefully followed. Extralabel use of doramectin or ivermectin in dairy cattle may require a milk withholding period of almost 60 days!

PYRETHRINS AND SYNTHETIC PYRETHROIDS

The pyrethrins are derived from the *Chrysanthemum* plant, but in recent years they have been slowly replaced with synthetic pyrethroids. The latter are more resistant to breakdown, which results in greater residual activity than the natural pyrethrins. Pyrethrins and pyrethroids are often formulated with insect growth regulators, synergists, and/or repellents to enhance efficacy. The more frequently used pyrethroids in veterinary formulations include permethrin, fenvalerate, cypermethrin, and phenothrin. These may be formulated as pour-ons, spray-ons, barn misters, feed-throughs, and shampoos.

CHEMISTRY. Natural pyrethrins occur as six compounds pyrethrin I, pyrethrin II, jasmolin I, jasmolin II, cinerin I, and cinerin II (Kaneko and Miyamoto 2001). The

molecular weight of these insecticides ranges from 316.4 to 374.5 and log Ko/w ranges from 4.3 to 5.9. The synthetic pyrethroids are structurally similar to the natural pyrethrins, and many of those used in veterinary medicine have a wider range of molecular weights (302.4 to 416.3), logKo/w (4.6 to 7.4), and LD50 (105.8 to 4240 mg/kg). Depending on the literature reviewed, the pyrethroids can be classified in a number of ways. Some authors have grouped them into two broad generations of pyrethroids, with the first-generation being characterized as esters of chrysanthemic acid and alcohols having furan ring and terminal side-chain moieties. These pyrethroids are sensitive to light and temperature, and are therefore most effective when used indoors. The second-generation pyrethroids and for that matter, the majority of pyrethroids in veterinary use today, have a 3-phenoxybenzyl alcohol in the alcohol moiety and replacement of the photolabile moieties with dichlorovinyl, dibromovinyl substituent, and aromatic rings. These modifications provide excellent insecticidal activity and environmental stability for this class of pyrethroids.

Another classification system groups the pyrethroids into four generations, with the first generation reflecting the same properties as the first generation in the earlier classification scheme. The first-generation pyrethroids (e.g., allethrin) are similar to the natural pyrethrin, cinerin I, and therefore lack environmental stability. The second-generation pyrethroids (e.g., resmethrin and tetramethrin) are significantly more stable than the first generation and have significantly greater killing capacity than the natural pyrethrins. The third-generation pyrethroids include the ever-popular fenvalerate and permethrin, which are noted for their photostability and potency. Permethrin in particular is the most ubiquitous pyrethroid formulated with veterinary ectoparasiticidal products. The fourth-generation pyrethroids are the most potent (e.g., cypermethrin and cyfluthrin) and also the most persistent. For this reason they are most often formulated in ear-tags.

Pyrethroids are also classified as Type 2 pyrethroids (e.g., fenvalerate) because they have an alpha-cyano moiety unlike Type 1 pyrethroids (e.g., permethrin) which lack this moiety and thus are less toxic than Type 2 pyrethroids. The reader should be aware that these pyrethroid insecticides can exist as chiral and geometrical isomers, with some isomers displaying different pharmacokinetic and pharmacodynamic properties from other isomers of the same pyrethroid. Many of these chemicals are stable in weakly acidic water, but very unstable in an alkaline medium.

PHARMACOKINETICS. Dermal absorption of pyrethrins and pyrethroids is indeed very limited (<1%) across the skin of domestic and laboratory animals and humans. (Baynes and Riviere 2001). This is primarily because these chemicals are very lipophilic (Ko/w range from 4.0 to 7.4) and they have large molecular weights. There is therefore the tendency for these chemicals to reside in the outermost layer of the skin (stratum corneum) with little or no penetration into the systemic circulation. For this reason, the pyrethroids are approved by US EPA and *not* US FDA. These chemicals are also rapidly detoxified to harmless alcohol and acid metabolites and conjugates in the liver and blood, with half-lives ranging from a few minutes to typically a few hours (Ray 2005). The *trans* isomers are hydrolyzed at a faster rate than the *cis* isomers, and the presence of α-cyano group in the third- and fourth- generation pyrethroids also slows down hydrolysis and oxidation. In spite of this, many of these pyrethroids do not result in significant meat or milk withdrawal times following topical administration to food animals (Riviere and Baynes 1998). For example, there are several approved pour-on products for food animals that contain as much as 1–5% permethrin or 1% cyfluthrin but have zero meat and milk withholding times.

MECHANISM OF ACTION. Many different mechanisms of action have been proposed for this class of insecticides. Potential targets in insects include voltage-gated sodium, chloride, or calcium channels; GABA-gated chloride channels; mitochondrial ATPase; and nicotinic receptors to mention a few of the many proposed targets for pyrethroids. However, the main target is the gating kinetics of Na^+ channels in nerves, which results in repetitive discharges or membrane depolarization and ultimately death of the ectoparasite. Pyrethroids are extremely selective for insects over mammals as insect sodium channels can be as much as 100 times more sensitive than mammalian brain channels (Warmke et al. 1997). In fact, the selectivity ratio (mammalian toxicity versus insect toxicity) of most pyrethroids exceeds 1,000.

Recall that in normal voltage-gated sodium channels it is the inward sodium current that produces the action potential and then it is rapidly closed at normal resting potentials. However, with the interaction of the pyrethroid with the sodium channel this causes the sodium channel to remain open. This leads to a slowing of both the activation and inactivation process, which causes the now

modified channel to be in a stable hyperexcitable state. Pyrethroid structure and stereo-specificity plays a significant role in the mechanism of action. For example, Type 2 pyrethroids such as fenvalerate keep the sodium channel open for a significantly longer period (i.e., prolongation of sodium channel current) than Type 1 pyrethroids such as permethrin, which in part explains the differential toxicity between these two classes of pyrethroids. The 1R and 1S cis isomers bind competitively while the 1R and 1S trans-isomers bind noncompetitively to another site. These insecticides, especially the Type 2 pyrethroids, could also suppress GABA and glutamate receptor-channel complexes. Pyrethroids are also classified as either Type I compounds (permethrin, resmethrin) because they cause rapid onset of hyperactivity and repetitive action potentials, or Type II compounds (fenvalerate, cypermethrin) because very low doses cause lethal effects and few behavior changes.

EFFICACY. Pyrethrins and pyrethroids are formulated in shampoos, sprays, collars, dips, dusts, and ear-tags to repel or treat for most of the known ectoparasites important to domestic animals. The discussion below attempts to review the more common applications of pyrethroid formulations used in veterinary medicine. Note that these are only examples, and that applications may vary depending on indication (spot-on versus spray) and this is related to the concentration of the pyrethroid in the formulation. These products may be formulated with synergist and/or insect growth regulators.

First-Generation Pyrethroids. Allethrin (d-trans allethrin) is most often formulated in shampoos for dogs and cats to kill fleas and/or ticks. An excellent example includes Mycodex® SensiCare™ Flea & Tick Shampoo, which has 0.12% d-trans allethrin.

Second-Generation Pyrethroids. Phenothrin (85.7%) is frequently used as a spot-on treatment for tick and fleas in dogs only. These spot-on products are *NOT* approved for cats as of 2005. There are phenothrin flea collars and a shampoo formulation available for both dogs and cats. Resmethrin (0.5%) is more often approved in foggers in stables and kennels, and it is also formulated as topical sprays for horses; there are a few shampoo formulations available for control of fleas and ticks on dogs and cats.

Third-Generation Pyrethroids. Permethrin is probably the most widely used pyrethroid in veterinary medicine. Almost all of the spot-on products are at high concentrations and are therefore approved only for dogs, and not cats, to manage fleas, ticks, and mites. The sprays, shampoos, and dusts are formulated at lower concentrations and thus approved for both species. Permethrin is also widely used in food animals as sprays and pour-ons to treat for ectoparasites and requires short withdrawal times provided the product is correctly diluted and is applied no more than every 2 weeks. For example, the Atroban spray products have a 5-day withdrawal time in swine treated with 0.11% permethrin for mange mites but 0 days in cattle treated with 0.02% pemethrin. Many products can have residual activity up to 28 days for some formulations.

Fenvalerate (8%) is formulated in ear-tags for cattle to control flies, lice, and ticks. There are no approvals for companion animals.

Fourth-Generation Pyrethroids. Cyfluthrin is approved for use as an ear-tag and as a pour-on for cattle (e.g., Cylence®, 1%) with no withdrawal time. As with other pyrethroids, there are some concentrates that are approved for use around livestock premises but not directly on animals. Cypermethrin is usually formulated as a spray and predominantly used as fly repellent around horses with some formulations marketed as being sweat resistant.

SAFETY/TOXICITY. The selectivity ratio, which compares toxicity in insects with that in mammals, is higher for pyrethrins and pyrethroids (>1000) than for organophosphates and carbamates (<100). Dermal exposure to pyrethrins and pyrethroids rarely results in systemic absorption to cause significant signs of toxicity in domestic animals, but grooming of the treated hair coat by cats can result in significant oral ingestion of pyrethroids. Cats, more so than dogs, are presented with clinical signs of toxicity, and this is often after the dog formulation was inadvertently applied topically to adult cats or kittens or the untreated cat comes into physical contact with a treated dog. Recall that cats are deficient in their ability to clear chemicals by hepatic glucuronidation. This explains why cats are more sensitive than dogs to pyrethroids. The dog-only spot-on flea and tick products can contain as much as 45–65% permethrin, which at this concentration can

be very harmful to most cats (Meyer 1999). Not only is permethrin toxicity in cats a great concern, but so is phenothrin toxicity in cats. Phenothrin, a Type 1 pyrethroid similar to permethrin, was originally approved as a spot-on product with 85.7% phenothrin for cats. These products were canceled in 2005 by the manufacturer because of the adverse effects and numerous deaths in feline patients.

Clinical signs of pyrethroid toxicity may be confused with OP or carbamate toxicity, and they include nerve and muscle disorders and can be grouped in Type 1 (T) poisoning and Type 2 (CS) poisoning. The onset of signs of toxicity can occur within minutes to hours depending on the route of exposure, and the signs may resolve within 24 to 72 hours following supportive therapy. The Type 1 syndrome is similar to DDT in that it involves progressive body tremors, exaggerated startle response, hyperexcitability, and death. Type 2 syndrome is associated with induced salivation, weakness, and distinctive burrowing syndrome. These signs appear in both dogs and cats and large animals, and the prognosis is guarded to good depending on the exposure level. Readers are encouraged to refer to other texts and references on appropriate therapy (Richardson 2000).

Aquatic animals such as fish and invertebrates are highly susceptible to pyrethroids (Smith and Stratton 1986); therefore their use on and around livestock facilities should ensure that there is minimal environmental impact.

ORGANOPHOSPHATES

Organophosphates (OPs) have insecticidal, ascaricidal, and helminthicidal activity, and are thus classified as broad-spectrum ectoparaciticides, which explains why they were used in veterinary medicine for at least 4 decades since their discovery during WW II. These chemicals are becoming less popular for use in and around domestic animals as there are safer products such as the ivermectins, pyrethroids, neonicotinoids, and fipronil. Another concern is related to their persistence in the environment, which can negatively influence the ecosystem. For these and many other reasons, many of the popular organophosphates that were approved by US FDA or US EPA for use in companion or food animal species are no longer marketed or available for veterinary use. However, there is still sufficient veterinary use of OPs that are US FDA–approved (Table 44.3) and US EPA–registered that the reader should be aware of their efficacy and be able to recognize signs of organophosphate toxicity in domestic animals.

CHEMISTRY. Organophosphates are usually classified as phosphates (e.g., dichlorvos), phosphorothioates (e.g., coumaphos), or phosphorodithioates (e.g., malathion, fenthion). The term "thioates" indicates that for some OPs, the double-bonded oxygen is replaced with a sulfur molecule. They can also be classified based on when these chemicals were first developed for commercial use. The aliphatics derivatives were the first OP products and are characterized by their aliphatic-like structures (e.g., dichlorvos, malathion). These were followed by the phenyl derivatives, which contain a phenyl ring with one of the ring hydrogens displaced by Cl, NO_2, CH_3, CN, or S, (e.g., fenthion, famphur) and then the heterocyclic derivatives where the ring structures are composed of different or unlike atoms, such as N or S (e.g., diazonon, chlorpyriphos). The latter group is the longest acting OP based on chemical structure. The molecular weights of many of these chemicals used in veterinary medicine range from 257 (trichlorfon) to 384 (ethion). These chemicals can be very lipophilic with octanol-water partition coefficients ranging from 2 to 6.

MECHANISM OF ACTION. The thioate compounds (P = S), unlike the phosphate (P = O) compounds, must first be metabolized in the liver to oxy compounds before they can irreversibly inhibit acetylcholinesterase (AChE) by phosphorylation. Inhibition of AChE results in accumulation of acetylcholine (ACh) at cholinergic receptors. Recall that ACh is a normal neurotransmitter released at synapses that mediates transmission of nerve impulses to effector organs or skeletal tissues to produce a response. AChE is normally present at these nerve endings to rapidly hydrolyze ACh to control the level and duration of synaptic transmission. With OPs inhibiting AChE the resulting accumulation of ACh leads to paralysis and death to the parasite.

EFFICACY. As of 2006, there were only 10 OP generics approved for veterinary use in the U.S. Systemic bioavailability following topical application is limited, but these chemicals are distributed across the entire coat of the animal by lateral diffusion following topical application to

a localized region. Several of these OPs are formulated as topical sprays and dusts or dip applications (coumaphos and phosmet), while many are formulated as ear-tags in cattle (pirimiphos and diazinon) and flea collars for dogs and cats (tetrachlorvinphos, dichlorvos, and diazinon). Chlorpyriphos and phosmet dips are the only OPs still approved for use in dogs to treat mange. Although chlorpyrifos was recently labeled for restricted use by US EPA, there are several Happy Jack products that are approved for use as shampoos and dips on dogs. These two products are indicated to kill fleas, ticks, and sarcoptic mange mites on dogs. Prior to the availability of avermectins for veterinary use, fenthion (Spotton®) and famphur (Warbex®), which are still US FDA approved drugs, were used extensively to control cattle grubs (*Hypoderma bovis* and *Hypoderma lineatum*) as well as lice. When treating for cattle grubs, the reader should be reminded that application of these therapeutics should occur soon after the heel-fly activity ceases. If the grub larvae are allowed to migrate to the esophagus or spinal canal, rapid killing of large numbers of these larvae following treatment can cause host-parasite reactions such as bloat, salivation, staggering, or paralysis.

SAFETY/TOXICITY. Inhibition of AChE can result in muscarinic and nicotinic effects. The muscarinic effects at the autonomic effector organs include miosis, lacrimation, vomiting, diarrhea, frequent urination, dypsnea, bradycardia, and hypertension. The nicotinic effects include effects at the neuromuscular junction such as muscle tremors and twitching, paresis, and possibly paralysis. Central nervous system signs may include depression, hyperactivity, and seizures, but these are rare events. Organophosphate-induced delayed neurotoxicity (clinical signs delayed for 7–21 days) may be observed in dogs and cats following exposure to some but not all OPs. The following drugs may potentiate the toxicity of OPs: phenothiazine tranquilizers, aminoglycoside antibiotics, and neuromuscular blocking agents such as levamisole and nicotine. Brahman, Charolais, and Simmental cattle are more sensitive than English breeds of cattle; greyhounds and whippets are the more sensitive dog breeds; cats are more sensitive than dogs; and poultry are more sensitive than mammals to organophosphates. Recall that several of these OPs are very lipophilic and potential residues in tissues and milk are possible. Except for fenthion and famphur, many of the currently marketed OPs approved for use in food animals as of 2006 have a very short withdrawal time or zero withdrawal times as they are less likely to cause residues in meat or milk when used according to label. These are all US EPA registered OPs, and they include coumaphos (Co-Ral®), which has a zero withdrawal time for meat and milk, and phosmet (Del-Phos® Emulsifiable Liquid Insecticide), which has a 3-day and 1-day meat withdrawal time for cattle and swine, respectively. Fenthion and famphur have very long meat withdrawal times—46 and 35 days, respectively—and are not approved for use in lactating dairy cattle.

CARBAMATES

Carbamates are cyclic or aliphatic derivatives of carbamic acid. These insecticides are generally safer than OPs, but they should be used with caution. The mechanism of action of carbamates is similar to that of OPs, except that inhibition is by carbamylation and the reaction is slowly reversible and spontaneous. The most frequently used carbamate is carbaryl, which may be formulated with pyrethrins and/or synergists. These products are approved for cats and dogs only as shampoos (0.5% carbaryl) and dusts (12.5% carbaryl). Unfortunately, these products need to be applied more often than the newer generation of veterinary insecticides and insect resistance is commonly reported. Propoxur is another carbamate that is slightly more potent than carbaryl, but it is included in flea and tick collars for dogs and cats. Toxicity associated with application of these two carbamates can be avoided if pets are not simultaneously exposed to anticholinesterase drugs or pesticides with similar mechanism of action, and exposure is limited to cats and dogs older than 12 weeks.

D-LIMONENE AND LINALOOL

These are volatile oil extracts from the peel of oranges, and it's their vapors and not necessarily direct contact that affects ectoparasites. This insecticide is formulated in shampoos and sprays. Although a relatively safe insecticide, *d-limonene* has caused *sporadic toxicoses* in cats (Hooser 1990; Lee et al. 2002). Clinical signs are not often seen at the label concentration, but they can occur at greater than five times the label dose. These signs can include excessive salivation, ataxia, and tremors as well as gross lesions in the scrotal and perineal area.

AMITRAZ

Amitraz is the only formamidine used in veterinary medicine, and is available in various formulations to treat for ticks, lice, and mites in dogs, swine, and cattle. To date, none of these approved products is labeled to repel or kill fleas. Although the mechanism of action of amitraz is not very clear, this ascaricide inhibits monamine oxidase (MAO) that normally metabolizes neurotransmitter amines present in the CNS of ticks and mites. There are no effects on cholinesterase activity.

EFFICACY. Amitraz is used as a dip (Mitaban®) to treat for generalized demodicosis (*Demodex canis*) in dogs. Amitraz can be applied as a 0.025% (250 ppm) sponge-on solution once a week (U.K.) or every 2 weeks (U.S.). However, this drug is not approved to treat localized demodicosis or scabies. There are several reports describing the use of higher concentrations (e.g., 1.25%) or more frequent applications to treat for scabies (Hugnet et al. 2001). These off-label protocols run the risk of dogs developing severe signs of amitraz-related toxicosis described below, and it's advisable to use the more safe drugs described for this condition. For example, selamectin is the only approved spot-on drug for treatment and control of scabies in dogs (Shanks et al. 2000). Amitraz is also impregnated in tick collars for dogs (Preventic®, 9% a.i.) and can kill ticks for up to 3 months, with activity beginning within 24 hours of placing the collar on the dog. These amitraz tick collars are not approved for cats.

Amitraz (e.g., Taktic® E.C., 12.5% a.i.) is approved for use in beef and dairy cattle for ticks such as *Amblyomma americanum* and *A. maculatum*; mites such as *Chorioptes bovis, Psoroptes,* and *Sarcoptes scabei;* biting louse (*Damalinia bovis)*; and sucking lice *Haematopinus eurysternus, Lignathus vituli*, and *Solenoptes capillatus.* This product is also approved for use in swine to treat for mange mites and louse. *Taktic® is not approved for use in horses or dogs as it may cause death!!!* Once the spray mixture has been prepared it must be applied within 6 hours or it will lose its efficacy.

SAFETY/TOXICITY. This drug is not approved for use in cats, Chiuahuas, pregnant or nursing bitches, or puppies less than 3 months old (Curtis 2004). In mammals, Amitraz activates α_2-adrenergic receptors, and adverse effects are similar to those seen with xylazine. Signs of toxicity include CNS depression, bradycardia, polyuria, hyperglycemia, and sedation, which can last for up to 24 hours. Dogs tested with 5 or 10 times the labeled dose usually develop most of these signs; therefore, the final dip solution needs to be accurately prepared. The adverse effects from amitraz toxicosis can be reversed in dogs with a low dose of atipamezol (50 μg/kg IM), which is an α_2-antagonist (Hugnet et al. 1996). Accidental consumption of amitraz flea collars by dogs has resulted in toxicosis (Grossman 1993). Swine should not be treated more than 4 times a year and should not be treated within 3 days of slaughter. Amitraz is a potential hazard to humans (Avsarogullari et al. 2006) if they do not wear appropriate personal protection such as chemical-resistant gloves, aprons, and goggles/face shields.

INSECT GROWTH REGULATORS (IGRs)

These agents first appeared on the market in the 1980s and 1990s, and were popular because the chemicals were promoted as not being a pesticide, and therefore harmless to pets, livestock, and humans. The oral LD50 in rats for these chemicals ranges from 2 to 10 gram/kg body weight, which supports the extreme safety of these IGRs. These chemical agents affect the developing stages (eggs, pupae, and larvae) of insects and arthropods and do not affect the adult ectoparasite. Because of this, effective control is not achieved until several weeks after treatment and many of these IGRs are often formulated with adulticides described earlier in this chapter. The IGRs can be grouped as juvenile-hormone analogs (JHAs) and insect development inhibitors (IDIs).

JUVENILE HORMONE ANALOGS (JHAs). The IGRs are juvenile hormone analogs, which falsely signal organisms such as ticks, fleas, and flies to remain in their immature egg or larval stage and not develop to adult stage. In the normally developing insect, the hormone levels usually decrease prior to the adult stage. The use of these JHAs therefore falsely signals to the developing insect to remain at its immature stage. Approved JHAs include methoprene, pyriproxifen, fenoxycarb, and cyromazine, with the former two JHAs being the most frequently used in veterinary medicine. Several of these JHAs are available as individual active ingredients in several topical formulations, but they are often formulated with adulticides such

as the pyrethrins and/or pyrethroids. *Methoprene* is used mainly to control horn flies in cattle by incorporating it into the cattle concentrate (0.4%) or block (0.01%). This method of application prevents the emergence of adult horn flies from cattle manure. Methoprene is formulated with adulticides for premises flea control, and also formulated with fipronil, phenothrin, and permethrin for flea and mosquito control in dogs and cats. Some of these spot-on applications may contain as much as 2–3% methoprene. *Pyriproxyfen* is often applied as a spot-on, and is effective against flea eggs in cats for up to 56 days (Rust 2005). This JHA applied every 3 months to cats significantly reduces flea numbers; 87% of the treated cats did not have fleas after 6 months (Maynard et al. 2001). As with methoprene products, pyriproxyfen is often formulated with adulticides such as permethrin and pyrethrins to be applied as sprays, spot-ons, and collars for cats and dogs.

INSECT DEVELOPMENT INHIBITORS (IDIs). The IDIs, such as the benzoylphenyl urea compounds (*diflubenzuron, lufenuron*), interfere with the development of the insect exoskeleton by inhibiting chitin synthesis or deposition pathways. Chitin is an essential constituent of flea eggshells and exoskeleton of immature fleas. Following oral ingestion of diflubenzuron, it passes unchanged in the feces where it contacts the eggs and larvae of developing flies. Lufenuron (Program®) is administered orally at monthly intervals to cats and dogs to control fleas. There is also a subcutaneous injectable (10 mg/kg) for cats that is efficacious for up to 6 months against fleas. No adverse effects have been observed in cats, but injectable lufeneron should not be given to dogs as it causes adverse local reactions at the injection sites. As this drug is lipophilic, its slow release from adipose tissues allows maintenance of effective blood levels for several weeks after administration. One of the more popular IDIs is the combination of lufenuron and milbemycin oxime that is used to control fleas on dogs as well as being a heartworm preventative.

SYNERGISTS AND REPELLENTS

Synergists such as piperonyl butoxide and N-octyl bicycloheptene dicarboximide (MGK 264) are often formulated with topical insecticide products to enhance the activity of insecticides. Almost all of the topicals formulated with these synergists contain pyrethroids and pyrethrins as the primary insecticide. These synergists inhibit oxidative and hydrolytic enzymes in the insects that are responsible for degradation of insecticides to harmless metabolites. It is believed that a carbene derivative forms and binds to the heme moiety of the cytochrome P450 enzyme making it inactive and unable to detoxify the insecticide. This then results in very high levels of the pyrethrin or pyethroid that are toxic and lethal to the ectoparasite (Murray and Reidy 1989). Synergists by themselves are less toxic than the active ingredients in a topical formulation. Owners and veterinarians should, however, be aware that when cats are exposed dermally to synergists such as piperonyl butoxide at concentrations greater that 1.5%, this may similarly reduce detoxification of pyrethrins in cats and thereby also enhance toxicity of the insecticide in cats (MacDonald and Miller 1986).

Repellents are also included in formulations to repel insects; although some repellents can be ectoparasiticidal such as permethrin, most repellents are not ectoparasiticidal. The primary advantage of the repellents is that they prevent transmission of vectorborne diseases even if these repellents are not ectoparasiticidal. A repellent can be effective via a number of mechanisms: preventing the ectoparasite from entering or landing on the hair coat, interfering with or inhibiting the ectoparasite's feeding, and causing the ectoparasite to become disoriented. Frequently used repellents include butoxypolypropylene glycol (Stabilene), di-n-propyl isocinchomeronate (MGK 326), and diethyl-m-toluamide (DEET).

DEET is an insect repellent approved by US EPA for use in dwellings; on the human body and clothing; and on cats, dogs, horses, and pet living/sleeping quarters (US EPA 1998). There are greater than 225 DEET products registered for use, with DEET concentrations ranging from 4% to 100%. However, DEET is not approved for direct application to the skin/coat of pets, and there are reports of adverse clinical signs in cats exposed to DEET topically (Dorman et al. 1990). Based on data from several experimental dermal absorption studies, DEET may influence the toxicity of insecticides by modulating insecticide dermal absorption (Baynes et al. 1997). Butoxypolypropylene glycol is usually formulated with a pyrethroid insecticide (e.g., resmethrin, permethrin) and/or a synergist (e.g., piperonyl butoxide). Most of these formulations are approved for use in horses, cats, and dogs, and formulated as sprays with concentrations ranging from 4.8 to 20%. No adverse effects in pets or laboratory animals have been

TABLE 44.5 Comparisons of US FDA CVM and US EPA with regard to ectoparasiticides

	US FDA CVM	US EPA
Mission	Approve and study effects of drugs and feed on animals	Preserve and improve quality of the environment and human health
	Company files a New Animal Drug Application (NADA) to FDA	Registration of pesticides
		Company files an Application for Pesticide Registration (APR) to EPA
Scope	Concerned with drugs that work systemically in the animal	Concerned with anything that affects air, water, and soil quality
	Includes any route of administration to the animal	Chemicals that are applied topically to animals but not absorbed systemically
Safety study requirements for FDA approval or EPA registration	Drug formulations must be evaluated in same species for which the drug is designated	Active ingredients are tested in lab animals
		Formulations do not have to be tested in the designated species
Efficacy	Flea control products must be at least 90% efficacious	Clinical studies not required
	Clinical studies required	Practical efficacy in marketplace is required
Drug distribution	Often by prescription from a licensed veterinarian	Often sold over-the-counter at retail outlets

attributed to this repellent (CA EPA 2002). MGK 326 is often formulated with pyrethroids and/or synergists to be used as sprays, dips, and shampoos in horses, dogs, and cats.

ECTOPARASITICIDE APPROVAL AND REGISTRATION IN THE U.S.

Unlike other drug classes discussed in this book, either the US EPA or the US FDA Center for Veterinary Medicine (CVM) is involved in the approval of ectoparasiticides. The US FDA CVM evaluates those chemicals that are administered orally or topically but exert their effects following systemic distribution. These chemicals are classified as drugs and many of these drugs require a veterinary prescription. The US EPA evaluates those chemicals applied topically, but exert their effect on the surface of the skin or around the farm premises, and don't often require a veterinary prescription. Table 44.5 summarizes the differences in function between these two critically important federal agencies in the U.S.

In spite of these clear distinctions there is still confusion among pet owners and even some veterinarians about how flea products are marketed in the U.S. as some products can be obtained over-the-counter (OTC) in pet and feed stores while others can be obtained only from the veterinarian. The latter is often referred to as the veterinary-channel products (e.g., fipronil and imidacloprid). Even though those flea products may not require a prescription, obtaining these products from a veterinarian only ensures that a client-patient-veterinarian relationship is established, which reduces the probability of insecticide toxicoses often associated with OTC products used by pet owners. As discussed in various sections of this chapter, this has often been the problem with OTC pyrethroid and OP products used in cats and dogs.

Another issue that is of concern to the federal government is the extralabel use of ectoparasiticides. The passage of the Animal Medicinal and Drug Use and Clarification Act (AMDUCA) in 1994 allows but does not encourage the extralabel use of approved animal or human *drugs* in special circumstances. As pesticides are not approved drugs, extralabel use of these chemicals is not covered by AMDUCA and extralabel use is strongly prohibited.

Use of anticancer drugs has become an important aspect of veterinary practice that, although increasingly used in general veterinary practice, is still ideally used in specialty practices that have adequate expertise and safety facilities. Significant advances have been made in understanding the biology of cancer including the use of therapies that are more specific for certain types of tumors. Successful application of the new concepts requires in-depth understanding of the natural history of each individual type of cancer as well as knowledge of the combinations of modalities that are appropriate for each type of cancer. Application of these approaches to treatment of animal cancer is slowed by species differences, expense, and nonavailability of adequate supportive therapies in many practices. Nevertheless, veterinary cancer therapy has made tremendous strides and patient quality and/or quantity of life can be increased through rational selection of patient and therapeutic goal, therapeutic approach, and effective client education.

TREATMENT PERSPECTIVES

Cancer is defined as cured when all cancer cells have been eradicated. Cure is the ideal goal, but producing remission and/or palliation is a worthy goal. A cancer is said to be in *remission* when all clinical evidence of cancer has disappeared, but it is noteworthy that microscopic foci of cancer cells may remain. *Palliative treatment* refers to the treatment of cancer (when cure is unlikely) to reduce pain, improve the sense of well-being, or to correct some physiological malfunction insofar as possible. The therapeutic regimen selected must be consistent with the goal for the patient (i.e., cure, remission, or palliation). It is increasingly recognized that cancer is a chronic disease and that stable disease with good quality of life is an acceptable goal.

Chemotherapy may be defined as the application of drugs to kill or inhibit the growth of viruses or foreign cells, such as bacteria, in the body. Cancer cells can be

TABLE 45.1 Examples of factors affecting therapeutic strategy

Patient	Species, breed, age, sex, health status, function/role
Neoplasm	Histologic type, natural history, stage (extent), grade, location
Facilities/treatments available	Primary modalities, secondary support for follow-up care, proximity
Owner	Ability to care for animal, relationship to pet, living circumstances, commitment, financial status

considered as "foreign" in this sense. *Immunotherapy* refers to the use of specific antibodies to tumor molecules and is becoming increasingly successful. The term *targeted therapy* is increasingly used for treatment with small molecule drugs (e.g., suffix "-tinib" = suffix of tyrosine kinase inhibitors) and antibodies (e.g., "-umab" = suffix for human antibody) that are directed at very specific enzymes and receptors identified by cancer biologists as key regulators involved in cancer.

Cancer chemotherapy was first successfully practiced when nitrogen mustards used as war gases were found to inhibit tumor growth. Unfortunately, they were extremely toxic. In contrast to radiation and surgery, where the limitation is access to metastatic lesions, chemotherapy is limited by resistant cells. It is difficult to completely cure many solid tumors consisting of more than one million cells (approximately 1 mg of tissue) with chemotherapy alone. Application of new technologies and diagnostic procedures that allow identification of specific subsets of cancer types and use of special targeting mechanisms that exploit nanoparticles and other technologies promise significant improvements in the future (Service 2005).

The decision to use one or several of the treatment modalities for a patient with cancer rests on the types of factors listed in Table 45.1. Detailed recommendation of specific treatment protocols is beyond the scope of this chapter. Protocols for timing, dosage, and special precautions of certain combinations of drugs have been published (Kitchell 2003; Morrison 1998, 2002a).

CANCER BIOLOGY

A brief review of certain aspects of cancer biology is presented as background to aid in understanding the significance of various approaches and limitations of chemotherapy. Discovery of qualitative differences between normal and cancer cells that would allow more selective toxicity to the cancer cells while sparing normal tissues is a goal of current research. Although some emerging therapies that rely on specific targeting mechanisms, e.g., use of drugs linked to antibodies or to specific receptor ligands (Low and Antony 2004) are relatively specific, selectivity for the most commonly used cytotoxic agents is currently based primarily on quantitative differences. That is, both normal and cancer cells have essentially the same ongoing biochemical processes, but the rates and timing may be very different. For most tumors the success of chemotherapy depends on having drugs that are taken up more avidly, bind more tightly to some tumor cell constituent, or affect processes that occur more rapidly in tumor cells, thus enhancing their effect on cancer cells relative to normal cells.

CELL CYCLE. The *cell cycle* is the progression of a dividing cell from one mitosis to the next. Transitions between the phases of the cell cycle are controlled by the activity of specific cyclin-dependent kinases (CDKs) that are activated by cyclins, small regulatory proteins. Mutation or loss of one of these proteins or increased activity of CDKs or cyclins can lead to unrestrained cell division. Discussion of this rapidly changing field, which is beyond the scope of this chapter, can be found in a review (Deshpande et al. 2005). G_1, a presynthetic phase, immediately follows mitosis and may be extremely variable in duration depending on the cell type, presence or absence of nutrients, growth factors, and metabolic by-products. During this phase normal cellular events continue. Protein and ribonucleic acid (RNA) synthesis occur in preparation for deoxyribonucleic acid (DNA) synthesis, the S phase. The S phase may require between 8 and 20 hours for completion. The next phase is G_2, which may last 3 hours in cancer cells, during which substituents required for mitosis are synthesized. Mitosis (M phase) typically requires 1 hour for completion to end the cell cycle.

For a variety of reasons, as tumors mature, certain cells may stop traversing the cell cycle. Others may traverse it so slowly that for purposes related to cancer therapy, they are not in the population of actively dividing cells. Operationally, these cells may be grouped and referred to as being in the G_0 phase. Such cells are not part of the "growth fraction" of the tumor. However, under proper growth conditions those that were merely traversing the cycle extremely slowly may be "recruited" back into the pool of actively dividing cells.

TUMOR GROWTH RATE. The clinically apparent growth rate of a tumor does not necessarily reflect the rate at which cells traverse the cell cycle. If it did, and the tumor consisted of only one cell type that was immortal, tumor growth could be described by a simple geometric progression, i.e., the number of cells would double after an interval equal to the cell cycle time. If this were the case, and if 10^9 cells were required for diagnosis of a tumor, it would require approximately 32 cell cycle times for a single cancer cell to result in a clinically apparent tumor.

In an experimental tumor system it was observed that the time required for the number of cells to double increased from 4 days to over 100 days as the mass grew from approximately 0.3 to 10 g. The growth fraction of the tumor decreased from 80 to 10% and time required for cells to complete a cycle increased from 0.8 to 1.6 days (Frei 1977). From similar studies and much clinical experience it has been established that tumor growth rate is complex and that the "fractional" growth rate tends to decrease as the tumor matures. Models of cancer cell growth have been reviewed (Dang et al. 2003).

Depending on the tumor type and growth conditions, time required to complete a cycle may range from less than 24 hours to several days. Because of cell death, decreased growth fraction, and extended cell cycle times as tumors grow larger, cell cycle time rarely equals doubling time over the course of a tumor's lifespan. Mean clinical doubling times for some human tumors range from 2 to 5 days for Burkitt's lymphoma to 34 days for osteogenic sarcoma to 134 days for adenocarcinoma of the lung (Shackney 1993). Another level of complexity is introduced when it is appreciated that the cell population itself is likely to be quite heterogeneous (Fang et al. 2005).

The *log cell-kill* hypothesis of Skipper (1971) states that the entire population of cancer cells in a patient must be eradicated to produce a cure. A large number of experimental studies have indicated that drug-induced cell kill is a first order process; i.e., a constant proportion of the cells present, both normal and cancerous, are killed with each round of therapy. Recall that differences between cancer cells and cells of some normal tissues are not great. Yet there must be a significant difference between the proportion of cancerous and normal cells killed with each cycle of treatment. Further, normal cells must rebound more quickly than cancer cells from the therapeutic insult. The magnitude of the problem is illustrated by the fact that reduction of normal cell population by 2 to 3 log units (i.e., 99 to 99.9%) may be fatal. Realization that as many as 10^9 cancer cells may still be present after induction of remission requires that additional courses of chemotherapy be given.

CHEMOTHERAPY OF THE CANCER CELL. Increased knowledge of cell and cancer biology has increased the number of molecular targets being explored for development of anticancer drugs. These include, but are not limited to, factors involved in the cell cycle, differentiation, apoptosis, angiogenesis, signaling cell-surface receptors, ErbB family of receptors, metastasis, intracellular signaling elements, nuclear transcription factors, cell surface antigens, and other targets such as the proteasome (Frei and Eder 2003). Increasing numbers of these potential targets are entering clinical trials in people and some have entered mainstream therapy. Unfortunately, species differences and resources have slowed application to animals. This chapter focuses primarily on drugs that are used in veterinary practice.

Chemotherapeutic agents may be divided into three classes with respect to their dependence on the cell cycle. Some drugs (e.g., alkylating agents) are said to be non–cell-cycle–specific. Although they are toxic to all cells, they are especially toxic to proliferating cells. Other drugs are cell-cycle–specific. Cells must be proliferating for these drugs to be effective. Cell-cycle–specific drugs may also be cell-cycle-phase–specific; such drugs may be active only in one stage of the cell cycle.

Practical application of knowledge regarding drug activity in various phases of the cell cycle lies in providing an understanding of why tumors with large growth fractions and rapid generation times usually respond more dramatically to therapy and in guiding drug selection, sequencing, and timing in the development of new protocols (Gaffney 2004).

DRUG TOXICITY. One of the paradoxes of cancer chemotherapy is that although the drugs are most toxic to cells rapidly traversing the cell cycle, many cancers have smaller growth fractions than certain normal tissues (e.g., bone marrow and intestinal epithelium). Normal tissues typically recover more rapidly than tumor cells. Nevertheless the necessity of supportive treatment for such conditions as cytopenias and gastrointestinal disturbances cannot be overstated.

Although there are important exceptions, antitumor compounds produce characteristic toxicity to various body tissues that are related to tissue growth rate. Lymphocytes and bone marrow cells are most profoundly affected. The expected consequences are anemia, thrombocytopenia, and leukopenia. Of these the most life threatening and most common significant sequela of anticancer chemotherapy is sepsis due to neutropenia. Close monitoring of leukocyte counts is an integral and crucial aspect of chemotherapy to allow prompt cessation of anticancer drug administration and institution of appropriate antiinfective therapy if necessary.

Acceptable regimens may lower the leukocyte count significantly. In the absence of sophisticated support capability, it is not advisable to allow the count to go below 2,000/mm^3, for then the risk of infection is too great. There is some evidence that biological response modifiers such as recombinant canine granulocyte colony-stimulating factors (rcG-CSF) and agents that induce it may antagonize the myelosuppression of some anticancer agents (Ogilvie et al. 1992). They may aid in preparing cats to undergo intense radiation therapy (Obradovich et al. 1993). Because of the longevity of erythrocytes, anemia does not appear as rapidly as myelosuppression, if at all. Utility of using androgens to stimulate erythrocyte production is not unequivocally established, but such intervention is usually not needed. Infusions of platelets may be used to counteract a severe thrombocytopenia. Most cytotoxic drugs produce myelosuppression and some degree of thrombocytopenia, but L-asparaginase, vincristine, and bleomycin are minimally toxic in this regard.

Mucosal cells of the gastrointestinal tract have a turnover time on the order of 5 days and thus have a high growth fraction. Many anticancer drugs, e.g., methotrexate and 5-fluorouracil, can produce diarrhea, vomiting, and ulcerations of the mucosa (i.e., mucositis, which may manifest as ulcerative stomatitis and enteritis). These disorders can be more disconcerting to the patient and owner than the less obvious, but potentially more important effects on cells derived from the bone marrow. GI signs appear to be less prevalent in animals than humans, but should be seriously regarded when they occur. Signs of severe vomiting and diarrhea are cause for temporary cessation of therapy, because they may presage dehydration or serious mucositis, which could be life threatening.

Basal cells of the skin and especially of the hair follicle in some breeds are also highly susceptible because of high growth fraction. Hair loss, usually thinning rather than complete loss, in breeds with continuously growing hair (e.g., Poodles, Kerry Blue Terriers, and Old English Sheepdogs) may occur especially in association with doxorubicin therapy. Notable hair loss may begin 1 month after therapy. In most cases hair growth returns to normal once therapy is stopped, often beginning within 1–3 months. Change of coat color in a Standard Poodle has been reported (Simonson and Madewell 1992). Cats may lose their whiskers and outer guard hairs (Rogers and Coppoc 1991). Other toxicities related to the skin are independent of cell growth rate and include direct tissue damage as can occur on extravasation of drug during administration and hyperpigmentation. Hyperpigmentation may occur after therapy with doxorubicin, cyclophosphamide, methotrexate, and bleomycin.

Drugs such as doxorubicin, dactinomycin, mitoxantrone, vincristine, and vinblastine are notable for the severe phlebitis, cellulitis, and necrosis that follow extravasation of drug during administration. It is highly recommended that proper technique be used for intravenous injection of these drugs via an intravenous catheter. This is such a serious issue that if there is doubt as to the placement of the catheter, it should be removed and placed in a different vein before infusion is begun. If extravasation occurs, quick response, including removal of as much of the drug as possible prior to removing the needle, is paramount. Various expedients have been recommended for treating accidental extravasations, but have not proven very efficacious. Sodium bicarbonate, sodium thiosulfate, corticosteroids, hyaluronidase, dimethyl sulfoxide (DMSO), DHM3, and butylated hydroxytoluene have all been claimed to be of value for specific toxins (Dorr et al. 1990; Endicott 2003). In fact, injection of these substances may increase diffusion of the vesicant, which should be avoided at all cost. If multiple attempts to place a catheter fail, it is best to send the animal home untreated than to risk extravasation of the vesicants, especially doxorubicin (Knapp 2006).

Liver and kidney cells respond to anticancer drugs in ways frequently unrelated to proliferation. Cisplatin is directly nephrotoxic, but renal failure has also been reported following L-asparaginase, mithramycin, and high dose methotrexate therapy (Knapp et al. 1987; Endicott 2003). Acute tumor lysis syndrome which occurs in people and has been reported in dogs may lead to death due to severe metabolic imbalance (Endicott 2003). Allopurinol, to reduce uric acid formation, and fluid therapy, to produce

diuresis, are prophylactic measures that reduce the risk of acute uric acid nephropathy and hyperkalemia that may result from rapid lysis of tumors during treatment. Hepatic fibrosis has been produced with folic acid antagonists such as methotrexate. The incidence may be higher when 6-mercaptopurine, daunorubicin, and cytarabine are added to methotrexate in combination chemotherapy.

As a group the cells of the central nervous system (CNS) are least affected by cytotoxic antitumor drugs because of the blood-brain barrier and their slow growth rate. Nevertheless, some of the drugs cause CNS toxicosis and it may be difficult to separate a direct drug effect on behavior from the combined effects of the tumor, debris from dying cells, poor nutritional status, and therapeutic regimen. CNS toxicity may be seen with vincristine, but peripheral neuropathies are more likely (Hamilton et al. 1991).

Allergic reactions have been reported following administration of doxorubicin, paclitaxel, etoposide, and L-asparaginase. Treatment of the reaction includes stopping administration of the drug and symptomatic therapy for allergic reactions and anaphylaxis, as appropriate. Endicott has reviewed this and other emergencies related to cancer and cancer therapy in animals (Endicott 2003).

Long-term hazards of certain anticancer drugs are their properties of oncogenesis, mutagenesis, and teratogenesis and infertility. Drugs have been categorized with respect to their carcinogenesis risk potential into four categories, but one should recognize the potential for harm with all classes of drugs. Examples of drugs in each risk category are as follows: high (mechlorethamine, nitrosoureas, etoposide); moderate (doxorubicin, cyclophosphamide, cisplatin); low (vinca alkaloids, methotrexate, L-asparaginase); and unknown (bleomycin, taxanes, mitoxantrone) (Erlichman and Moore 2001).

THERAPIST SAFETY. Anticancer drugs constitute potential hazards to those who handle and administer them, so great caution and good technique should always be observed. Accidental exposure via the skin, respiratory system, or digestive system must be prevented through the implementation of strict specific protocols. The US Department of Labor, Occupational Safety and Health Administration has issued guidelines for training of personnel in the storage, handling, and disposal of cytotoxic antineoplastic drugs (OSHA 2005). A discussion of chemotherapy safety procedures in veterinary medicine has been published (Takada 2003).

DRUG DOSAGE. Anticancer drugs are frequently dosed on the basis of surface area rather than body weight although one must be alert because there is evidence that the formula below may not be accurate for very small animals, and some anticancer drugs are dosed on the basis of weight (Frazier and Price 1998). A conversion of weight to surface area can be made with the following formula:

$$\text{Surface Area} = \frac{\text{Body weight}^{0.67} \times \text{K}}{10^4}$$

where surface area is given in square meters and body weight in grams. For cats and dogs, K is a constant with the value of 10.0 and 10.1, respectively. Conversion tables are widely available, but a few values may give one a perspective on the relationship. The following values list the weight in kilograms followed by the surface area in square meters: 1–0.1; 10–0.46; 20–0.74; 30–0.96; 40–1.17; and 50–1.36.

As one might predict, drug dosage, interval between doses, and duration of therapy are crucial factors in determining the success of cancer therapy (Frei and Eder 2003). It is important to realize that drugs must be used at the maximum dose possible to achieve optimum therapeutic effects. One is not justified in decreasing the dose of drug to a point that does not produce clinical toxicity, because the regimen will certainly fail.

RESISTANCE. Resistance to pharmacotherapy is a major problem in cancer chemotherapy. Resistance may result in therapeutic failure in over 90% of patients with metastatic cancer (Longley and Johnston 2005). The mass of cancer cells may be intrinsically drug-resistant or become resistant during therapy. The majority of cells in a tumor may be sensitive when therapy is begun yet the tumor may harbor a small fraction of resistant cells (innately or because of growth conditions) that become dominant as a result of selection pressure and death of sensitive cells (Goldie and Coldman 1984). According to the cancer stem cell hypothesis the cancer initiating cells may be transformed tissue stem cells (Weissman 2005). Further, there may be significant heterogeneity in these cells because of a variety of translocations that result in the development of oncogenic fusion genes (Moore 2005). The cancer stem cells may be sufficiently normal and different from the mass of the tumor that they are resistant to chemotherapeutic agents.

These may serve as a source for recurrence of a tumor that was in remission (Weissman 2005). In fact, it has been argued that the most important, and most difficult, target for cancer therapy is this stem cell population that, like all true stem cells, is normally quiescent. According to the cancer stem cell hypothesis, stem cells in such locations as the bone marrow and gut and many cancers have cells with constitutive drug resistance mediated by ABC transporters, detoxifying enzymes such as DNA repair mechanisms, and tolerance to damage (i.e., resistance to apoptosis) (Donnenberg and Donnenberg 2005).

Many tumors have a tremendous increase in mutation rate over normal cells, as much as 1 thousand to 1 million times greater in cancer cells versus normal epithelial cells (Welch 2003). This genomic instability may lead to resistance. Except in the case of multidrug resistance related to ABC transporters, such as P-glycoprotein (P-gp), mutations usually lead to resistance to a single class of agents.

Resistance can occur at many levels ranging from changes in pharmacokinetics of drugs (e.g., absorption, distribution, biotransformation, and elimination), to molecular changes in the cancer cells. Some of the mechanisms discussed below will overlap. For example, the discussion of ABC transporters is relevant to various epithelial barriers such as the blood-brain barrier and to events in organs of absorption and elimination as well as to individual cancer cells. Resistance can be due to decreased intracellular drug concentration due to decreased influx or increased efflux, decreased activation of prodrugs or increased drug inactivation in cancer cells, increased or decreased levels of target enzyme, alteration of the drug target that leads to decreased affinity for the drug, increased repair of drug damage as can occur with DNA repair systems, decreased activity of apoptotic mechanisms, decreased checkpoint function, and decreased rate of cell division as can occur as tumors outgrow their blood supply. The reader is referred to recent reviews for information on mechanisms of resistance and ways of overcoming it that are beyond the scope of this chapter (Longley and Johnston 2005; Cole and Tannock 2005; Weissman 2005; Frei and Eder 2003).

The classical mechanism of Multiple Drug Resistance (MDR) results in resistance to drugs from such structurally and mechanistically diverse classes as the vinca alkaloids and the anthracyclines. The commonality of these drugs is that they are nonpolar. MDR due to the ABC transporters is currently a major and somewhat confusing topic because of imprecise terminology. An excellent review of the ABC transporters as targets in cancer therapy has been published (Cooke et al. 2005). ABC transporters are so-called because they belong to a family of ATP-Binding Cassette transporters that use energy derived from ATP-hydrolysis to function. The first transporter to be described was the P-glycoprotein (P = *pleiotropic;* P-gp). In the new, standard terminology, this protein is encoded by the multidrug-resistance (*MDR1*) gene (gene symbol *ABCB1*). The superfamily of more than 48 proteins in humans is comprised of seven subfamilies (A through G). Other major families include "multidrug resistance protein 1" (*MRP1*; gene symbol *ABCC1*) and the "breast cancer resistance protein" (*BCRP;* gene symbol *ABCG2*). *BCRP* is also known as *MXR* for "mitoxantrone resistant protein." "Lung resistance protein" (LRP or MVP) does not belong to the ABC superfamily, but is associated with drug resistance in clinical samples. Details of the structure and mechanism of these transporters are described in reviews (Choi 2005; Cole and Tannock 2005; Dean 2002).

The physiological functions of these classes are not definitively established, but they are expressed constitutively in many normal cells such as the small and large intestine; liver and pancreas; endothelial cells; and epithelial cells of the kidneys, adrenals, brain, and testis. Absorption and secretion (excretion) of endogenous and exogenous substances are likely functions. Because a major function is to pump lipids, drugs, natural products, and peptides from cells, they have been dubbed "hydrophobic vacuum cleaners" that expel nonpolar compounds from the membrane bilayer. Of the more than 48 ABC genes reported for people, functions have been described for 16 and disease syndromes are related to 14 (Choi 2005).

Veterinary therapeutic implications of the P-gp (MDR1) have been reviewed (Mealey 2004). BCRP (ABCG2) is expressed in mammary gland alveolar epithelial cells during pregnancy and lactation. In this location it actively secretes various substances including drugs and toxins into the milk. This action has obvious ramifications for suckling babies, animals, and consumers of dairy products (van Herwaarden and Schinkel 2006). The role of biotransformation and the ABC transporters in drug delivery has been reviewed (Katragadda et al. 2005).

The ABC transporters are important modifiers of the concentration of their substrates in normal and cancerous cells by decreasing absorption from the gut and transport from the blood into the brain, hastening elimination of their substrates by the kidney and liver, and pumping

drugs from cells. Implications related to absorption and elimination are that they decrease oral bioavailability of relevant drugs, requiring many of them to be intravenously administered. Even for drugs administered intravenously there can be therapeutic ramifications of genetic variation as shown by increased toxicity of doxorubicin in collies and related breeds with a deletion mutation in the canine MDR1 gene (deltaMDR1 295–298) caused by a reduced rate of drug elimination (Mealey et al. 2003). This is the same deletion mutation that leads to increased ivermectin sensitivity in collies (Mealey et al. 2002). The breed distribution and lineage of this deletion has been reviewed (Neff et al. 2004).

Intense effort is underway to find specific inhibitors of the various ABC transporters. These have been variously called *chemosensitizers*, MDR modulators, and MDR reverters (Choi 2005). A limiting caution is that results from trials in humans may not reflect results that will be obtained in animals. In a study of various substrates in an in vitro model of P-gp transmembrane flux, it was found that human and rhesus monkey membranes had binding affinities that were more similar to each other than to those of the dog. The results were consistent with gene and amino acid composition of the three species (Xia et al. 2006).

First-generation inhibitors, such as verapamil and cyclosporin A have been largely disappointing when used in conjunction with cytotoxic drugs in therapy of people because of a lack of specificity that limited dosages. A second-generation chemosensitizer is a nonimmune suppressant analog of cyclosporin A known as PSC 833 (Valspodar). PSC 833 has chemosensitivity enhancement effects on P-gp–mediated MDR about 10 times greater than that of cyclosporin A. PSC 833 reversed the P-gp–resistant phenotype in sporadic appendicular canine osteosarcoma. Simultaneous administration with doxorubicin allowed a 30% decrease in the dose of doxorubicin required to give therapeutic exposure equivalent to the nonresistant phenotype (Cagliero et al. 2004).

Concentration of reducing agents such as sulfhydryl-containing molecules in cells can provide protection against drugs that produce reactive intermediates or free radicals. Reduced glutathione (GSH) can inactivate peroxides and free radicals produced by drugs such as doxorubicin. It can also react with activated alkylating agents, cisplatin, carboplatin, and oxaloplatin to lead to conjugates that are nontoxic and that can be removed from the cell primarily by ABC transporters MRP1 and MRP2 as well as a glutathione-conjugate carrier. The conjugation reaction is catalyzed by cytosolic GSH S-transferase and glutathione peroxidase (Cole and Tannock 2005; Longley and Johnston 2005).

SELECTION OF REGIMENS. Selection of a treatment regimen for an individual patient is empirical and is based largely on the results of clinical trials of drugs in cases at a similar "stage," i.e., similar anatomic location, extent, pathologic diagnosis, and evidence of metastasis as well as local support sophistication and commitment on the part of the owner and the veterinary practice. Formal mechanisms of staging tumors have been published (Henderson et al. 1995). Histopathologic grade is an excellent prognostic tool that may provide guidance for therapeutic decisions. Significant effort to identify better predictors of success has included in vitro assays of drug effectiveness against cultured explants of the tumor. Current emphasis on the genetic and molecular basis of cancer is leading to efforts to use molecular markers as basis for predicting the course of a cancer and, hopefully, eventual success of a regimen in veterinary oncology (Mukaratirwa 2005).

MULTIMODAL THERAPY. Classical modalities of cancer therapy include surgery, radiation, and chemotherapy with surgery being the primary modality in most veterinary practices. Although techniques such as surgery and radiation have improved, it is still apparent that many patients die of cancer after the primary tumor has been "successfully" removed.

The term *adjuvant therapy* was classically used to describe chemotherapy that accompanied surgery or radiation therapy. There was controversy over the advocacy of adjuvant therapy because of the potential for producing needless toxicity in patients if no micrometastases were present and because of the carcinogenic potential of some drugs (Erlichman and Moore 2001). However, with the newer generations of therapeutic possibilities, the use of multimodal therapy has become more common. Adjuvant therapy has been successfully employed in the treatment of canine osteosarcoma in conjunction with surgery (Bergman et al. 1996).

COMBINATION CHEMOTHERAPY. A combination chemotherapy treatment regimen denotes the use of two

or more chemotherapeutic agents at specified dosages and intervals. Combination protocols to be tested in clinical trials are carefully designed using knowledge of pharmacology and toxicology of drugs and their effects on tumors as individual entities.

The rationale of combination therapy is based on the facts that additive effects on tumors are frequently more pronounced than on normal tissues, there is a decreased tendency toward the development of resistance, a combination may be less toxic than an equivalently effective single agent, and heterogeneous stem cell populations usually fail to respond uniformly to a single agent. Some common-sense rules guiding selection of combinations are that each drug should be active on the tumor, drugs should have different mechanisms of action, toxicities should overlap minimally if at all, and each drug should be given at a time during the cell cycle when it will exert its maximum effect. The dosage regimen should be optimized for maximum effect on cancer cells at the shortest dosage interval that allows key normal tissues to recover.

Some success has been achieved by alternating regimens to decrease the occurrence of resistant cells during the course of therapy, but this approach has not improved long-term results against tumors that contained small numbers of genetically resistant cells at the beginning of therapy (Shackney 1993). With current advances in cancer biology, clinical trials are exploring what has been called *holotherapy*, treatment drawn from all classes of therapeutic agents, e.g., chemotherapy, immunotherapy, hormones, antibodies, antiangiogenesis, antimatrix, gene therapy, control of cell cycle (anticyclins CDK, transcriptional control, antisense), and enzyme-inhibitory drugs (Frei and Eder 2003; Varmus 2006). Cancers are increasingly being subdivided as molecular attributes are used to characterize the tumor in a specific patient, thus allowing more individualized therapy in people. These approaches will be available in clinical veterinary practice as the promises of *molecular oncology* are realized for animals.

DRUGS

Drug groups and individual drugs are discussed in this section. Extensive coverage of drugs, formulations, typical doses for dogs and cats, and specific tumor types is available in recent reviews (Morrison 2002b). Practical information on storage of these expensive drugs for veterinary medicine has been published (Rosenthal 1991).

ALKYLATING AGENTS. Alkylating agents are highly reactive molecules in their active state. Alkylating agents undergo strongly electrophilic chemical reactions through formation of carbonium ion intermediates or transition complexes with the target molecules. The intermediates then react with strongly nucleophilic substituents in the cell (e.g., phosphate, amino, sulfhydryl, hydroxyl, carboxyl, imidazole groups), to form covalent bonds. The target molecule is then said to have been alkylated. Alkylation of DNA is the effect primarily responsible for the cytotoxic activity. Such alkylation, of which the 7-nitrogen atom of guanine is an important site, may lead to covalent cross-linking of DNA strands or linking of DNA to a closely associated protein if the drug is a bifunctional alkylating agent. Alkylation of guanine may also shift its electron configuration so that it base pairs with thymine rather than cytosine, ultimately resulting in the substitution of an adenine-thymine pair in place of a guanine-cytosine pair. Labilization of the imidazole ring may cause the guanine to be lost from the DNA strand, with resultant breaking of the chain. It is not difficult to see how the alkylating agents could be mutagenic and carcinogenic.

Alkylating agents are not regarded as being cell-cycle–specific because they have more profound effects on nonproliferating cells than many of the other groups of drugs. But they are still most effective against cells rapidly traversing the cell cycle, i.e., in tumors with a high growth fraction. For this reason they are much more toxic to bone marrow than to such organs as liver and kidney. Infertility in both males and females may be a problem.

Alkylating agents are frequently referred to as radiomimetic drugs because their action in causing DNA strand breaks resembles that of radiation. Their action is also conceptually similar to that of cisplatin. Alkylating agents have a relatively wide spectrum of antitumor activity and are useful in treating tumors of lymphoreticular tissues. They have limited activity against sarcomas and carcinomas.

Tumors commonly, but slowly, develop resistance that may extend across the class of alkylating or "DNA cross-linking" agents. Several major mechanisms are involved (Cole and Tannock 2005). There may be an increase in the concentration of intracellular nucleophilic substrates (e.g., metallothionein or glutathione) that can compete with DNA for the drugs; thus, the drugs are inactivated by conjugation. There may be increased concentration of aldehyde dehydrogenase in the case of cyclophosphamide.

There may be increased activity of DNA repair systems. Reduced intracellular drug accumulation may be a factor due to decreased transport into the cell or increased removal.

Resistance to one alkylating agent does not necessarily imply resistance to the others. For example, melphalan is transported into cells by the leucine transport system whereas mechlorethamine is taken in by the choline transport system. If resistance were due to a change in one of these mechanisms, cross-resistance would be unexpected.

Nitrogen Mustards. Differences among the nitrogen mustards are primarily pharmacokinetic. The mustards are especially toxic to lymphocytes and bone marrow cells. In affected cells, mitosis is stopped and disintegration of formed elements of lymphoid tissue and bone marrow is evident within hours of a therapeutic dose. Immunosuppression and myelosuppression is profound and is a dose-limiting factor in therapy. Although large doses of the mustards can be severely toxic to the GI tract, proportionately this tendency is less severe than with other groups of drugs. The most commonly used nitrogen mustard is *cyclophosphamide.*

Cyclophosphamide, USP (Cytoxan), is widely used in veterinary medicine especially in combination with other drugs. The first of multiple steps in the activation of cyclophosphamide is accomplished by a hepatic cytochrome P450 mixed function oxidase. One of the metabolites, aldophosphamide, may be converted to the toxic compounds phosphoramide mustard and acrolein in target cells. Phosphoramide mustard alkylates and cross-links DNA strands. Increased levels of aldehyde dehydrogenase concentration have been documented in some tumors resistant to cyclophosphamide.

The important side effects of cyclophosphamide are related to myelosuppression. Neutropenia and milder thrombocytopenia are dose-limiting adverse effects with a nadir of 7–10 days. Nausea and vomiting are said to be rare, but vomiting has been observed in cats with high doses (Fetting et al. 1982). Cats given greater than 300 mg/kg exhibited reversible neurotoxicity characterized by head bobbing, broad-based stance, and falling. Alopecia may occur in continuous hair growth dogs.

Sterile necrotizing hemorrhagic cystitis, probably caused by the acrolein formed from cyclophosphamide, has been associated with administration of cyclophosphamide in both cats and dogs and is a cause for stopping therapy with the drug. To decrease the incidence of this cystitis, which is manifested by bloody urine, the drug should be administered in the morning, water intake should be high, and the animals should be encouraged to urinate frequently. Bladder irrigation with thiol compounds may help. Systemically administered N-acetylcysteine may also be of value. Mesna (sodium 2-mercaptoethanesulfonate, Mesnex) is an injectable used prophylactically and specifically to reduce the incidence of cystitis. The inert mesna disulfide (administered form) is reduced by renal tubules to mesna. Mesna binds to and detoxifies urotoxic metabolites of cyclophosphamide and ifosfamide (Elias et al. 1990).

Mechlorethamine (Mustargen) an original member of this group is rarely if ever used clinically today except, perhaps, in relapsed canine lymphoma as a member of the MOPP protocol (Mustargen, Oncovin [vincristine], procarbazine, prednisone) (Rassnick et al. 2002). It is so unstable that it must be given intravenously (IV), freshly prepared. Conversely, chlorambucil and cyclophosphamide are so stable they can be given orally. *Melphalan,* USP (L-Phenylalanine mustard, L-PAM, L-Sarcolysin, Alkeran) is used on occasion in veterinary oncology (Fujino et al. 2004). *Chlorambucil* USP (Leukeran), which is sometimes a replacement for cyclophosphamide due to its lower bladder toxicity, has been used in dogs for mast cell tumors, chronic lymphocytic leukemia, lymphoma, and some tumors in cats (Kleiter et al. 2001). *Ifosfamide* (Mitoxana, IFEX) is a structural analog of cyclophosphamide and has similar pharmacologic and toxicologic properties, including a greater tendency to produce hemorrhagic cystitis (Moore and Kitchell 2003).

Nitrosoureas. The nitrosoureas used clinically include *carmustine* and *lomustine.* A significant advantage for these drugs is their high lipid solubility that allows them to be used against tumors of the CNS. They have also been used effectively in combination protocols against relapsed canine lymphoma (LeBlanc et al. 2006). Streptozotocin, another nitrosourea, is rarely used in treatment of animal cancers. These drugs are primarily bifunctional alkylating agents that can form DNA-DNA and DNA-protein links. The O-6 methyl group of guanine is a key site of alkylation. DNA polymerase, DNA ligase, glutathione reductase, and enzymes involved in RNA synthesis and processing are also inhibited by an isocyanate produced from lomustine.

Limiting toxicities of this group are severe and include cumulative myelosuppression and thrombocytopenia that

do not reach their maximum until about 7–10 days after administration of the drug in dogs. In humans the nadir is reached in 4–6 weeks! This delayed and cumulative bone marrow suppression is a noteworthy characteristic of the nitrosoureas.

There is no cross-resistance with other alkylating agents. The drugs are not cell-cycle–specific. The nitrosoureas have extremely short plasma half-lives. Lomustine is primarily biotransformed in the liver in most species. For more detailed information see Moore and Kitchell (2003).

Lomustine (cyclohexylchoroethylnitrosourea, CCNU, CeeNU) use in dogs and cats has been reviewed (Moore and Kitchell 2003). It has been used with some success in canine lymphoma, canine mast cell tumors, and possibly feline lymphoma (Fan 2003). In dogs, the half-life is approximately 15 minutes and the drug quickly enters the CSF. By 30 minutes, the plasma:CSF ratio is 1:3. Preclinical studies revealed adverse effects on the bone marrow, liver, kidneys, and gastrointestinal tract. At doses less than 100 mg/m^2, as recommended in typical clinical application, acute neutropenia was the dose-limiting toxicity with a thrombocytopenia nadir at 7 to 14 days postadministration. Lomustine is biotransformed by hepatic microsomes, so care should be observed in animals with poor liver function. Resistance is related to enhanced repair by guanine-O-6-transferase and increased glutathione concentration (Moore and Kitchell 2003).

Carmustine, N,N-bis (2-chloroethyl)-N-nitrosourea (BiCNU, BCNU), is used in humans in meningeal leukemia and other brain tumors. It has been tested in treatment of relapsed canine lymphoma as a member of a combination protocol (BOPP) that included carmustine, vincristine, procarbazine, and prednisone (LeBlanc et al. 2006). Significant neutropenia, thrombocytopenia, and gastrointestinal toxicity were observed in a promising trial, but the authors concluded that protocol needed to be optimized for the combination.

Other Alkylating Agents. *Busulfan,* USP (Myleran) is an alkylsulfonate used in people undergoing transplant surgery (Martins et al. 2005). It is seldom used in veterinary oncology. *Dacarbazine,* USP (5-(3,3-dimethyl-1-triazenyl)-1H-imidazole-4-carboxamide; DTIC, DTIC-Dome, DIC), is the only triazine compound used in tumor therapy and is rarely used in veterinary medicine.

Platinum Coordination Complexes. *Cisplatin, carboplatin, oxaliplatin,* and *lobaplatin* resemble the alkylating agents in that they form strong chemical bonds with nucleophiles such as nitrogen in nucleic acids and sulfur in proteins. Although they may be conceptually linked with alkylating agents, there are significant differences in their antitumor and toxic effects. Cisplatin is unique among anticancer drugs in being an inorganic compound; it contains two "cis-" chloride atoms and two "cis-" amino groups. The "trans-" derivatives are not effective as antitumor agents. In noncisplatin members of this group, the chloride atoms have been replaced with organic moieties that alter the toxicity pattern. For example, cisplatin produces significant renal and neurotoxicity, whereas carboplatin produces primarily hematopoietic toxicity. Lipophilicity and distribution of the various agents is determined by the substitutions on the amino groups.

Although it is possible that the chloride residues in cisplatin and the carboxyl ester groups in carboplatin and oxaliplatin can be directly replaced by nucleophiles, the reactions proceed much more rapidly if they are first replaced by water in a process called *aquation.* These aquated compounds then complete the reactions. It appears that the antitumor action of the cis-platinum agents is due to preferential reaction with the N-7 atom of deoxyguanylic acid in DNA, which results in interstrand cross-links. Intrastrand DNA cross-links may equally correlate with cytoxicity. These compounds are active against both proliferating and nonproliferating cells although cisplatin may have maximum lethal effect in late G1 phase (Boyer and Tannock 2005).

Preclinical studies of platinum complexes have been recently reviewed (Galanski et al. 2005). Cisplatin and carboplatin have been extensively used in veterinary oncology. No veterinary trials of oxaliplatin were found. Lobaplatin has been investigated as an adjuvant for therapy of canine osteosarcoma (Kirpensteijn et al. 2002) and cisplatin and carboplatin have been investigated in canine osteosarcoma (Chun and de Lorimier 2003). Resistance to platinum compounds has been linked to increased cellular concentrations of glutathione and metallothionein, presumably because of the thiol groups in the protein.

Cisplatin has been incorporated into treatment of several solid tumors including those of the testis, ovary, bladder, head, and neck in people. In dogs, activity has been demonstrated against transitional cell carcinoma, squamous cell carcinoma, osteosarcoma, and nasal adenocarcinoma (Knapp et al. 1988; Hahn et al. 1992). Because it has been

so effective against a variety of tumors, there have been many investigations into reducing the adverse effects through localized, intralesional therapy. For osteosarcoma in dogs, these have included such approaches as intramedullary administration (Hahn et al. 1996b) and use of a biodegradable cisplatin-containing implant inserted into the limb-sparing surgery site at the time of surgery (Withrow et al. 2004). Intratumor administration of cisplatin was judged beneficial for cutaneous tumors of horses (Theon et al. 1999). Cisplatin is contraindicated in cats because it causes fatal pulmonary toxicity (Knapp et al. 1987), although special formulations of the drug may reduce the toxicity (Fox et al. 1999).

Cisplatin is included in many combination therapy regimens. It has been especially effective when combined with bleomycin and vinblastine against testicular tumors and with doxorubicin for ovarian tumors in humans. One especially well-known regimen for treating human testicular tumors is Einhorn, which includes cisplatin, vinblastine, and bleomycin; etoposide may or may not be included.

Cisplatin is given as a rapid IV infusion. It has a biphasic plasma-decay curve with an initial half-life of 22 minutes (probably distribution) and a terminal half-life of 5 days (probably elimination) in dogs. It is known that intracellular half-life in humans may be as long as 30 days. This presumably represents drug bound to tissue macromolecules. High tissue concentrations have been found in kidney, liver, ovary, testis, and uterus (Williams and Whitehouse 1979).

Nephrotoxicity is a dose-limiting adverse effect of cisplatin in most species, including dogs. Other major toxicities include intractable nausea and vomiting even when antiemetics are used, ototoxicity (hearing loss), anaphylactic-like reactions, and neurotoxicity. Emesis in dogs typically begins 2 hours after cisplatin administration and lasts 2–3 hours, but appears to be less severe than in people (Morrison 2002a). Myelosuppression is mild relative to alkylating agents, but thrombocytopenia and granulocytopenia may be observed by day 7–9 and 17–19 after injection, respectively. GI toxicity manifests as diarrhea and anorexia may also be observed.

Nephrotoxicity is dose-related, cumulative, apparently irreversible in some cases, and primarily affects proximal tubules in which tubular degeneration, loss of brush border, necrosis, and mineralization of tubular epithelial cells may be observed. Serum urea nitrogen may be elevated by day 7–9 after injection. Continuation of treatment should be based on evidence of suitable renal function as judged by renal concentrating ability, urine sediment, and serum creatinine concentration. Much emphasis is placed on finding ways to reduce the incidence and severity of cisplatin induced nephrotoxicosis. Hypersalination (i.e., induction of forced diuresis with infusion of hypertonic sodium chloride solution) is beneficial. Other approaches demonstrated in clinical or laboratory studies that may reduce toxicity include the use of methimazole (Vail et al. 1993), rosiglitazone (Lee et al. 2006), and L-arginine (Saleh and El-Demerdash 2005). On a practical level there is circumstantial evidence that administering cisplatin in the morning may reduce toxicity (Morrison 2002b). The mechanism of the toxic effect is uncertain.

A typical protocol for use of cisplatin in dogs is to administer 60 to 70 mg/m^2 intravenously every 3 weeks. Fasting the dog 12 hours prior to administration reduces the severity of emesis and nephrotoxicity. A recommended saline diuresis protocol in dogs is to give 18 ml/kg/hr of normal saline beginning 4 hours prior to beginning cisplatin infusion and for 2 hours after infusion (Knapp 2006). The animal should be watched carefully to ensure that it is well hydrated in the postinfusion period. Cisplatin drug should not be prepared with or administered through an aluminum needle because aluminum reacts with and inactivates the drug.

Carboplatin (CBDCA, JM-8, Paraplatin) is an analogue of cisplatin that is effective in treating human ovarian tumors. It has the same mechanism of action as cisplatin, with which cross-resistance has been reported, but is less reactive, produces a different pattern of toxicity, and can be used in cats.

It has been found to be effective in animal tumors, including post surgical osteosarcoma (Chun and de Lorimier 2003). Unlike cisplatin, carboplatin has shown no efficacy in the treatment of canine transitional cell carcinoma (Morrison 2002a). An advantage over cisplatin is that it can be used more conveniently on an outpatient basis. Its major toxicity is bone marrow depression. In dogs, leukopenia and thrombocytopenia may be severe at approximately 2 weeks after administration of high doses (Page et al. 1993). Nausea and vomiting, although common, are less severe than with cisplatin. In contrast to cisplatin, carboplatin is not regarded as nephrotoxic although it did reduce glomerular filtration rate of dogs in one study. Diuresis is not required. Because it is primarily eliminated via the kidney, preexisting renal disease can

significantly increase toxicity. The dose-limiting toxicity in cats is neutropenia (Hahn et al. 1997). Pharmacokinetics of carboplatin have been studied in dogs (Page et al. 1993).

ANTIMETABOLITES. Antimetabolites resemble normal cellular substituents and either compete with them in enzymatic reactions to slow key cellular processes or replace them as substrates leading to false products that then interfere with important cellular processes. Most antimetabolites are prodrugs, i.e., they must be intracellularly converted to their active form. Clinically useful antimetabolites typically inhibit DNA synthesis as their major anticancer mechanism although their site of action may be several steps removed. In some cases, e.g., 5-FU, inhibition of RNA processing may also be important. The relative importance of altered DNA versus RNA synthesis and function may be tumor-type–dependent. Antimetabolites profoundly inhibit replication of bone marrow cells. Some cause even greater GI toxicity. As their parent category implies, these agents are highly cell-cycle–specific when inhibition of DNA synthesis is the dominant effect. Because cells are far more sensitive to some antimetabolites while in the S phase, those antimetabolites are further categorized as phase-specific.

Folic Acid Analogs. Agents that act on the folic acid pathways are used in medicine to treat cancer, infectious diseases, rheumatoid arthritis, psoriasis, and graft versus host diseases have been recently reviewed (Walling 2006). Aminopterin, the first folic acid derivative heralded the introduction of antimetabolites in cancer therapy. Aminopterin provided only brief induction of remission, but led to the development of *methotrexate* (MTX). MTX is a venerable drug that is included in cancer and nonmalignant applications in both people and animals. Members of the folic acid analog group include agents that target several key enzymes as follows: dihydrofolate reductase (DHFR) inhibitors (e.g., MTX, *edatrexate*, *trimetrexate*, and *PDX*), thymidylate synthase (e.g., CB3717, *raltitrexed*, *plevitrexed*, and AG337), purine enzymes glycinamide ribonucleotide formyl transferase (GARFT) and aminoimidazole carboxamide formyl transferase (AICARFT) (e.g., *lometrexol*, LY309887, and AG2034), and multiple folate-requiring enzymes (e.g., *pemetrexed*). Folylpolyglutamate synthase (FPGS) is a key enzyme that adds terminal glutamate residues to folic acid analogs. Reduced ability of FPGS to form polyglutamates of MTX is a mechanism of resistance to MTX; therefore, nonclassical antifolates have been developed (e.g., trimetrexate, piritrexim, plevitrexed, and AG337). These molecules are sufficiently lipid soluble that they may be effective in tumors with defective folate transport pathways. Drugs that exploit different isoforms of the folate receptor in various tissues are also being developed (e.g., LY309887) (Walling 2006). Extensive effort is being placed on covalently linking drugs that act through other pathways to folic acid to exploit the unique properties of the folic acid family receptors (Low and Antony 2004). Most of the drugs listed above are in various stages of clinical development, but MTX, trimetrexate (Neutrexin), and pemetrexed (Alimta) are marketed in the U.S. Published clinical applications in animals were found only for MTX.

Methotrexate, USP (Amethopterin), is a folic acid analog used against a wide variety of neoplasms including human choriocarcinoma. It is commonly used in combination regimens in veterinary medicine, e.g., in treatment of lymphosarcoma and osteosarcoma (Morrison 2002a). It has provided some benefit in a combination protocol in hemangiosarcoma (Smith 2003).

Methotrexate (MTX) acts as a false folate cofactor, thereby inhibiting key steps in the de novo purine and thymidylate biosynthetic pathways. After being transported into cells MTX binds strongly to dihydrofolate reductase (DHFR). The resulting inhibition of DHFR depletes cellular tetrahydrofolic acid (THF), which functions as a donor of one-carbon moieties important in the synthesis of nucleic acids. Conversion of deoxyuridylate into thymidylate by thymidylate synthase requires 5, 10-methylene tetrahydrofolate. De novo synthesis of purines requires 10-formyl tetrahydrofolate as a formyl donor. Although inhibition of DHFR is the dominant mode of action, MTX also inhibits thymidine kinase, GARFT (5-phosphoribosylglycinamide formyltransferase) and AICARFT (Aminoimidazole carboxamide ribonucleotide transferase). Inhibition of the latter two enzymes depends on the degree to which MTX is converted to the polyglutamate derivative. Increased concentration of folic acid or of the DHFR protein decreases the effectiveness of MTX. Binding of MTX increases the concentration of DHFR presumably through translational autoregulation (Walling 2006).

Methotrexate is actively transported into cells by a saturable, carrier-mediated system, so it is active at extremely low concentrations in some cell systems. It does not readily

enter cells by passive diffusion and crosses the blood-brain barrier poorly. Decreased cellular accumulation of MTX due to impaired transport or decreased retention leads to resistance. Decreased retention can be caused by lack of polyglutamate formation or an increase in gamma glutamyl hydrolase activity. Two other means of resistance are production of DHF reductases that have decreased affinity for the drug and increased concentrations of the reductase through gene amplification.

The major adverse effects of methotrexate are myelosuppression and gastrointestinal mucositis at doses typically used in animals. If higher doses are used it may be advisable to monitor renal function prior to and during therapy because methotrexate produces renal tubular necrosis when given in high doses.

Pyrimidine Analogs. Because nucleic acids are involved in cell growth control, attention was given to finding analogs of natural pyrimidine and purines that could interfere with processing of DNA and/or RNA to inhibit or kill cancerous cells. The classical view is that quantitative, but not qualitative, differences exist in pathways involving the nucleic acids between normal and cancer cells providing a basis for selectivity, although emerging knowledge about single nucleotide polymorphisms (SNPs) may modify this view in the future. These "false" nucleotides may be incorporated into RNA and DNA producing nucleic acids that cannot be replicated or lead to miscoding. They may also act on regulatory processes, i.e., in feedback loops to deplete critical intermediates. Repair enzymes may negate or enhance the effect of the presence of the false nucleotides in the DNA. Nucleoside analogs may alter transport of normal nucleosides in or out of normal and cancer cells.

The natural pyrimidine cytosine is found in both DNA and RNA. Uracil is found only in RNA, but is a precursor of thymine, which occurs in DNA. Clinically used pyrimidine analogs include the uracil analog *5-fluorouracil* and cytosine analogs *cytarabine*, *5-azacytidine*, and *gemcitabine* (Pizzorno et al. 2003).

Cytarabine, USP (cytosine arabinoside, arabinosyl cytosine, Ara-C, Cytosar) differs from the endogenous nucleoside deoxycytidine only in that the sugar is arabinose instead of deoxyribose, i.e., position 2 of the sugar is hydroxylated. It is one of the most important agents in the treatment of acute myeloid leukemia in people and it also is active against other leukemias and lymphoma. It is not very effective against solid tumors (Pizzorno et al. 2003). It has been used for lymphoreticular and myeloproliferative disorders in dogs and cats.

Cytarabine enters cells via a membrane transporter and by passive diffusion at higher concentrations.

Cytoplasmic deoxycytidine kinase converts cytarabine (ara-C) to cytosine arabinoside monophosphate (ara-CMP), which is ultimately converted to cytosine arabinoside triphosphate (ara-CTP) by other enzymes. Cytidine deaminase effectively inactivates ara-C so the anticancer activity and toxicity of the drug is influenced by the relative activity of these enzymes in the tissues. Ara-CTP, a competitive inhibitor and false substrate for DNA polymerase, is the active form of the drug which causes inhibition of nuclear DNA synthesis by three mechanisms; inhibition of initiation of new replication units following incorporation of ara-C into the primer, retardation of DNA-chain elongation because of incorporation of ara-C into DNA, and inhibition of DNA primase. High concentrations of ara-CTP may increase the termination of DNA-chain elongation with chains ending in ara-C. Exonucleases, e.g., TREX 1 or 2 and p53 could remove ara-C from these terminal positions to decrease its cytotoxic effect (Pizzorno et al. 2003). The ultimate effect of the abnormal DNA produced is the induction of apoptosis.

Acquired or de novo resistance may be related to increased intracellular concentration of cytidine deaminase, which converts cytarabine to ara-U, which is less toxic. Resistant mutants that lack deoxycytidine kinase, the activating enzyme, have been identified. Some resistant mutants have been shown to have high intracellular concentrations of deoxycytidine triphosphate (dCTP) causing decreased activation (phosphorylation) of cytarabine.

Bone marrow suppression is the dose-limiting toxicity. It is manifest by leukopenia, thrombocytopenia, anemia, and megaloblastosis. It should be used with caution in animals with compromised liver function.

Intravenously administered cytarabine is included in many protocols for treatment of CNS leukemia and lymphoma in dogs and cats (Morrison 2002a). A pharmacokinetic study revealed that cytarabine did cross the blood-brain barrier and therapeutic doses could produce effective concentrations in the cerebrospinal fluid (CSF) (Scott-Moncrieff et al. 1991). The plasma elimination half-life in dogs was approximately 64 to 69 minutes, whereas the half-life of cytarabine in CSF was 165 minutes. The peak concentration of cytarabine in CSF was 29 μM.

Gemcitabine (2,2′-difluorodeoxycytidine, dFdC, Gemzar) is a cytosine analog with similarities to cytarabine except that it also has activity against solid tumors in people. It was licensed for use in people for pancreatic carcinoma and non–small-cell lung cancer, but has found application in combination therapy for other solid tumors. It has been evaluated for various tumors in dogs (Kosarek et al. 2005; Moore and Kitchell 2003). However, caution is recommended because anecdotal evidence is available that some dogs are especially sensitive and may show toxicity at doses of 675 mg/m^2 (Knapp 2006). Pharmacokinetics of gemcitabine and its primary metabolite following intravenous bolus (Freise and Martin-Jimenez 2006a) and infusion (Freise and Martin-Jimenez 2006b) to dogs have been reported.

Fluorouracil, USP (5-fluoro-2,4(1H,3H)-pyrimidinedione; 5-FU, Efudex, Adrucil), is a pyrimidine analog that resembles both uracil and thymine, components of RNA and DNA, respectively. It is used in people for carcinomas of the mammary gland and GI tract, e.g., colorectal carcinomas. Although rarely used in veterinary oncology it has shown promise in adjuvant postoperative chemotherapy of dogs with mammary cancer in combination with cyclophosphamide (Karayannopoulou et al. 2001). Topical preparation of 5-FU has been used in cutaneous squamous cell carcinomas of horses (Fortier and Mac Harg 1994).

Both DNA synthesis and RNA synthesis and function are altered by 5-FU metabolites. The prodrug, 5-FU, is metabolized intracellularly to 5′-fluorouridine monophosphate (FUMP) and then to 5′-fluorodeoxyuridine monophosphate (FdUMP). FdUMP, a potent inhibitor of thymidylate synthetase, decreases the synthesis of DNA precursors. Fluorouracil is also incorporated into RNA. It is highly cell-cycle–specific, but no clear association with a particular phase can be demonstrated. The relative importance of inhibition of DNA synthesis versus effects on RNA synthesis appears to be tumor-dependent. Severe inhibition of thymidylate synthetase in noncancer cells could lead to host toxicity due to "thymineless" death. It has been hypothesized that administration of exogenous thymidine could reverse this 5-FU induced toxicity. Unfortunately, under certain circumstances, administration of thymidine actually enhanced toxicity.

Fluorouracil is most toxic to bone marrow and oral and GI mucosa. Thus, bone marrow suppression manifested by leukopenia, thrombocytopenia, and anemia is severe and is the major dose-limiting factor. Anorexia, nausea, and vomiting are seen. Diarrhea and stomatitis are indications for the interruption of therapy. CNS toxicity is regarded as unusual in humans, but may be more common in animals. The signs include dementia, excitement, tremors, and ataxia, sometimes followed by opisthotonos, tonic-clonic convulsions, dyspnea, shock, and death. The neurotoxicity may be due to metabolites of 5-FU in the dog (Yamashita et al. 2004). Neurotoxicity contraindicates the use of 5-FU in cats (Morrison 2002a). A cream formulation has been shown to be very toxic if accidentally eaten. A 5% cream (Efudex) is intended for actinic keratoses and superficial basal cell carcinoma.

Capecitabine (pentyl[1-(3,4-dihydroxy-5-methyl-tetrahydrofuran-2-yl)-5-fluoro-2-oxo-1H-pyrimidin-4-yl]aminomethanoate, Xeloda) is an oral fluoropyrimidine derivative that facilitates administration and sustained drug exposure. Use of this drug in veterinary oncology is not established.

Purine analogs are prodrugs that must be converted to the nucleoside triphosphate to be active. Examples include *mercaptopurine*, USP (6-mercaptopurine, 6-MP, Purinethol), *thioguanine*, *azathioprine* (Imuran, primarily used as an immunosuppressant), and the new derivative, *fludarabine* (1-fluoro-ara-AMP, Fludara). Mercaptopurine, which is primarily used to treat lymphoreticular tumors in people, was used in older protocols for lymphosarcoma and osteosarcoma in veterinary oncology, but it and thioguanine are seldom used now.

NATURAL PRODUCTS

Microtubules. Microtubules are important for mitotic spindle formation among other important roles in normal cell structure and function. Microtubules are polymers composed of alpha- and beta-tubulin heterodimers that are dynamically assembled and disassembled as a normal aspect of cellular function and division. The mechanism of action of vinca alkaloids and taxanes is closely linked to their activity on the function and dynamics of microtubules, especially of the highly dynamic mitotic-spindle microtubules. The classical view is that these changes usually have the net effect of producing mitotic block, cell cycle arrest, and apoptosis (although some may also lead to necrosis). Potential mechanisms by which the drugs alter microtubular dynamics are complex and vary with the drug.

Three main classes of drug binding sites on tubulin have been identified: the paclitaxel site, the vinca domain, and

the colchicine domain. In addition microtubule-regulatory proteins may serve as targets. Because the drugs act on different sites and have different effects on downstream signaling pathways that lead to cell death, there is potential for synergy among the drugs. Differences such as those above explain why the microtubular toxins differ in effectiveness against a variety of tumors and why significant attention is being given to development of additional drugs that alter microtubular function.

Resistance to microtubule-targeted agents may involve tubulin mutations, altered expression of tubulin isotypes, and altered expression or binding of microtubule-regulatory proteins.

A complete dissection of the complexities, including concentration effects and timing of exposure of cancer cells to these drugs, is beyond the scope of this discussion, but the reader is referred to Zhao et al. (2005).

Vinca Alkaloids. The vinca alkaloids are large, complex substances derived from the periwinkle plant (*Vinca rosea* L.). Although similar in structure, *vincristine sulfate*, USP (Oncovin), *vinblastine sulfate*, USP (Velban, Velsar), and *vinorelbine* (Navelbine) differ considerably in antitumor efficacy as well as in the doses that produce toxic effects. Vincristine is a member of many protocols used in people as well as animals. Typical indications for people include acute lymphocytic leukemia, neuroblastoma, Wilm's tumor, rhabdomyosarcoma, Hodgkin's disease, and non-Hodgkin's lymphoma. Vincristine is one of the major drugs used in veterinary oncology. It is effective against canine transmissible venereal tumor as a single agent (Nak et al. 2005). It is a member of many "named" combination protocols for lymphoreticular tumors and soft-tissue sarcomas where it is identified by the letter *O* for Oncovin, its commercial name. A vinblastine and prednisone combination has been found effective in cases of metastatic canine mast cell tumors (Govier 2003).

Vinca alkaloids are taken into cells by an energy-dependent carrier-mediated transport system. There is no cross-resistance between vincristine and vinblastine except when the tumor is multidrug-resistant due to expression of multidrug-resistance transporters (Huisman et al. 2005).

Vinblastine may produce a dose-limiting leukopenia, the nadir of which occurs at 5–10 days. Hematologic effects of vincristine are mild, but neutropenia was observed in cats treated with vincristine alone (Hahn et al. 1996a) and it can also be produced in dogs (Kanter et al. 1994). Thrombocytopenia and anemia are rare with both drugs. Vincristine induces thrombocytosis. Both are severe tissue irritants and must be administered via an indwelling catheter.

Although neither drug penetrates into the brain or CSF sufficiently for therapy, vincristine is much more likely than vinblastine to produce neurotoxicity. This difference, which may be due to differential rates of transport out of the CNS by P-gp, is paradoxical because vinblastine is more lipid soluble. One hypothetical explanation is that the slower elimination of vincristine relative to vinblastine may lead to prolonged exposure of nerve tissue to high concentrations of vincristine. The neural effect of vincristine ranges from mild to dose-limiting. A combination of vincristine, cyclophosphamide, and prednisone produced peripheral neuropathy in a dog that improved after the vincristine was removed from the protocol. Onset was sudden and included difficulty in locomotion (Hamilton et al. 1991). Neuropathy may also be manifest as paresis and voice change.

Vincristine disappears rapidly from the plasma and appears to be concentrated in platelets and cells with a large volume of distribution. Vincristine and vinblastine can be eliminated into the urine by the MDR1 gene product P-gp transporter located on the apical surface of the renal proximal tubule. Vinca alkaloids are also eliminated in the bile.

Taxanes. Plant alkaloids known as *taxanes* currently used in clinical medicine include *paclitaxel* (Taxol) and *docetaxel* (Taxotere). Paclitaxel is derived from the bark of the Pacific yew tree *Taxus brevifolia* and docetaxel is a semisynthetic derivative from the needles of the European yew tree *Taxus baccata*. These drugs have found application in treatment of ovarian, breast, lung, bladder, and head and neck cancer in people. Effectiveness of paclitaxel and docetaxel in animals is still in the early stages of evaluation, but because of their effectiveness in humans and probable eventual use in animals, some key aspects of the drugs will be covered.

The taxanes' poor water solubility requires special formulations with nonionic surfactants to allow intravenous administration. These surfactants are not pharmacologically inert and their necessary use significantly complicates both the pharmacokinetic properties and the toxicity of the commercially available forms of taxanes; therefore, their commercial names of Taxol and Taxotere will be used where appropriate. The docetaxel formulation in polysor-

bate 80 is commercially known as Taxotere. The commercial form of paclitaxel, Taxol, is formulated in alcohol and Cremophor EL (Cr-EL; polyoxyethylated castor oil). This has two important ramifications. First, in a dose escalation study, if was found that the Cr-EL affects the toxicity by releasing histamine following intravenous administration. Administration of antihistamines prior to infusion of Taxol is required. Despite this precaution, some dogs showed evidence of histamine release (Poirier et al. 2004). Second, the presence of the surfactant vehicle has profound effects on the pharmacokinetics of paclitaxel. Drug is entrapped in micelles, thus reducing the free fraction and altering the distribution and other pharmacokinetic parameters of the drug. In a study of a 1-hour versus a 3-hour infusion it was found that clearance and volume of distribution were significantly dependent on infusion duration. The 3-hour schedule tended to produce more hematologic toxicity "consistent with increased exposure to unbound drug." The findings help explain the fact that short-infusion schedules of Taxol lack significant myelotoxicity, but have greater potentially Cr-EL–related adverse effects, e.g., peripheral neuropathy (Gelderblom et al. 2002). Another example of the effect of the Cr-EL formulation on distribution is provided by the fact that mixing Taxol with DMSO for intravesicular instillation in dogs increased the free fraction to 92% and increased tissue penetration of paclitaxel (Chen et al. 2003).

Other potential complications for veterinary cancer studies are that interaction with other anticancer drugs can alter kinetics of paclitaxel (Kroep et al. 2006) and that there can be confusion between vehicle effects and direct effects of the drug. For example, in people, it is known that Cr-E is mainly responsible for ganglionopathy, axonopathy, and demyelination, but there is strong clinical data and data from non–Cr-EL-containing formulations that paclitaxel also produces dose-limiting neurotoxicity. This is likely due to its effects on microtubules in perikaryons, axons, and glia cells.

Taxol produced partial remission of malignant histiocytosis, mammary carcinoma, and osteosarcoma in a preliminary study in dogs that had advanced relapsed disease. Results were judged to merit further study under more optimal conditions and as part of combination protocols (Poirier et al. 2004).

Addition of cyclosporin A, an inhibitor of P-gp transporter (ABC-B1) and cytochrome P450 isoenzyme CYP3A in intestinal epithelial cells, increased oral bioavailability of docetaxel (Taxotere) from 20% to 100%. Gastrointestinal toxicity was dose-limiting in this canine study which included detailed pharmacokinetic analysis at 3 doses (McEntee et al. 2006).

Epipodophyllotoxins. Podophyllotoxin is an extract of the mandrake plant that has led to the development of two synthetic derivatives; *teniposide* (Vumon, VM-26) and *etoposide* (Etopophos, Vepesid, VP-16, VP-16–213). Teniposide and etoposide have become important in the treatment of some human tumors, e.g., Hodgkin's disease, non-Hodgkin's lymphoma, acute myelogenous leukemia, Kaposi's sarcoma and cancers of the testis, lung, and breast. They have not yet found mainline application in veterinary medicine.

Camptothecins. Two derivatives of the plant alkaloid 20(s)-camptothecin are approved for clinical use in people: *topotecan* (Hycamtin) and *irinotecan* (Campto). They are used for cancers of the ovary, lung, and colon in people. No published clinical trials of these drugs in animals were found.

Antibiotics—Topoisomerase Inhibitors. Topoisomerase enzymes control and modify the topologic states of DNA. The extremely long strands of DNA are tightly coiled in a double helical structure in the nucleus except when being transcribed or duplicated. For these processes to occur, the twisted, supercoiled DNA must be "unwound" to allow the DNA and RNA polymerases to function. Mammalian nuclei contain various isoforms of topoisomerase I and topoisomerase II. These enzymes cleave the phosphodiester backbone of DNA, form a covalent enzyme-DNA linkage that allows another single- or double-strand DNA to pass through the nick, and then reseal the backbone. Topoisomerase inhibitors prevent the religation of the DNA strands by binding to and stabilizing the DNA/topoisomerase complex to cause DNA strand breaks that are lethal to the cell. Any abnormal function of cyclins, cell- cycle–regulated kinases, or phosphatases can influence the cytotoxicity of topoisomerase I inhibitors and some dysfunctions can lead to resistance to the anticancer drugs. Doxorubicin and dactinomycin inhibit both topoisomerase I and II. Topoisomerase II is inhibited by anthracyclines and epipodophyllotoxins. The anthracyclines that inhibit topoisomerase II have long been known to intercalate between two adjacent base pairs, so it was originally thought that this was the primary means of action and, hence, of classifying them as "intercalating

agents" as is common in older literature (Ratain and Plunkett 2003).

The exact mechanism by which interaction of the drugs with the topoisomerase inhibitors causes cell death is not well established. Resistance can occur when levels of topoisomerase I or II are reduced, thereby reducing the number of drug-DNA-topoisomerase complexes that can be formed. This reduces the chance that the damage will be detected to trigger an apoptotic response. Resistance can also be due to mutant, but still active, forms of topoisomerase II that have lower affinity for the drugs (Stewart and Ratain 2001). Some epigenetic mechanisms can increase the activity of the topoisomerase inhibitors. Hyperacetylated histones permit transcription to occur, e.g., treatment of leukemic cells with a histone deacetylase inhibitor increases expression of topoisomerase II thus increasing the potential target for topoisomerase inhibitors (Cole and Tannock 2005). An interesting aspect of the topoisomerase inhibitors that illustrates the complexity of the interlocking signaling pathways in cells is that they may be involved in controlling caspase-2 premessenger RNA splicing (Solier et al. 2004).

Anthracyclines. *Doxorubicin*, the first anthracycline derivative, was isolated from *Streptomyces* spp. *Daunorubicin, epirubicin*, and *idarubicin* are semisynthetic derivatives. The anthracyclines are tetracycline ring structures substituted with the sugar daunosamine. *Dactinomycin* (actinomycin D, Cosmegen) has seen little use in veterinary oncology, but a recent study found that replacing doxorubicin with it in a combination protocol for canine lymphoma warranted further investigation (Siedlecki et al. 2006). *Mitoxantrone* is often classified with the anthracyclines, but it is a synthetic anthracenedione derivative and lacks a sugar moiety.

Doxorubicin hydrochloride, USP (Adriamycin, Doxil [liposomal formulation]) is an extremely important anthracycline derivative that has antitumor activity against a wide variety of tumors in both people and animals as a single agent and in combinations. Examples of applications in people include cancers of the breast, genitourinary system, thyroid, lung and stomach; soft-tissue, osteogenic, and other sarcomas; Hodgkin's disease; non-Hodgkin's lymphoma; and acute leukemia. The list for animals is also long. It has shown activity, usually as a component of a combination, against thyroid tumors; sarcomas such as lymphosarcoma, hemangiosarcoma, and osteosarcoma; and a wide variety of carcinomas such as mammary tumors and squamous cell carcinomas, and transitional cell carcinomas (Klein 2003; Henry 2003; Sorenmo 2003; Chun and de Lorimier 2003; Kent et al. 2004). Nasal tumors were effectively treated with alternating doses of doxorubicin, carboplatin, and oral piroxicam (Langova et al. 2004). Use of doxorubicin as a sole agent in adjuvant therapy in high- grade soft-tissue sarcomas did not prove beneficial (Selting et al. 2005).

It is well established, as described above, that doxorubicin inhibits topoisomerase I and II, but it also damages DNA through free-radical generation by the electron accepting and donating quinone and p-hydroquinone moieties that cause membrane damage and DNA strand breaks. The mechanism by which doxorubicin generates free radicals has been claimed to be due to oxidation of its p-hydroquinone moiety. The resulting free radicals can cause genotoxicity and cardiotoxicity as well as participate in the anticancer action. It is likely that the carcinogenic action of doxorubicin is due to this free radical induced genotoxicity. Further, there is evidence that the critical apoptotic trigger of doxorubicin may be oxidative DNA damage by the direct H_2O_2 generation induced by doxorubicin in addition to its effects on topoisomerase II (Mizutani et al. 2005). There is also evidence that some apoptosis may be initiated by free radical independent mechanisms (Suzuki et al. 2005).

Detection of DNA damage by the cell and effective activation of apoptotic pathways is crucial to the cytotoxic effect of doxorubicin and other anticancer modalities. Dysregulation of apoptotic pathways in, e.g., breast cancers, may be due to down-regulated death receptor pathway function (Munoz-Gamez et al. 2005).

Doxorubicin enters cells by a passive process and is extensively bound in the tissues. Anthracyclines have low concentrations in the CNS either because of their low lipophilicity or because of the P-gp transporter in brain endothelial cells or both. It is biotransformed to an active metabolite (doxorubicinol) and inactive compounds in the liver and is excreted in the bile. Induction of cytochrome P450 enzymes decreases plasma doxorubicin concentration pointing to the possibility for drug interactions (Stewart and Ratain 2001).

The pharmacokinetic profile of doxorubicin in people is highly variable, with interindividual variability for most parameters ranging from 37% to 93%. Intraindividual variability ranges from 6% to 59%. Obesity has been shown to reduce clearance by approximately 50% in people, but perhaps not in dogs (see below). Pharmacoki-

netic variability may have a significant effect on the effects observed with doxorubicin therapy because dogs treated for lymphoma that responded to the therapy had longer terminal half-lives of the drug than dogs that did not respond (Selting et al. 2006). This study also showed that supplementation with n-3 fatty acids did not alter the doxorubicin pharmacokinetics as might have been predicted (Ogilvie et al. 2000). Pharmacokinetic values obtained after one dose were as follows: AUC = 427 ± 44 ng/ml·h, Cmax = 879 ± 83 ng/ml, Terminal $t_{1/2}$ = 8.7 ± 1.0 Vss = 703 ± 50 l/kg, CL = 83 ± 8 l/h/kg (Selting et al. 2006). The fact that no difference was found related to obesity in this study may be due to the degree of obesity as compared to some morbidly obese people.

Multidrug resistance due to the P-gp product of the MDR1 (ABCB1) gene and other members of the ATP-binding cassette (ABC) transporters was discussed previously in this chapter. Despite frequent success in in vitro studies (Page et al. 2000) attempts to use chemosensitizers, e.g., tamoxifen, cyclosporin A, and newer second-generation P-gp inhibitors such as PSC 833 (Valspodar) have produced mixed results in clinical trials. It is also likely that increased concentrations of glutathione in cells decreases the effectiveness of doxorubicin because a component of its action is to generate free radicals.

Toxicoses caused by doxorubicin have been reviewed and classified as acute, short-term, or chronic. Acute toxicosis manifests as head-shaking, localized urticaria along the course of the vein used for administration of the drug, and signs associated with histamine release including generalized blushing of the skin and acute collapse if administered too rapidly. Rapid administration may result in acute GI upset (anorexia, vomiting, and bloody diarrhea) within 12–24 hours. Histamine related signs may be decreased by pretreating dogs with diphenhydramine hydrochloride (e.g., Benadryl), 1.0 mg/kg. Improperly formulated or prepared doxorubicin may lead to increased frequency of acute reactions.

Short-term reactions include weight loss, anorexia, diarrhea, vomiting, myelosuppression, bone marrow hypoplasia, lymphoid atrophy, and alopecia. Dogs developing signs of toxicosis after their first dose of doxorubicin were 17 times more likely to develop toxicoses after the second dose (Ogilvie et al. 1989). Hematologic changes are the short-term dose-limiting manifestation of toxicity. Neutropenia is common, with a nadir at 7–10 days after treatment and returning to normal by 3 weeks. Less commonly, one may see thrombocytopenia (nadir between 3 and 8 days) and anemia that follows the same pattern. Doxorubicin produces poikilocytosis in cats (O'Keefe and Schaeffer 1992). Chronic toxicosis is associated with hair loss, testicular atrophy, and dose dependent cardiac toxicosis leading to arrhythmias and cardiomyopathy. For more details on non–cardiac-related toxicity see Ogilvie et al. (1989a).

Anthracyclines cause two types of cardiac toxicity, one immediate and the other cumulative. During IV administration, one may see cardiac arrest preceded by electrocardiographic changes such as T-wave flattening, S-T segment depression, voltage reduction, and arrhythmias. This is usually brief and is not necessarily an indication to stop using doxorubicin. If the changes are minor, some clinicians cautiously continue with slower administration of drug. Others recommend discontinuing therapy with doxorubicin until a later time. Cardiac arrest can usually be avoided by premedication with antihistamines which may be considered if an animal has previously shown a tendency to arrhythmias.

Cumulative myocardial toxicity, which ultimately manifests as congestive heart failure, is more severe and necessitates permanently stopping doxorubicin therapy. Clinical cardiac abnormalities include arrhythmias and nonspecific alterations in the R wave, ST segment, or QRS duration as well as congestive heart failure, which may be fatal. Noninflammatory myocardial degeneration was observed in the hearts of dogs that died (Mauldin et al. 1992). The risk of congestive heart failure is thought to increase sharply above 250 mg/m^2 total dose in dogs. Cats given a cumulative dose of 300 mg/m^2 had no grossly observable clinical evidence of heart disease, but some did have echocardiographic signs of heart disease and the hearts of all had myocyte vacuolization and myocytolysis as well as histological and functional evidence of renal disease (O'Keefe et al. 1993). Because of the cumulative toxicity, one should maintain a record of the total amount of doxorubicin given, stop therapy when the limit is reached, and watch carefully for signs of congestive heart failure.

The exact mechanism by which doxorubicin causes myocardial toxicity is unknown, but at least one mechanism is believed to be through the production of reactive oxygen species (ROS). ROS produced in the mitochondria and calcium may play a key role in stimulating doxorubicin-induced intrinsic (mitochondria-mediated) and extrinsic (FAS/Fas L [Fas-ligand]–mediated) forms of apoptosis in cardiac cells (Kalivendi et al. 2005). Cumulative loss of myocardial fibers may be the cause of the diffuse cardio-

myopathy that is manifested by arrhythmias and congestive heart failure.

Means of decreasing the myocardial toxicity are a significant area of research. Various agents—for example, dexrazoxane (ICRF-187) tested in dogs (Imondi et al. 1996), aminoguanidine in rats (Cigremis et al. 2006), amifostine in rats (Bolaman et al. 2005), and amifostine in humans with breast cancer (Catino et al. 2003) attenuated the adverse effects. Pifithrin-alpha, a *p53* inhibitor, interferes with doxorubicin induced apoptosis in rat H9c2 cells in culture (Chua et al. 2006). Exercise has been found to reduce the cardiac toxicity induced by anthracyclines (Peng et al. 2005).

Various formulations of doxorubicin have been developed in an attempt to increase its therapeutic index. One of the more prominent is pegylated-liposomal doxorubicin (Doxil) that has been found to significantly alter the drug's pharmacokinetics. Doxil was found to be effective in reducing tumor volume and in causing apoptosis in some tumors in immune compromised mouse models with xenografts of canine transmissible venereal tumor, thus showing promise of effectiveness in dogs (Stettner et al. 2005). The relative advantages of various liposome formulations of anthracyclines such as STEALTH and DaunoXome have been reviewed (Allen and Martin 2004). Liposomes targeted with anti-CD19 antibodies may offer increased therapeutic index (Allen et al. 2005).

Doxil was found to be well tolerated and effective in dogs with cancer at doses equivalent to those of free drug. The maximally tolerated dose in these dogs was found to be 1.0 mg/kg intravenously every 3 weeks. Cutaneous toxicity that resembled palmar-plantar erythrodysesthesia was dose-limiting (Vail et al. 1997). Dosage and cautions during administration of standard doxorubicin formulations have been published (Morrison 2002a).

Doxorubicin is a severe tissue irritant (see earlier discussion of precautions regarding administration of vesicant drugs) and causes mild alopecia and hyperpigmentation in the axillary and inguinal regions. Urine may be colored red while significant quantities of the red drug and its metabolites are being eliminated. This is medically harmless and temporary.

Daunorubicin hydrochloride (daunomycin, rubidomycin, Cerubidine, DaunoXome [liposomal formulation]) differs from doxorubicin only by having a proton in place of a hydroxyl group. It is similar to doxorubicin in mechanism and toxicity except that it has more pronounced cardiomyopathic effects. It is not effective against solid tumors and seems to have primary utility in treatment of acute lymphocytic and granulocytic leukemias in combination with cytarabine. *Idarubicin* (Zavedos) is a synthetic daunorubicin analogue, with increased lipophilicity over its parent. It can be given orally and is biotransformed to an active intermediate, idarubicinol. Cardiotoxicity is less marked than with doxorubicin. Gastrointestinal toxicity and myelosuppression were observed in cats. It has been used to treat lymphosarcoma in cats. *Epirubicin* (Ellence) is a stereoisomer of doxorubicin with increased lipophilicity relative to doxorubicin and with fewer side effects. Epirubicin is administered intravenously (Ogilvie 1994; Morrison 2002a).

Anthracenediones. *Mitoxantrone* (Navatrone) is an anthracenedione that was synthesized to find a less toxic drug than the anthracyclines from which it differs by the absence of the tetracyclic ring and sugar moiety. With its three planar rings, it preferentially intercalates between guanine-cytosine base pairs of DNA. Although it is less toxic than doxorubicin, it also has a narrower spectrum of anticancer activity. Its lower cardiac toxicity as well as lower potential for nausea, vomiting, and extravasation injury may be caused by the decreased ability of mitoxantrone to participate in production of oxygen free radicals. It is an inhibitor of topoisomerase II. Mitoxantrone is subject to multidrug resistance mediated by ABC transporters BCRP (ABCG2, MXR1) and MRP2. It has activity against a variety of malignancies in dogs and cats and although less effective than doxorubicin may benefit some patients (Ogilvie et al. 1991, 1993, 1994b). Mitoxantrone was found to be effective in intracavitary treatment of carcinomatosis, sarcomatosis, and mesothelioma in dogs (Charney et al. 2005).

Enzymes. *L-Asparaginase* (L-asparagine amidohydrolase, L-asp) is an enzyme derived from bacteria that is important in treatment of lymphoid malignancies in people (Kurtzberg et al. 2003). In veterinary medicine it has primarily been used to treat canine lymphomas as a component of combination protocols (Siedlecki et al. 2006). There is evidence that L-asp should be reserved for treating relapses (MacDonald et al. 2005).

The use of L-asp stems from its asparagine amidohydrolase activity in which it hydrolyzes asparagine to aspartic acid and ammonia. In contrast to most normal cells many malignant cells have very low concentrations of L-asparagine synthetase, an enzyme that synthesizes aspara-

gine required for cell growth. Such cancer cells survive by scavenging asparagine from the extracellular fluids. Administration of L-asp hydrolyzes circulating asparagine, thus depriving the cancer cell of an important nutrient and leading to death of the cells. This was long held to be an example of a qualitative difference between normal and susceptible cells, but it is now known that many normal tissues require preformed asparagine. Lack of asparagine impairs the synthesis of such proteins as insulin, prothrombin, albumin, and parathyroid hormone.

L-Asparaginase is derived from *E. coli* (commercially available as Elspar) and *Erwinia chrysanthemi* (Erwinia asparaginase, not officially approved by the US FDA, but available from Ogden BioServices unit, which was purchased by McKesson Corporation in 2006). Erwinia asparaginase is officially available in many European countries as Erwinase. The two preparations have generally been judged to be essentially equivalent in effectiveness, but a prospective clinical trial in human patients treated for either ALL or lymphoblastic non-Hodgkins lymphoma found that although Elspar caused slightly more coagulation related adverse effects than Erwinase, it was more effective in the treatment of these cancers (Duval et al. 2002). The *E. coli* form of the drug has been covalently linked to monomethoxy-polyethylene glycol and is known as PEG-L-asparaginase or pegasparaginase (Oncaspar). This formulation has been approved by the US FDA for treatment of people who are allergic to Elspar (Kurtzberg et al. 2003).

The main side effects of L-asp are anaphylaxis, pancreatitis, diabetes, and coagulation abnormalities that may lead to intracranial thrombosis or hemorrhage (Duval et al. 2002). The prevalence of anaphylaxis in dogs receiving L-asp for the first time is extremely low (Ogilvie et al. 1994a). It is used only once in many protocols for animals. Precautions should be taken to counteract the potential allergic reactions.

Other Natural Products. *Plicamycin,* USP (mithramycin, Mithracin) and *mitomycin* (mitomycin C, Mutamycin) have not been used much in veterinary oncology.

Sterile Bleomycin Sulfate, USP (Blenoxane) is actually a mixture of glycopeptides of which bleomycin AV2 V and BV2 V are dominant in the commercial form. This glycopeptide has an amino terminal tripeptide (S tripeptide) able to bind to DNA, and a heavy metal (copper and iron) binding component located at the opposite end. Bleomycin has produced excellent results in humans in treatment of lymphoma and embryonal testicular tumors and good results in tumors of the head, neck, and skin, including squamous cell carcinoma. It has shown activity against squamous cell carcinoma in dogs and cats. It has shown activity against confirmed canine oral melanoma when combined with electrochemotherapy (ECT). ECT combines local administration of the drug with delivery of permeabilizing electric pulses of appropriate waveform that result in increased uptake of the drug. Overall response rate of 10 treated client-owned dogs was 80% with 50% long-term control (Spugnini et al. 2006). It is highly valued in multidrug regimens because its toxicity does not overlap that of other anticancer drugs.

Bleomycin is cell-cycle-phase–specific. It is most active in G2, but is also active in late G1, early S, and M phases.

Bleomycin is unique in that although it causes chromosomal abnormalities, it causes no clinically significant toxicity to the bone marrow or GI tract. Dose-limiting toxicity of bleomycin is usually pulmonary fibrosis. Part of the explanation for this tissue selectivity may be that bleomycin is metabolized by an aminopeptidase B–like enzyme called *bleomycin hydrolase* present in most tissues except the skin and lung. Thus signs of toxicity are related to the skin and lung where drug concentration is highest.

If the endothelial lining is damaged or if the drug is given intratracheally and if significant bleomycin reaches the interstitium of the lungs or macrophages, it may be possible to produce pulmonary fibrosis with a single low dose. In dogs, bleomycin initially produces interstitial pneumonia and after intensive treatment causes pleural scarring and pulmonary fibrosis. Risk factors include total dose, age, and concomitant use of other drugs. Treatment should be stopped immediately if impairment of pulmonary function is noted. In veterinary clinical practice, a shorter duration of therapy with bleomycin lessens the likelihood of occurrence of this chronic toxicity.

Toxic effects on the skin include desquamation, hyperpigmentation, and pruritic erythema. Stomatitis, nausea, vomiting, and anorexia may be seen. Severity of reactions ranges from fever and chills to anaphylaxis. Bleomycin should be used with caution in the presence of renal or pulmonary disease. Local therapy as used in the electrochemotherapy of canine melanoma produced minimal toxicity (Spugnini et al. 2006).

Bleomycin is distributed widely throughout the body after parenteral administration, but does not enter the CSF. Decreased renal function slows elimination and

necessitates dosage reduction in humans and, presumably, animals. Bleomycin is not active orally.

HORMONES AND ANTAGONISTS. Estrogens, progestins, androgens, glucocorticoids, and thyroid hormones have been used in the treatment of cancer, but are essentially only palliative. Pharmacologic doses are usually required for antitumor effects, so one should expect adverse reactions to be those of hormone excess. The spectrum of antitumor activity is limited to the usual target tissues or those that are the target of other hormones that may be affected by the hormone given. The toxicities and mechanisms of hormones are discussed in Section 8.

Estrogens. Estrogens such as *diethylstilbestrol*, USP, and *estradiol cypionate*, USP, have been used in the treatment of mammary gland cancer, prostatic hyperplasia and carcinoma, and perianal glandular neoplasms. However, the role estrogen plays in causing mammary cancer has led to a more dominant role for drugs that would decrease estrogen concentration. Toxic effects include bone marrow suppression, feminization with gynecomastia, and fluid retention.

Aromatase Inhibitors and Antiestrogens. Aromatase inhibitors and antiestrogens are used extensively in treatment of breast cancer in women. Aromatase is an enzyme that converts androstenedione and testosterone to estrone and estradiol. It is expressed in human placenta and in granulosa cells of ovarian follicles as well as in such nonglandular tissues as subcutaneous fat, liver, muscle, brain, normal breast, and breast-cancer tissue. Aromatase inhibitors currently used or in clinical trials in people include first-generation *aminoglutethimide* (Cytadren; AG), second-generation *formestane* (Lentaron) and *exemestane*, and third-generation *anastrozole* (Arimidex) and *letrozole* (Femara). Aromatase inhibitors and antiestrogens are seldom used in veterinary medicine. Consult Chabner et al. (2006) for further information.

Antiestrogens such as tamoxifen citrate (Nolvadex) may be used in the treatment of estrogen-dependent disseminated mammary gland cancer. Adverse effects of tamoxifen are mild bone marrow suppression (leukopenia, thrombocytopenia, and anemia), skin rash, alopecia, and stump pyometra. A dose escalation study of tamoxifen in dogs listed gastrointestinal toxicity and reversible neurotoxicity at doses of 600 mg/m^2 every 12 h. Detailed pharmacokinetics of tamoxifen were not reported, but peak plasma tamoxifen and its major metabolite, NDMT (N-desmethyl tamoxifen, which is active), combined was 6–11 μM at an oral dose of 600 mg/m^2 administered every 12 hours for 7 days (Waddle et al. 1999).

Adrenocorticosteroid Hormones. Adrenocorticosteroid hormones, most commonly prednisone, USP, have been used in cancer therapy for two types of action. For nonlymphoid tumors like brain tumors, they are palliative by decreasing inflammation and swelling. For lymphoreticular neoplasms and possibly mast cell tumors they may be cytotoxic. They have been shown to induce DNA fragmentation in human lymphoid leukemia cells. Resistance develops rapidly in some patients. Ideally, the glucocorticoids should be used in large doses for the minimal time required to produce remission, and then tapered as rapidly as possible. Long-term use at high doses leads to toxicity (often without benefit to the patient) and iatrogenic adrenal hypercorticism. Toxicity includes gastric ulcer, osteoporosis, and increased susceptibility to infection. Polydipsia, polyuria, polyphagia, and excessive panting are especially common and troublesome when patients are chronically maintained on these drugs. Another use of these drugs as stated above is for management of secondary complications of cancer (i.e., to elevate mood, stimulate appetite, and decrease reaction to dying cells). In addition, they are useful in the management of tumor-associated pain, hypercalcemia, hypoglycemia, and increased intracranial pressure.

Antiandrogens. Benign prostatic hypertrophy and prostate cancer of dogs have been evaluated as models of equivalent diseases in humans (Madewell et al. 2004). Few significant clinical trials in canine cancer of drugs being developed for use in people were found. Consult Chabner et al. (2006) for further information.

MISCELLANEOUS AGENTS. *Hydroxyurea*, USP (Hydrea), acts as an antimetabolite by inhibiting ribonucleotide reductase, thus limiting the availability of deoxyribonucleotides needed for DNA synthesis. Hydroxyurea is cell-cycle-phase–specific, acting on the S phase. It has been used in people for chronic myelogenous leukemia, polycythemia vera, essential thrombosis, sickle-cell disease, and as an adjunct in AIDS therapy. It is infrequently used in

veterinary oncology, but has been used therapeutically in the treatment of polycythemia vera.

CYCLOOXYGENASE INHIBITORS. *Piroxicam* (Feldene) and other nonsteroidal antiinflammatory drugs have been reported to have antitumor activity against transitional cell carcinoma of the urinary bladder (Mutsaers et al. 2003) and squamous cell carcinoma of the oral cavity and skin in dogs (Schmidt et al. 2001). Although these agents have only recently received attention for the treatment or prevention of human cancer, their activity in dogs was reported several years ago (Knapp et al. 1992). Greater antitumor effects may be observed when COX inhibitors are combined with chemotherapy (Knapp et al. 2000; Boria et al. 2004). Piroxicam combined with doxorubicin was effective against multicentric lymphoma in dogs, but was not superior to doxorubicin alone (Mutsaers et al. 2002).

The mechanism of antitumor effect has not been established, but may include multiple effects. An antiangeogenesis effect has been postulated from in vitro studies of canine osteosarcoma cells (Royals et al. 2005). In vitro studies with meloxicam, a nonsteroidal COX-2 inhibitor, revealed that it caused apoptosis in canine osteosarcoma (D-17) cells (Wolfesberger et al. 2006). Increased apoptosis and reduction in urine basic fibroblast growth factor concentration has been observed (Mohammed et al. 2002). Apoptosis may be increased in oral cavity cancer cells through induction of NAG-1 (Kim et al. 2004). NAG-1 is a TGF-beta superfamily protein that has antitumorigenic activity and stimulates apoptosis in colorectal and other cancer cell lines (Baek et al. 2001). The NSAID effect on NAG-1 may be independent of an action on cyclooxygenase (Jang et al. 2004). The complexity of mechanism of nonsteroidal antitumor activity is further demonstrated by the finding that four NSAIDs, including piroxicam, given 30 minutes prior to radiation may radiosensitize tumors by increasing oxygen content in the tumors (Crokart et al. 2005).

Adverse effects of piroxicam include gastrointestinal ulceration and subclinical renal papillary necrosis (Knapp et al. 1992, 1994). Renal adverse effects may be pronounced when piroxicam is combined with cisplatin (Knapp et al. 2000).

NEW APPROACHES AND INVESTIGATIONAL COMPOUNDS. The explosion of knowledge in cancer biology and genomics has led to the development of approaches to cancer therapy that are "molecularly targeted" at specific enzymes or receptors (Adjei and Hidalgo 2005). Although a detailed discussion of these developments is beyond the scope of this chapter, the major areas will be outlined. Many of these have reached clinical use or are in clinical trials in people with cancer.

Differentiating Agents. Differentiating agents, e.g., the retinoid *tretinoin* (ATRA), are compounds that, as the name states, can facilitate induction of differentiation. Tretinoin is effective in treating acute promyelocytic leukemia.

Proteasome Inhibitors. Proteasomes process and/or degrade many regulatory proteins involved in controlling cell division, growth, and apoptosis. Chemotherapy-induced stress can activate proteasome-dependent pathways that protect a cell from apoptosis that would otherwise result from the action of the drug. By reversibly inhibiting the chymotrypsinlike activity of the proteasomes, *bortezomib* (PS-341, Velcade) decreases the protective response to the stress and enhances the activity of some chemotherapeutic agents. Because of the widespread interference in cellular regulation caused by the proteasome inhibition, bortezomib may also be an effective anticancer agent in its own right against specific tumor types. It has been approved by the FDA for use in human patients with relapsed refractory myeloma (Chabner et al. 2006).

EGFR Targets. Epidermal growth factor receptor, EGFR, is a tyrosine kinase receptor of the ErbB family that serves key roles in intracellular signaling by phosphorylating and recruiting several downstream substrates. The net effect of these changes is to promote survival of the cell, mitogenic signaling, and tumor promotion. Although normally well regulated, EGFR may be amplified or mutated in tumors. Some tumors, especially those that are more aggressive, are susceptible to inhibition of EGFR by such agents as *erlotinib* (Tarceva) and *gefitinib* (Iressa), which can prevent the ligand activation of the pathway, thereby resulting in cell cycle arrest, promotion of apoptosis, and inhibition of angiogenesis (Doroshow 2005).

Other tyrosine kinase inhibitors include *Imatinib* (Glivec, Gleevec, ST1571), the first drug introduced into clinical medicine to have such activity (Heinrich et al. 2003). Since that introduction other tyrosine kinases have

entered either standard clinical use or are in clinical trials. Examples of these include *dasatinib* (Sprycel, BMS-354825) a dual SRC/ABL kinase inhibitor that is active in some cell lines resistant to imatinib, and *lapatinib* (Tykerb, GW572016, which inhibits both EGFR and ErbB-2 [HER-2] tyrosine kinases).

Clinical Use in Animals	1244
Adverse Effects	1244

Conditions that require immunosuppressive drugs include skin diseases such as pemphigus, pemphigoid, and lupus-like syndromes. Systemic immune-mediated diseases requiring immunosuppressive drug therapy include immune-mediated hemolytic anemia (IMHA), systemic lupus (SLE), and immune-mediated thrombocytopenia (ITP). For management of some of these disorders, corticosteroids, alkylating agents, cytotoxic drugs, cyclosporine, and gold compounds have been used. NSAIDs alone are not usually effective.

GLUCOCORTICOIDS

Glucocorticoids are usually the initial drugs used for treating immune-mediated diseases. They are consistently effective, but have multiple side effects and adverse effects, especially with long-term use. The pharmacology of glucocorticoids was discussed in detail in Chapter 30 and readers are referred to that chapter. Briefly, glucocorticoids exert their action via binding to intracellular receptors, translocating to the nucleus, and binding to receptor sites on responsive genes (Rhen and Cidlowski 2005; Boumpas et al. 1993), where they modulate the transcription of glucocorticoid-responsive genes (Barnes and Karin 1997; Barnes 2001; Hayashi et al. 2004; Rhen and Cidlowski 2005). By regulating glucocorticoid-responsive genes, protein synthesis is altered, which affects cell function.

CELLULAR EFFECTS. Corticosteroids increase the circulating numbers of mature neutrophils. There is a release of cells from the marginal pool of neutrophils and decreased migration and egress into inflammatory tissue. This effect is attributed to decreased expression of adhesion molecules, reduced adherence to the vessel endothelium, and reduced diapedesis from the vessels. Subsequently, there is decreased movement of inflammatory cells into tissues in response to chemotactic stimuli. Glucocorticoids affect leukocyte traffic more than cellular function.

Glucocorticoids also affect many functions of macrophages. They suppress the function of macrophages and decrease the inflammatory response, generation of cytokines, and the ability of macrophages to process antigens. They also inhibit phagocytosis of macrophages.

Corticosteroids decrease the numbers of lymphocytes in the peripheral circulation—caused by a redistribution of circulating lymphocytes—depress lymphocyte activation, and decrease participation of lymphocytes in inflammation. T-cells are affected more than B-cells. B-cells are generally resistant to the immunosuppressive effects of glucocorticoids, and there is minimal effect on immunoglobulin synthesis. However, high corticosteroid doses will decrease immunoglobulin levels, probably because of increased catabolism, as well as through the secondary effects to suppress accessory cells and cytokine synthesis. At antiinflammatory doses, glucocorticoids do not decrease an animal's ability to mount a normal immune response (e.g., from vaccinations) (Nara et al. 1979).

Glucocorticoids inhibit release of inflammatory cytokines from leukocytes (e.g., IL-1, TNF-α, prostaglandins). Glucocorticoids decrease expression of cytokines from lymphocytes (e.g., IL-2).

IMMUNOSUPPRESSIVE EFFECTS. It is difficult to separate the antiinflammatory from the immunosuppressive effects of glucocorticoids. For a complete review of these effects see the articles by Cohn (1991) and Barnes (2006). For severe immune-mediated disorders (e.g., autoimmune skin disease, immune-mediated hemolytic anemia and thrombocytopenia, SLE, arthritis) glucocorticoids suppress the immune system response to alleviate clinical signs. In a study in which various treatments for immune-mediated hemolytic anemia were examined, corticosteroids alone were as effective as combination treatments (for example, with azathioprine, cyclophosphamide, etc.) (Grundy and Barton 2001).

The immune-suppressing effects require higher dosages of corticosteroids than are necessary for antiinflammatory therapy (often by a factor of at least 2×). The mechanism of action for the immunosuppression caused by corticosteroids is complex. In the study by Ammersbach et al. (2006), the authors demonstrated decreased neutrophil migration and survival, decreased cytokines, decreased adhesion expression, and a decrease in the cytotoxic lymphocyte function as well as lymphocyte apoptosis. The dose used in this study in dogs was approximately 2 mg/kg per day for 3 days.

CHOICE OF DRUGS. For long-term therapy, intermediate-acting steroids (prednisone, prednisolone) are used most often because they can be administered on an every-other-day (EOD) basis. However, dexamethasone is often used for acute, short-term treatment.

DOSES. Initial (induction) dosage regimens employ daily doses of 2.2 to 6.6 mg/kg (prednisolone or prednisone). Doses greater than 6 mg/kg are rarely used in dogs. Initial doses generally are in the range of 2–4 mg/kg/day. One study reported that the optimal induction doses for skin diseases were 4.4 mg/kg/day for dogs and 6.6 mg/kg/day for cats. After an induction period, if the patient responds favorably, the dose may be decreased by a factor of 2. Eventually one should attempt to maintain the patient on this

low dose on an EOD basis. Some diseases are slow to respond and a reduction of doses should be done on a gradual and prolonged schedule. For example, lowering the dose based on an evaluation every 2–4 weeks may be necessary. Eventually, for immune-mediated disease, maintenance doses of 1 mg/kg, EOD are possible but higher doses or adjunctive therapy may be necessary in individual patients. At the high dose ranges, side effects are common.

ADVERSE EFFECTS. Side effects associated with treatment—but not necessarily reasons for discontinuing therapy—include polyuria/polydipsia, increased appetite (polyphagia), and behavior changes (increased restlessness for example). Adverse effects from immunosuppressive doses of corticosteroids include risk of infectious diseases, adrenal suppression, pancreatitis, delay of healing, catabolic effects on muscle and connective tissues, and hepatopathy.

RATIONALE FOR EVERY-OTHER-DAY (EOD) THERAPY. If a glucocorticoid is used that has a duration of action of 12–36 hours (intermediate-acting), the hypothalmic-pituitary-adrenal (HPA) axis has an opportunity to recover before the next dose. It is important that one chooses a glucocorticoid that does not have a long duration of action for EOD therapy—for example, dexamethasone is unacceptable because its duration is at least 36–48 hours. After 1 mg/kg every 48 hours of prednisolone ACTH was suppressed in dogs for 18 to 24 hours, and returned to normal until the next scheduled dose (Brockus et al. 1999). EOD therapy will minimize, but *will not* prevent adrenal atrophy, and other adverse effects such as those on the immune system, and the effects on metabolism.

CYCLOSPORINE

Cyclosporine is a fat-soluble, cyclic polypeptide fungal product with immunosuppressive activity. It has been an important drug used in humans, primarily to produce immunosuppression in organ transplant patients. It has gained recognition for veterinary use because of availability of a veterinary formulation of cyclosporine (Atopica).

Cyclosporine binds to a specific cellular receptor on calcineurin and inhibits the T-cell receptor-activated signal transduction pathway (Fig. 46.1). Particularly important are its effects to suppress interleukin-2 (IL-2)

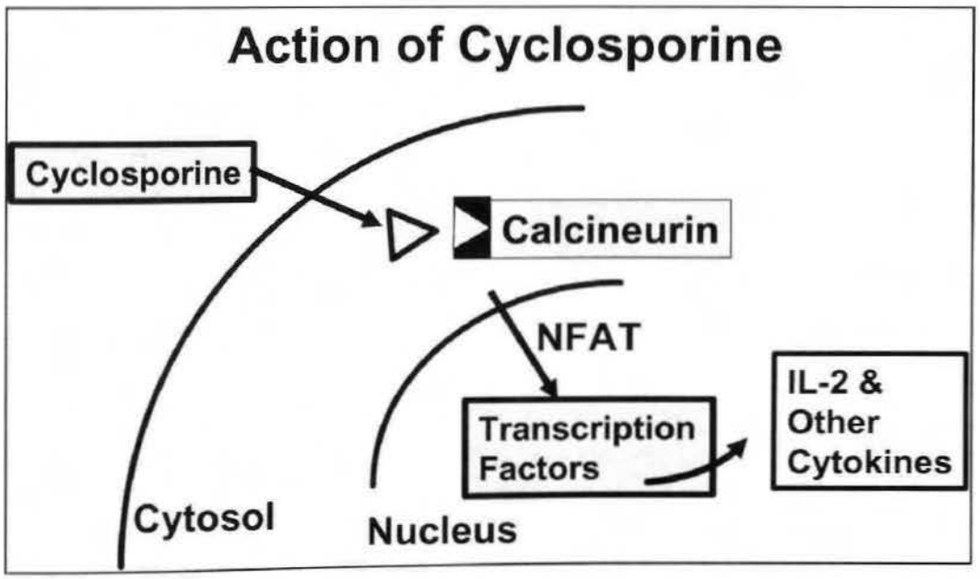

FIG. 46.1 Mechanism of action of cyclosporine. Cyclosporine enters the cytosol, where it binds and inhibits calcineurin at a specific receptor site. By inhibiting calcineurin, the movement of the nuclear factor of activated t-cells (NFAT) is prevented from entering the nucleus. Without the action of NFAT, transcription factors that produce cytokines is inhibited. (See text for additional details.) Tacrolimus is also capable of inhibiting calcineurin.

and other cytokines, and block proliferation of activated T-lymphocytes. The action of cyclosporine is more specific for T-cells as compared to B-cells. One important advantage in comparison to other immunosuppressive drugs—especially corticosteroids—is that it does not cause significant myelosuppression or suppress nonspecific immunity.

CLINICAL USE. Cyclosporine has been used for a number of diseases in veterinary medicine. Many of these diseases have been dermatologic, as reviewed by Robson and Burton (2003). In dogs, when used in the treatment of perianal fistulas, (Mathews et al. 1997; Griffiths et al. 1999) an 85% healing rate was found in one study (Mathews et al. 1997) (2.5–6 mg/kg/day); in sebaceous adenitits, good response was reported in one case (Carothers et al. 1991); and in idiopathic sterile nodular panniculitis, excellent results were seen in two reported cases which were followed for 6 months following discontinuance of the cyclosporine (Guaguère 2000).

USE FOR IMMUNE-MEDIATED DISEASES. Cyclosporine has been used for treatment of a variety of immune-mediated diseases that include immune-mediated hemolytic anemia (IMHA), inflammatory bowel disease (IBD) (Allenspach et al. 2006), immune-mediated polyarthritis, and aplastic anemia (AA). For more severe diseases that require a more consistent immunosuppressive activity, higher doses are used than for atopic dermatitis. For example, for some immune-mediated disease the dose should be in the range of at least 10 mg/kg/day, and perhaps twice a day to produce clinical effects. For these diseases, trough blood cyclosporine concentrations should be at least 600 ng/ml.

For treating immune-mediated skin diseases, the results from pilot studies for treating pemphigus foliaceous in dogs have been disappointing (Rosenkrantz et al. 1989). It did not help any patients with mycosis fungoides. In a study in which five dogs with pemphigus foliaceous were treated, there was little benefit (Olivry et al. 2003). The dogs with pemphigus foliaceous were initially treated with the "atopy dose" of 5 mg/kg/day. If there was no response the dose was increased to 10 mg/kg/day. At the end of the trial, it was concluded that at 5–10 mg/kg/day cyclosporine was unable to produce complete remission in any of the five dogs. In a case study of immune-mediated polyarthritis in dogs (Clements et al. 2004), dogs were treated with prednisolone and various other immune-modifying drugs. Three dogs treated with cyclosporine at 5 mg/kg per day did not respond.

ATOPIC DERMATITIS. In people it has been used successfully for treatment of atopic dermatitis (Camp et al. 1993). Because of this efficacy, the use of cyclosporine for treating canine atopic dermatitis has been investigated in dogs (Marsella and Olivry 2001). In a pilot study, cyclosporine was effective in 13/14 dogs with atopic dermatitis (Fontaine and Olivry 2001). In another trial of 30 dogs treated with cyclosporine (5 mg/kg/day) or prednisolone (0.5 mg/kg/day), the efficacy of cyclosporine was not statistically different than prednisolone (Olivry et al. 2000 2002). Reductions in mean lesion scores were 60% and 59% in prednisolone and cyclosporine groups, respectively. Reduction in mean pruritus scores were 81% and 78% in prednisolone and cyclosporine groups, respectively. In another published study from the same author, 91 dogs with atopic dermatitis were treated with cyclosporine. Two doses were examined, 2.5 mg/kg/day, and 5 mg/kg/day. The formulation used was *Neoral* (formulations to be discussed below). There was a dose-dependent effect. Dogs treated with 5 mg/kg had statistically significant reduction in pruritus scores (45%) and skin lesions (67%). The dose of 2.5 mg/kg was not statistically different from placebo. Some dogs may benefit from less than once-daily administration as shown in another study (Steffan et al. 2003). In this study, administration of cyclosporine (5 mg/kg) was compared to methylprednisolone (0.75 mg/kg) for treatment of canine atopic dermatitis. The response was not different between the drugs, but there was an overall better assessment of efficacy and more gastrointestinal problems in dogs treated with cyclosporine. In the cyclosporine-treated dogs, the dose was started at 5 mg/kg/day for 4 weeks, but eventually half of the dogs were adjusted to an EOD dose, and one-quarter of the dogs were given cyclosporine at 5 mg/kg only twice a week.

USE IN CATS. For organ transplantation in cats (Mathews and Gregory 1997; Kadar et al. 2005) a dose of 3 to 4 mg/kg q12h was used to achieve blood concentrations of 300–500 ng/ml. For treatment of inflammatory disease in cats, including eosinophilia granuloma complex, lower

doses are possible. A good response to a dose of 25 mg/cat was seen in six cases of eosinophilic plaque and 3 cases of oral eosinophilic granuloma (Guaguère and Prèlaud 2000). In the report by Vercelli et al. 2006) cats with allergic pruritus were improved with 8 mg/kg oral q24h. Cats with plasmacytic stomatitis, and feline allergic disease have also showed improvement with oral administration of cyclosporine (Vercelli et al. 2006).

One of the capsule sizes is 25 mg and a common dosage is 25 mg/cat, once daily. (Smaller capsules are also available for veterinary use—see below.) The most common adverse effects are anorexia, vomiting, and refusal to eat their food if cyclosporine is mixed with food. Toxoplasmosis has been reported in cats treated with cyclosporine, presumably due to the immunosuppression.

FORMULATIONS AND PHARMACOKINETICS. The pharmacokinetics of cyclosporine are complicated because of the differences between dosage forms, presence of many metabolites, influence of drug interactions, and variability in oral absorption. The formulation called *Sandimmune* was used for many years but was absorbed inconsistently. A more recent human formulation is a microemulsion called *Neoral* which has a much more consistent rate and extent of absorption that is less affected by factors such as feeding than Sandimmune (Lown et al. 1997). There are now human generic equivalents of this formulation. The introduction in late 2003 of Atopica represents the first oral veterinary formulation of cyclosporine. The formulation is exactly the same as Neoral (microemulsion), except that there is a greater variety of capsule sizes available (10, 25, 50, and 100 mg). Absorption, kinetics, and dissolution are the same as for Neoral.

A human formulation called *Gengraf* is a unique formulation. Gengraf capsules have improved solubilzation by dispersing the drug in polyethylene-glycol, propylene glycol, cremophore, and polysorbate. Its interchangeability with Atopica has not been reported.

The pharmacokinetics of cyclosporine in treated animals has been examined (Steffan et al. 2004). Cyclosporine is metabolized in the intestine and liver to several metabolites. Twenty-five to thirty such metabolites have been identified. The prehepatic intestinal enzymes account for significant metabolism of cyclosporine (Wu et al. 1995), and systemic absorption in dogs is only 20–30% (Myre et al. 1991). Systemic absorption in cats is similar at 25–29% (Mehl et al. 2003). The intestinal metabolism by cytochrome P450 enzymes (CYP) and the efflux caused by intestinal p-glycoprotein (P-gp) account for most of the loss in systemic availability after oral administration. Drug enzyme inhibitors such as ketoconazole, diltiazem, or the flavonoids in grapefruit juice can inhibit the presystemic metabolism and produce a profound increase in systemic availability of cyclosporine. For example, 5–10 mg/kg of ketoconazole once daily can decrease the dose of cyclosporine because clearance is reduced by 85% (Myre et al. 1991).

ADMINISTRATION. As cited in the clinical trials above, for treating dermatitis in dogs, the effective dose has been 5 mg/kg/day. Some clinicians have been able to lower the dose, or administer the dose every other day, and still maintain clinical remission. Approximately half of treated dogs can be maintained by increasing the dose interval.

For organ transplantation in people, higher doses are used (e.g., 5–10 mg/kg/day) to achieve targeted whole blood concentrations of 150–400 ng/ml. In people, dosages are adjusted to meet the needs of the individual patient on the basis of clinical response and monitoring trough plasma concentrations. For organ transplantation in cats (Mathews and Gregory 1997) a dose of 3 mg/kg q12h of the Neoral formulation was used to achieve trough blood concentrations of 300–500 ng/ml. At NCSU we routinely administer 25 mg/cat for suppression of immunity for transplantation and modify as needed with monitoring. For organ transplant in dogs, 10 mg/kg q12h to achieve concentrations of 500–600 ng/ml has been used (Mathews et al. 2000).

A report on treating perianal fistulas in dogs (Mathews and Sukhiani 1997) found that an average dose of 6 mg/kg q12h was needed to achieve a targeted blood concentration of 400–600 ng/ml. However, this recommendation was later modified to 2.5 to 6 mg/kg/day. The most common dose for treating perianal fistulas is 3 mg/kg q12h.

MONITORING. Steffan and colleagues (2004) found that when administering approved doses to dogs with atopic dermatitis, routine monitoring of blood cyclosporine concentrations was not necessary. When animals were administered a dose of 5 mg/kg/day, there did not appear

to be a strong correlation between blood concentration achieved and clinical response. However, because of wide individual variation in cyclosporine pharmacokinetics, monitoring has been used to determine the optimum dose in some patients. According to one paper, clinical benefits have not been observed when trough concentrations have fallen below 50 ng/ml; therefore, blood testing of patients failing therapy was suggested to reveal inadequate dosing (Robson and Burton 2003).

One must be cognizant of the assay used when monitoring cyclosporine. Plasma values will be lower than whole-blood assays because as much as 50–60% and 10–20% of the dose is concentrated in erythrocytes and leukocytes, respectively. Nonspecific assays will report higher values than a more specific (monoclonal or HPLC) assay. Despite the hypothesized higher specificity when using the monoclonal assay, important discrepancies between these assays and the more specific HPLC assay have been reported (Steimer 1999). For example, in people the difference between HPLC and the commonly used TDx monoclonal immunoassay was 57%. In cats, the TDx assay overestimated the true cyclosporine concentration by a factor of approximately two (that is, TDx assay reporting 500 ng/ml corresponded to an actual value of 250 ng/ml). In dogs, the TDx assay overestimates the true cyclosporine concentrations by a factor of 1.5 to 1.7 (Steffan et al. 2004). When using a specific radioimmunoassay or HPLC assay the true concentrations are measured. But, when using a TDx fluoroescence polarization assay (monoclonal whole blood), multiply the feline concentrations by 0.5 to get the true concentration, and multiply the canine concentration by 0.6 to get the true concentration.

Most current recommendations are based on trough blood sample monitoring. Trough samples are collected immediately before the next scheduled dose; therefore the sample is either 12 or 24 hours after the last dose. These recommendations are being modified in human medicine to a recommendation of a 2-hour sample (C_2). Apparently there is evidence that a C_2 blood sample value correlates better with clinical results than trough samples (Levy et al. 2002; Nashan et al. 2002). In cats, levels are approximately twice as high at 2 hours compared to the levels at 12 hours (Mehl et al. 2003).

ADVERSE EFFECTS AND PRECAUTIONS. Cyclosporine can cause vomiting, diarrhea, anorexia, secondary infections, and gingival hyperplasia (Vaden 1995) (Table 46.1). Hyperplastic skin lesions have occasionally developed in dogs treated with cyclosporine (Favrot et al. 2005). Papillomavirus can be detected in some skin lesions. Tremors or shaking have been observed in dogs administered high doses. One reference noted few adverse effects as long as blood concentrations were kept within accepted limits (Mathews and Sukhiani 1997).

TABLE 46.1 Adverse reactions of cyclosporine (http://www.fda.gov/cvm/)

Cats: most common adverse events
- Anorexia (#1)
- Vomiting
- Weight loss, depression

Dogs: most common adverse events
- Vomiting (#1)
- Diarrhea
- Depression
- Lethargy
- Pruritus
- Anorexia
- Increased liver enzymes

The most common clinical problem with cyclosporine in dogs that has been cited in the clinical trials discussed previously (Olivry et al. 2000, 2001, 2002; Steffan et al. 2003) is gastrointestinal problems. Vomiting, anorexia, and diarrhea can be seen. When anorexia and vomiting are reported, veterinarians have tried various interventions such as lowering the dose, or administration of the dose with some food. However, whether this decreases the efficacy of the drug should be considered. Feeding will reduce the amount of cyclosporine absorbed in dogs by 15–20%, but it is unlikely that this decrease will be severe enough to affect efficacy.

Nephrotoxicity, once a problem with older forms, is rare with current formulations. Secondary malignancies are a possible complication to long-term therapy but have not been reported in dogs or cats.

DRUG INTERACTIONS. Several drugs may interact with cyclosporine. For example, coadministration of ketoconazole to treat secondary fungal infections will decrease metabolism of cyclosporine (Myre et al. 1991). Ketoconazole has been used deliberately to reduce the need for cyclosporine in some investigations (Patricelli et al. 2002) and doses have been reduced by one-third of the original dose when administered with ketoconazole. In

one study with cyclosporine in the treatment of perianal fistulae, the dose of 1 mg/kg cyclosporine combined with 10 mg/kg ketoconazole was used. The author felt that a dose of 0.5 mg/kg combined with 10 mg/kg ketoconazole also could be used (Mouatt 2002). Erythromycin, grapefruit juice, and diltiazem also may inhibit cyclosporine metabolism and increase blood concentrations.

OPHTHALMIC USE. *Keratoconjunctivitis sicca:* Cyclosporine (Optimmune) is approved to increase tear production in dogs with keratoconjunctivitis sicca (KCS). Success rates are high. Topical cyclosporine has also been used to treat other immune-mediated diseases of the eye. It is available as a 0.2% ophthalmic ointment.

Anterior uveitis: Cyclosporine intraocular implants have been developed by an ophthalmologist at NCSU (Gilger et al. 2006). These implants are administered to horses to treat anterior uveitis. This method of treatment slowly releases the medication and can produce a long-term sustained therapeutic effect.

TACROLIMUS, PIMECROLIMUS, AND SIROLIMUS

Tacrolimus (Prograf) is approved for use in people as 1 and 5 mg capsules and injection. This drug has similar immunologic effects on lymphocytes as cyclosporine. Like cyclosporine, it binds to an intracellular receptor that inhibits IL-2 gene expression in T-helper lymphocytes. It also may bind to receptors that inhibit expression of other cytokines. It has not been used systemically in veterinary medicine and may produce unacceptable adverse effects in dogs.

Tacrolimus (Protopic) has been used topically in dogs with some dermatoses. Systemic absorption is so low that it is safe for topical administration to dogs. More recently, pimecrolimus has been used in people as a topical treatment for atopic dermatitis. Pimecrolimus (Elidel) is available as a 1% cream. There is minimal systemic absorption of pimecrolimus after application.

Sirolimus (Rapamycin) is similar to tacrolimus and has been used to prevent transplant rejection in people. In dogs, sirolimus produced severe gastrointestinal toxicity with mucosa necrosis and submucosa vasculitis.

CYCLOPHOSPHAMIDE (CYTOXAN®)

Cyclophosphamide is one of the nitrogen mustards and is one of the most potent immunosuppressive drugs available. More details on the pharmacology of cyclophosphamide can be found in Chapter 45.

MECHANISM OF ACTION. The immunosuppressive effects of the nitrogen mustards can be attributed to the cytotoxic effect on lymphocytes caused by damage to DNA. Cyclophosphamide is metabolized initially to 4-hydroxyphosphamide and then at target sites metabolized spontaneously (nonenzymatically) to active compounds acrolein and phosphoramide mustard. (Fig. 46.2) Phosphoramide mustard is responsible for alkylating bases on the DNA molecule. Because of the cytotoxic action on lymphocytes, it can directly suppress B-cell activity and antibody formation. B-cells are affected more than T-cells because their rate of recovery from an alkylating agent is slower.

ADVERSE EFFECTS. Cyclophosphamide is a potent immunosuppressive drug with a high risk of myelosuppression. In dogs the most serious toxic effect is bone marrow suppression, which can lead to secondary infections, thrombocytopenia, and anemia. Another adverse effect is sterile hemorrhagic cystitis. The incidence has been estimated to be as high as 24% in treated dogs and 3.7% in treated cats. The injury to the urinary bladder is caused by the toxic effects of metabolites on the bladder epithelium (especially acrolein) that are concentrated and excreted in the urine. Various strategies have been used to decrease the injury to the bladder epithelium. Corticosteroids are usually administered with cyclophosphamide to induce polyuria and decrease the toxic effect of the drug on the epithelium. In people, and occasionally in dogs, the drug mesna (Mesnex, mercaptoethanesulfonate) has been used to prevent drug-induced cystitis. Mesna provides free active thiol groups to bind metabolites of cyclophosphamide in the urine. Another therapy that has been used to reduce hemorrhagic cystitis is the administration of furosemide. In a study of 216 cases (Charney et al. 2003), there was less hemorrhagic cystitis when furosemide was administered concurrently, compared to cyclophosphamide alone. The dose of furosemide used was 2.2 mg/kg IV administered at the time of cyclophosphamide administration.

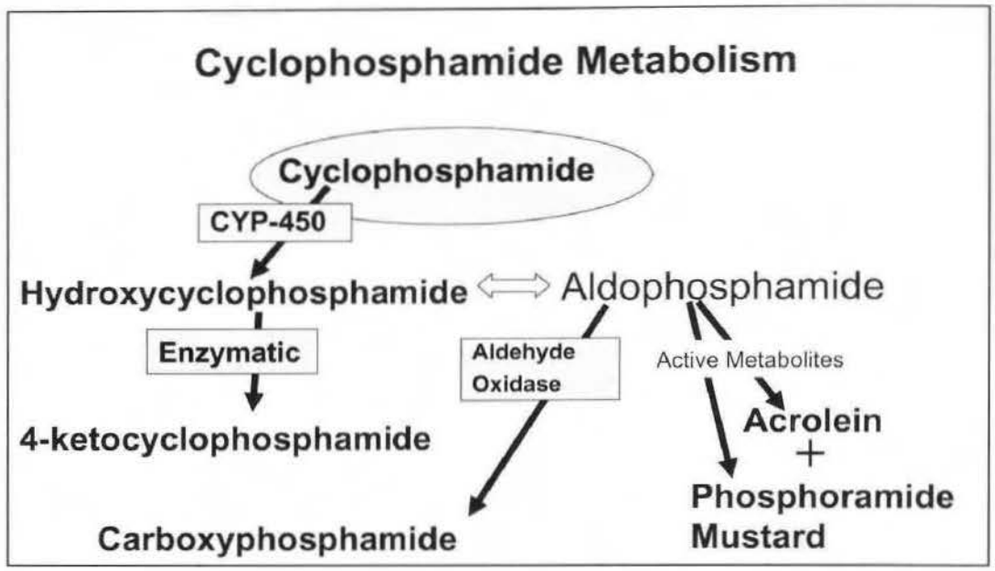

FIG. 46.2 Metabolism of cyclophosphamide. Cyclophosphamide is metabolized by cytochrome P450 enzymes to hydroxycyclophosphamide, which in turn is metabolized enzymatically to 4-ketocyclophosphamide, an inactive metabolite. Conversion of hydroxycyclophosphamide to aldophosphamide leads to nonenzymatic (spontaneous) conversion to the active metabolites, acrolein (responsible for toxicity), and phosphoramide mustard (responsible for cytotoxic, or alkylating effect).

Cats are resistant to hemorrhagic cystitis from cyclophosphamide. Gastrointestinal effects such as nausea, vomiting, and diarrhea also are possible in any species treated.

In people, long-term therapy is discouraged because of the risk that cyclophosphamide will induce secondary malignancies. Secondary malignancies have not been reported in animals that have been treated.

CLINICAL USE. The dose administered to dogs is 50 mg/m^2, which is approximately 1.5 mg/kg for large dogs and 2.5 mg/kg for small dogs. It is available in 25 and 50 mg tablets. This dose has been administered every other day (EOD) with corticosteroids administered on the alternate days. Cyclophosphamide also is administered at this dose by some clinicians as a pulse dose of 4 consecutive days/week (4 days on, 3 days off). Cats have received a total dose of 6.25–12.5 mg, once daily, 4 days per week.

For treatment of immune-mediated hemolytic anemia, the efficacy of cyclophosphamide has been questioned (Mason et al. 2003). In a study in which dogs were randomized to receive cyclophosphamide plus glucocorticoids or glucocorticoids alone, there was no added benefit from cyclophosphamide. Regeneration of red blood cells was suppressed in cyclophosphamide-treated animals.

CHLORAMBUCIL

Chlorambucil (Leukeran) also is a nitrogen mustard and is sometimes used as a substitute for cyclophosphamide. It has a similar action as cyclophosphamide, but is one of the slowest-acting of the class of nitrogen mustards. Although little has been published on the clinical use of chlorambucil, it may be effective in dogs and cats for immune-mediated disease. However, direct comparisons to other immunosuppressive drugs has not been reported. One of the most frequent uses has been for treatment of immune-mediated skin diseases of cats. In one report, cats with pemphigus and eosinophilic granuloma complex (EGC) responded favorably with few side effects (Helton-Rhodes and Shoulberg 1992).

ADVERSE EFFECTS. Chlorambucil lacks some of the adverse effects of cyclophosphamide. This drug has been administered for months to years to people safely. The bone-marrow suppressing effects are only moderate, com-

pared to other nitrogen mustards, and are rapidly reversible. Chlorambucil has not caused cystitis, which is reported for cyclophosphamide.

CLINICAL USE. The usual dose in cats is 0.1 to 0.2 mg/kg, orally, q24h. The usual dose in dogs is 2–6 mg/m^2 q24h. After remission these doses are administered EOD. It is available as 2 mg tablets. The EOD dose may be given with oral prednisolone on alternate days.

THIOPURINES (AZATHIOPRINE)

As first-line therapy, or as an alternative to nitrogen mustard alkylating agents for treatment of immune-mediated disease, thiopurines are often administered. The most common of the thiopurines used for this purpose is azathioprine (Imuran).

MECHANISM OF ACTION. Despite the widespread use, little is known in dogs about its metabolism, risk of adverse reactions, and mechanism of immune-suppression (Rinkardt et al. 1999; Ogilvie et al. 1988). In people, azathioprine is rapidly and spontaneously metabolized to 6-mercaptopurine (6-MP). 6-mercaptopurine is further metabolized to 6-methylmercaptopurine nucleotides (6-MMPN) and 6-thioguanine nucleotides (6-TGN). (Fig. 46.3). Conversion to metabolites may occur at target cells responsible for immune effects because direct administration of 6-MP is not as effective as administration of azathioprine as a prodrug. 6-TGNs are the active cytotoxic metabolites. They are responsible for the bone-marrow toxicity, cytotoxic effects, and immunosuppression of lymphocytes (Stefan et al. 2004; Lennard et al. 1989). 6-MMPNs, on the other hand, are inactive metabolites, but can produce some adverse effects. As a consequence of the active metabolites, azathioprine interferes with lymphocyte proliferation because it inhibits de novo synthesis of purines, which is critically important for activated lymphocytes.

CLINICAL USE. In veterinary medicine, azathioprine is one of the most commonly administered drugs to suppress

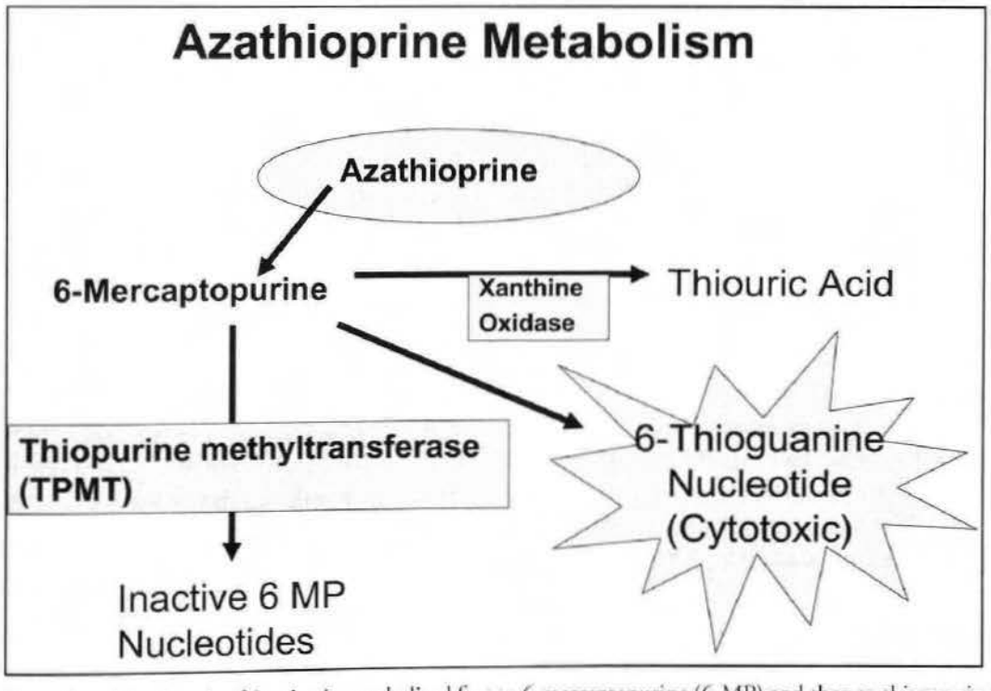

FIG. 46.3 Metabolism of azathioprine. Azathioprine is metabolized first to 6-mercaptopurine (6-MP) and then to thioguanine (6-TG) nucleotide metabolites, which produce the cytotoxic (immunosuppressive) activiy. 6-MP is also metabolized by the enzyme thiopurine methyltransferase (TPMT) to inactive metabolites. Individuals low in TPMT may have exaggerated toxic effects (myelosuppression), and individuals high in TPMT may have diminished therapeutic response. Drugs that inhibit xanthine oxidase (e.g., allopurinol) may also produce adverse effects.

immunity in dogs for treatment of dermatologic disease, immune-mediated hemolytic anemia, intestinal disease, and other immune-mediated diseases (Grundy and Barton 2001; Olivry et al. 2004; Hostutler et al. 2004; Weinkle et al. 2005).

Azathioprine is available as 50 mg tablets. It is dosed at 2 mg/kg, orally, q24h. Long-term therapy is administered at a dose of 0.5 to 1.0 mg/kg, every other day, with prednisolone administered on the alternate days. In cats, the doses are much lower, with 0.3 mg/kg being the safest (discussed below). In people there is a long lag-period before successful treatment is recognized with azathioprine, which may be as long as 2–8 months. In veterinary medicine this lag-period is probably shorter and therapeutic benefits have been observed after only 3–5 weeks, or less.

ADVERSE EFFECTS. Azathioprine myelotoxicity has been well documented in dogs (Rinkardt and Kruth 1996; Rodriguez et al. 2004). Leukopenia and thrombocytopenia can be serious. Animals that are treated with azathioprine should have the CBC monitored during therapy to identify the animals that may be at risk for toxicity and to adjust doses accordingly.

Gastrointestinal effects such as nausea and diarrhea may be only temporary and subside after several days of therapy. In people, elevated levels of 6-MMPNs are associated with hepatotoxicity (Stefan et al. 2004). Canine patients also have developed hepatic toxicity within 2–4 weeks after initiating azathioprine therapy. Signs of hepatopathy include liver enzyme increase and clinical signs that may result in discontinuation of treatment.

Long-term effects related to the immunosuppression produced by azathioprine include Demodex infection, recurrent pyoderma, and dermatophyte infections. Sterile hemorrhagic cystitis, the complication cited for cyclophosphamide, has not been seen with azathioprine. There has also been association (but not well documented) between the administration of azathioprine plus prednisolone and the development of acute pancreatitis in dogs. It has been suggested that this is caused by azathioprine's effect on decreasing pancreatic secretion in animals.

PROBLEMS IN CATS. Some veterinarians have administered azathioprine to cats at a total dose of about 6.25 mg per cat (1/8 tablet) EOD. However, doses of 2.2 mg/kg EOD produced profound neutropenia in cats (Beale et al. 1992). Although doses of 1.1 mg/kg every day, or every other day, for treatment of pemphigus have been administered to cats (Cacioloet al. 1984), other references have discouraged its use in cats because of the bone-marrow suppressing effects, even at this dose (Helton-Rhodes 1995). Differences in metabolism may explain the susceptibility in cats (discussed below under metabolism). Because of the concern for toxicity, if azathioprine is used, a recommended dose is 0.3 mg/kg once daily to every other day.

IMPORTANCE OF METABOLIC PATHWAY FOR DETERMINING TOXICITY. Azathioprine toxicity may have a genetic component. After azathioprine is converted to 6-MP, it is further metabolized by three routes to other metabolites. One metabolic route is via xanthine oxidase to inactive metabolites. Allopurinol will decrease this route because it inhibits xanthine oxidase. Another metabolic route is via thiopurine methyltransferase (TPMT), which is responsible for conversion to nontoxic 6-MP nucleotides. In people there is genetic polymorphism that determines high or low levels of TPMT. People with low TPMT activity are more responsive to therapy, but have a high incidence of toxicity (myelosuppression); people with high levels of TPMT activity have low incidence of toxicity but lower efficacy (Lennard et al. 1989). Most of the human population has high TPMT activity, but about 11% have low levels and are more prone to toxicity. In people with low TPMT activity, doses must be lowered.

In dogs, levels of TMPT also are highly variable. TPMT activity varied ninefold in a population of 177 dogs (Kidd et al. 2004). Another study with fewer dogs indicated 90% of dogs showing normal TPMT activity and 10% with low activity (White et al. 1998). The variation appears genetically determined, as it is in people. However, at this time, it is not clear whether low levels of TPMT in dogs represent a risk. In some dogs with a history of azathioprine associated myelotoxicity the animals had either intermediate or high levels of TMPT (Rodriguez et al. 2004).

Cats, as suspected because of their susceptibility to toxicity, have low TPMT activity (Foster et al. 2000). Therefore, cats are sensitive to the toxicity of azathioprine. If azathioprine is used in cats, dose should be much lower than in dogs.

MYCOPHENOLATE

Mycophenolate mofetil is metabolized to the active compound mycophenolic acid (MPA). T- and B-lymphocytes are critically dependent on de novo synthesis of purine nucleotides and mycophenolic acid is a potent inhibitor of inosine monophosphate dehydrogenate (IMPDH), an enzyme important for synthesis of purines in lymphocytes. Therefore it suppresses lymphocyte proliferation and decreases antibody synthesis by B-cells. It is available as a 250 mg capsule (CellCept). In people it is used as a replacement for azathioprine and has been primarily used for immune suppression in liver and kidney transplant patients. It is usually used in combination with glucocorticoids and/or cyclosporine.

CLINICAL USE. In dogs, mycophenolate has been used on a limited basis to treat some immume-mediated diseases. According to pharmacokinetic studies with mycophenolate in dogs, the elimination rate was rapid (half-life less than 1 hour), which may require frequent dosing in dogs to achieve successful results. For treatment of pemphigus foliaceous it was given at a dose of 22–39 mg/kg/day divided into three treatments. It was well tolerated, but only three out of eight dogs completed the study and were improved (Byrne et al. 2001). It has also been used to treat myasthenia gravis in dogs.

ADVERSE EFFECTS. The use has been uncommon and there are not many reports of adverse events in animals. In dogs, nausea, vomiting, and diarrhea have been observed, which appear dose-related.

DANAZOL

Danazol (Danocrine) is an androgenic agent that has been used for treating refractory patients with immune-mediated thrombocytopenia and immune-mediated hemolytic anemia. Its mechanism of action is not understood. It may interfere with antibody production, or interfere with the binding of complement or antibody to the platelet or red blood cell. It may also reduce receptors on monocytes for antibodies bound to platelets or red blood cells. It has been administered to dogs at a dose of 10 mg/kg q12h PO.

GOLD THERAPY (CHRYSOTHERAPY)

Drugs such as aurothioglucose (Solganal) have been used to treat some immune-mediated diseases, but its use in veterinary medicine has diminished considerably. In people, its most common use is for rheumatoid arthritis. It was originally used in the 1800s to treat tuberculosis. The exact mechanism of action is unknown but it may exert the immunomodulating through its effects on T-lymphocyte cell-mediated immunity or via inhibition of sulfhydral enzyme systems. There also may be an antiinflammatory effect on macrophages and neutrophils. A disadvantage of gold therapy is that it must be administered IM (usually once/week) and it may take several weeks for positive effects to occur. For example, in people, aurothioglucose has an onset of action of 6–8 weeks; in dogs this may be as long as 6–12 weeks.

AVAILABLE DRUGS. Gold therapy—referred to as chrysotherapy in some textbooks—includes various formulations of gold. Older formulations no longer exist commercially. Gold sodium thiomalate (Myochrysine) is available as 25 or 50 mg/ml injection in sesame oil. Aurothioglucose (Solganal) is a 50 mg/ml injection in an aqueous formulation. Oral treatment uses auranofin (Ridaura), which is available in 3 mg capsules.

CLINICAL USE. Controlled studies are lacking in veterinary medicine and case reports of successful therapy in the veterinary literature are lacking. The most common use is treatment of immune-mediated dermatologic disease unresponsive to corticosteroids alone, or in cases in which one wishes to decrease the patient's reliance on corticosteroids.

DOSES. Usually a 1 mg test dose is administered or 5 mg to larger canine patients. Doses are administered once/week until remission, and usually maintenance doses are in the range of 1–2 mg/kg every 2–4 weeks. Auranofin, an oral drug, is reported to have less efficacy in animals than injectable formulations and is not often used.

ADVERSE EFFECTS. The adverse effects are described in people, in which there is a 10–50% incidence, but they

are not well documented in animals. Reported adverse effects include dermatitis (which could be confused with the underlying problem being treated), nephrotoxicity, and blood dyscrasias. When administered to animals it is recommended to monitor CBC periodically to detect drug-induced problems. Diarrhea has been reported with the oral product. In pregnant animals these drugs should not be used. They cause abortion and fetal resorption or congenital malformations in laboratory animals.

DAPSONE

Dapsone is a sulfone, which shares chemical properties with sulfonamides. It has been in use for over 50 years in human medicine. It has been used in combination with other drugs to treat leprosy in humans caused by *Mycobacterium leprae*. Other uses include prophylaxis for malaria and treatment of *Pneumocystis carinii* infections in AIDS patients. The dermatological uses include treatment of dermatitis herpetiformis, SLE, pemphigoid, subcorneal pustular dermatosis and other inflammatory dermatoses.

MECHANISM OF ACTION. For treating leprosy, dapsone acts as a folate antagonist, similar to sulfonamides. For other conditions, the mechanism is unknown, but its action appears to be attributed to a suppression of neutrophil function (Booth et al. 1992). It may suppress respiratory burst in inflammatory cells.

PHARMACOKINETICS. Similarities in metabolism to the sulfonamides are expected. It is highly absorbed with a long elimination half-life of 11–13 hrs in experimental dogs. Comparison of metabolic pathway between dogs and people and between cats and people may explain susceptibility to toxicity (see discussion of adverse effects below). In people, one pathway for metabolism is acetylation (N-acetylation). The other metabolite in people is a hydroxylamine metabolite (N-hydroxylation). This hydroxylamine metabolite is responsible for adverse effects caused by dapsone, such as methemoglobinemia (Helton-Rhodes et al. 1992). Dogs cannot acetylate drugs and a pattern of metabolism of sulfonamides has been identified in dogs that indicates that this lack of acetylation may account for a greater accumulation of toxic metabolites and increased risk of adverse effects. The same metabolic fate may explain the risk of adverse effects from dapsone in dogs.

CLINICAL USE IN ANIMALS. In animals dapsone has been used for feline leprosy, although efficacy for this disease is uncertain. In dogs, it has been used for dermatologic conditions characterized by vascular disorders, inflammatory skin disease, immune-mediated disease, and subcorneal pustular dermatosis. Since specific studies have not been performed, doses are extrapolated from humans or based on empiricism. Doses listed in textbooks are in the range of 1 mg/kg once, twice, or three times daily. It is available in 25 and 100 mg generic tablets.

ADVERSE EFFECTS. The adverse effects in animals are not well documented, but can be severe enough to discontinue therapy. In people, dapsone causes agranulocytosis, aplastic anemia, methemoglobinemia, and blood dyscrasias. Toxic dermatological reactions (e.g., toxic epidermal necrolysis) may occur. Because of the similarity to sulfonamides, do not administer to animals sensitive to sulfonamides. Since some dogs may have an inability to detoxify the hydroxylamine metabolite, this could possibly lead to a higher risk of toxicity. Cats are reported to be susceptible to hepatitis and blood dyscrasias. In people, one of the metabolites responsible for toxicity is excreted as a glucuronide metabolite. Cats may be unable to rapidly glucuronate this metabolite, which may increase a cat's risk of toxicosis compared to other animals.

ANTIEMETIC DRUGS

NEUROTRANSMITTERS INVOLVED IN VOMITING.

Several neurotransmitters are important for stimulating vomiting (Table 47.1) and successful therapy involves blocking one or more of the receptors for these neurotransmitters. There are differences between dogs and cats with respect to importance of various receptors, and there are also differences between dogs, cats, and people. Dogs respond readily to administration of apomorphine, which is an

TABLE 47.1 Neurotransmitters important in vomiting

- Dopamine (type 2)
- Histamine (H_1)
- Serotonin (5-HT)
- Acetylcholine (muscarinic type 1)
- Substance P (Neurokinin NK-1)

agonist for dopamine. Cats vomit more readily from stimulation of α_2-adrenergic receptors than dogs, and respond more consistently to administration of xylazine. Histamine seems to be a more important neurotransmitter in the chemoreceptor trigger zone (CRTZ) of dogs than cats, and it is a more potent stimulant in people than in dogs. These differences and overlapping effects of neurotransmitters can be confusing, but some generalities are as follows.

In the emetic center (vomiting center), serotonin (5HT), histamine (H_1), acetylcholine (muscarinic M_1), serotonin ($5\text{-}HT_3$), dopamine (D_2), and neurokinin (NK-1) all play some role, although the importance may vary among species.

In the CRTZ, dopamine, serotonin, and acetylcholine (muscarinic) all play a role. Histamine is important in dogs, but less so in cats. Drugs that block dopamine can be effective antiemetics from stimulation of the CRTZ in most animals.

In the vestibular apparatus (motion sickness) acetylcholine (muscarinic receptor) and histamine (H_1) are important. Serotonin and adrenergic receptors also may play a role. Anticholinergic drugs (e.g., scopolamine) and antihistaminic drugs (e.g., diphenhydramine) can produce an antimotion sickness, antiemetic effect in people, but are less effective in dogs.

Afferents from the gastrointestinal system may mediate vomiting. Cancer drugs (e.g., cisplatin) injure the GI tract and release serotonin ($5\text{-}HT_3$). Cancer drugs also may stimulate the CRTZ directly.

Neurokinin (Substance P, NK-1) is a recently described neurotransmitter that stimulates vomiting from several sources. NK-1 receptors are found in the emetic center and the CRTZ, but the most important are those receptors in the emetic center. Drugs described as NK-1 receptor blockers (e.g., maropitant, aprepitant) block vomiting from several sources.

Efferents from the emetic center trigger the sequence of events that is familiar: nausea, abdominal contraction, stomach contraction, and vomiting.

TABLE 47.2 Antiemetic drugs and doses

ANTIHISTAMINES	
diphenhydramine (Benadryl)	2–4 mg/kg, IM, PO, q8–12h
dimenhydrinate (Dramamine)	4–8 mg/kg, PO, q8–12h
promethazine (Phenergan)	0.2–0.4 mg/kg, PO,IM, q8h
PHENOTHIAZINES	
chlorpromazine (Thorazine)	0.5 mg/kg, IM,PO,q6–8h
prochlorperazine (Compazine)	0.1–0.5 mg/kg, IM, q6–8h
Acepromazine	0.1 mg/kg, IM, PO, q12h
trifluprornazine (Vesprin)	0.1–0.3 mg/kg, IM, PO, q8–12h
trifluperazine (Stelazine)	0.03 mg/kg, IM, q12h
triethylperazine (Torecan)	0.13–0.2 mg/kg, IM, q8–12h
metoclopramide (Reglan)	0.1–0.3 mg/kg, IM, PO, q12h
ANTICHOLINERGIC DRUGS	
Atropine	0.02–0.04 mg/kg, IM,SC, q8–12h
methscopolamine (Pamine)	0.3–1.0 mg/kg, PO, q8h
isopropamide (Darbid)	0.2–1.0 mg/kg, PO, q12h
ANTISEROTONIN DRUGS	
ondansetron (Zofran)	0.5 to 1.0 mg/kg, IV or oral 30 min prior to administration of cancer drugs. For vomiting from other causes, 0.1–0.2 mg/kg slow IV injection and repeated every 6–12h to control vomiting.
NK-1 RECEPTOR BLOCKERS	
Aprepitant (Emend, human drug)	1 mg/kg PO, q24h.
Maropitant (Cerenia)	1 mg/kg SC, q24h, 2 mg/kg oral q24h or 8 mg/kg oral (for prevention of motion sickness).

PHENOTHIAZINE TRANQUILIZERS. Dopamine is one of the neurotransmitters in the emetic center and CRTZ for stimulating vomiting. Phenothiazine tranquilizers such as chlorpromazine (Thorazine®), prochlorperazine (Compazine®), promethazine, and acepromazine antagonize stimulation from dopamine in the CNS (Table 47.2). In addition to the antidopamine effects, these drugs can block alpha-adrenergic receptors (α_1) in the emetic center. Some phenothiazines also block the histaminic and muscarinic (M_1) receptors. Because of this broad action, and ability to inhibit vomiting from a variety of stimuli, this group of drugs has been called "broad-spectrum" antiemetics. Their side effects may limit clinical use in some patients. These side effects include sedation, altered involuntary motor activity (extrapyramidal signs), and peripheral α-adrenergic receptor blockade (vasodilation).

ANTIMUSCARINIC DRUGS. Drugs that block muscarinic receptors (muscarinic M_1-receptor) include atropine, scopolamine, aminopentamide (Centrine®), and isopropamide (isopropamide is combined with prochlorperazine in Darbazine®) (Table 47.2). These drugs decrease vomiting from various causes, including vomiting caused by vestibular stimulation (motion sickness) and stimulation of the CRTZ. In people, scopolamine has been one of the most effective agents for treating motion sickness (Transderm-Scop®), but it is less effective in dogs and cats. The adverse effects of anticholinergic drugs include xerostomia, decreased stomach emptying, ileus, urine retention, and constipation. These drugs should be used cautiously in patients with glaucoma because there is a risk of increased intraocular pressure. Scopolamine has produced excitement in animals, particularly cats.

ANTIHISTAMINIC DRUGS. The histamine H_1- and H_2-receptor is involved in transmission of vomiting. Histaminic nerve transmission stimulates vomiting from the CRTZ and vestibular apparatus, but apparently this effect is more prominent in dogs than cats. Antihistamines also can produce antimuscarinic (atropinelike) effects as well. Some of the phenothiazine drugs also act on histamine receptors and there is some crossover between these drug groups. Antihistamine drugs administered to control vomiting include diphenhydramine (Benadryl®), dimenhydrinate (Dramamine®), promethazine (Phenergan®, a phenothiazine with antihistamine effects), and cyclizine, (Marezine®) (Table 47.2). Diphenhydramine is the active component of dimenhydrinate. Histamine and antagonists are covered in more detail in Chapter 16.

Adverse Effects. The antihistamines are relatively safe drugs. The most significant side effect of therapy is sedation, but this usually is not undesirable in most patients being treated for vomiting. Sedation occurs because the H_1-receptor regulates sleep-wake cycles. The ethanolamines (diphenhydramine and dimenhydrinate) have the greatest sedative effects. Paradoxically, some of the antihistamines have caused excitement in cats.

METOCLOPRAMIDE (REGLAN®). This drug is also discussed later in the section on prokinetic drugs.

Metoclopramide has antiemetic effects via three mechanisms:

1. Metoclopramide (at low doses) inhibits dopaminergic (D_2) transmission in the CNS, similar to phenothiazines.
2. Metoclopramide has peripheral effects on the GI tract that increase emptying of the stomach and upper duodenum.
3. Metoclopramide (at high doses) inhibits serotonin (5-HT_3) receptors.

5-HT_3 stimulates vomiting in dogs and cats either in the CRTZ or vagal afferent neurons. Metoclopramide is a broad-spectrum antiemetic that has gained popularity in small animal medicine, particularly for animals that vomit because of drug therapy (e.g., cancer drugs). However, for control of vomiting caused by cancer drugs the results have often been disappointing (Fukui et al. 1992).

Pharmacokinetics. There is large variability in the pharmacokinetics of metoclopramide in dogs. The half-life has ranged from about 100 to 190 minutes; the systemic availability of an oral dose is only about 50%.

Adverse Effects. Metoclopramide is a dopamine antagonist and at high dosages it can produce adverse reactions that are similar to those caused by phenothiazine drugs. Adverse CNS effects from metoclopramide include excitement and behavior changes. To produce adequate antiemetic effects from blocking 5-HT receptors, often high doses are needed that increase the risk of extrapyramidal CNS effects attributed to central dopamine (D_2) antagonism.

The increase in GI motility may produce some abdominal discomfort. Because metoclopramide stimulates upper GI motility, it should not be administered if there is an obstruction. Metoclopramide produces transient endocrine changes, including an increase in prolactin.

SEROTONIN ANTAGONISTS. Specific serotonin antagonists include ondansetron (Zofran), granisetron (Kytril), palonosetron (Aloxi), and dolasetron (Anzemet). New drugs in development include tropisetron and azasetron. Of these, *ondansetron* (Zofran®) is the best known of the specific serotonin (5-HT_3) inhibitors. It is most often used as an antiemetic in cancer chemotherapy. The drugs in this group are expensive to use in veterinary patients, but have nevertheless been used to prevent vomiting associated with cancer drugs and from other

gastrointestinal diseases. The doses used are 0.5 to 1.0 mg/kg, IV or oral 30 min prior to administration of cancer drugs. Serotonin and antagonists are covered in more detail in Chapter 16.

As mentioned above, metoclopramide at high doses of 1–3 mg/kg can act as a serotonin antagonist and have been used as an IV infusion during cancer chemotherapy to decrease vomiting. As mentioned above, side effects are more likely at these high doses.

GLUCOCORTICOIDS. Glucocorticoids such as dexamethasone have antiemetic properties, possibly by inhibiting prostaglandin synthesis. These drugs are used sometimes in addition to other drugs for decreasing vomiting, particularly when it is caused by cancer chemotherapy. Glucocorticoids are covered in more detail in Chapter 30.

CANNABINOIDS. Cannabinoids have been used in people who have not responded to any other antiemetic drugs (e.g., patients that are receiving anticancer drugs). They have also been used to increase the appetite in patients with terminal disease, cancer, and AIDS. Their use has not been reported in veterinary patients, but they have been used by some veterinarians to increase the appetite in cats.

The site of action for cannabinoids is unknown, but there is some evidence that the active ingredients may affect opiate receptors, or they may affect other receptors in the emetic center. Synthetic marijuana (THC) is available as a prescription drug (dronabinol) for antiemetic therapy; it is marketed as Marinol®. Cannabinoids are relatively well tolerated in people, but side effects include drowsiness, dizziness, ataxia, and disorientation. Withdrawal signs may occur after abrupt discontinuation following repeated doses. For dronabinol, the oral absorption is good, but bioavailability is low due to high first-pass effects. The volume of distribution is very high.

Suggested doses for dronabinol (Marinol) in animals (but untested in clinical trials) are 5 mg/m^2, and increased as needed up to 15 mg/m^2 for antiemetic administration prior to chemotherapy. For appetite stimulation in animals, doses start at 2.5 mg before meals. It is available as 2.5, 5, and 10 mg capsules.

NK-1 RECEPTOR ANTAGONISTS. The neurotransmitter neurokinin-1 (NK-1, also known as Substance P) has several functions (Table 47.3). A new class of antiemetics was approved for use in people for cancer chemotherapy-induced vomiting. Aprepitant (Emend) was the first substance P/neurokinin-1 (NK-1) receptor antagonist (Dando and Perry 2004). It is used primarily with drugs known to be highly emetic, such as cisplatin. This drug is effective because chemotherapy drugs release substance P, which is highly emetic. Other standard treatments for chemotherapy-induced vomiting are dexamethasone plus ondansetron. The cost of one dose of aprepitant is approximately $100 per day. The use of NK-1 receptor antagonists such as aprepitant in dogs was primarily experimental until recently (Wu et al. 2004; Watson et al. 1995; Huskey et al. 2004; Fukuda et al. 1999; de la Puente-Redondo et al. 2007; Vail et al. 2007). In 2007, a new member of this class was approved for use in animals. Maropitant (Cerenia) was registered for use in dogs. It is available as a 10 mg/ml injection to be administered 1 mg/kg once daily SC for up to 5 days, or a tablet 16, 24, 60, or 160 mg to be administered at a dose of 2 mg/kg per day, PO, for up to 5 days. The tablet can also be used to prevent vomiting caused by motion sickness (vestibulitis) at a dose of 8 mg/kg for up to 2 days. The available research has shown maropitant to be an effective antiemetic for a variety of stimuli, including cisplatin (chemotherapy)-induced vomiting, copper sulfate and apomorphine-induced vomiting, motion sickness, and ipecac-induced vomiting (Table 47.4).

TABLE 47.3 Function and location of NK-1 receptors

- Regulates vascular tone
- Regulates vascular permeability
- Respiratory tract—regulates mucus production and bronchial tone
- Tachycardia
- CNS: Locomotor activity, grooming in cats, aggression in cats
- Emetic center

TABLE 47.4 NK-1 receptor blocker (maropitant) effective for vomiting caused by

- Pancreatitis
- Enteritis (dietary indiscretion)
- Cisplatin
- Copper sulfate
- Apomorphine
- Ipecac
- Parvovirus enteritis

The efficacy of maropitant is attributed to its central site of action. It blocks neurokinin-1 (NK-1) receptors in the area of the brain called the *nucleus tractus solitarius*—the site known as the *emetic center*. Input into the emetic center may come from different sources: gastrointestinal tract, higher brain centers, chemoreceptor trigger zone (CRTZ), and vestibular apparatus (motion sickness). These inputs also utilize a variety of neurotransmitters: dopamine, histamine, acetylcholine, and serotonin. Traditionally, to block emesis from these stimuli, multiple drugs may be needed: antihistamines, antidopamine drugs (e.g., metoclopramide), dopamine antagonists (e.g., phenothiazines), and serotonin antagonists (e.g., ondansetron). Because NK-1 inhibitors—such as maropitant—block input from multiple sources regardless of the input *they are considered broad spectrum* in action.

In clinical and research trials, maropitant has been effective to treat and prevent chemotherapy-induced vomiting in dogs (Vail et al. 2007; de la Puente-Redondo 2007; Benchaoui et al. 2007) and a wide range of stimuli such as viral disease, food and toxin ingestion, enteropathy, and other diseases (de la Puente-Redondo et al. 2007). It was more effective than metoclopramide in this trial.

Pharmacokinetics. Maropitant is extensively metabolized by the liver and there is little clearance by the kidney. No dose adjustments are necessary in patients with compromised renal function. Absorption from SC administration is rapid and complete (91% absorption), but oral absorption is limited by the first-pass metabolic effects (24% at 2 mg/kg and 37% at 8 mg/kg) (Benchaoui et al. 2007). The half-life is 7.75 hours and 4–5.5 hours after SC and oral administration, respectively. However, the effects persist for at least 24 hours after a dose, presumably because of binding to the CNS NK-1 receptor that maintains the drug at the site of action. Penetration across the blood-brain barrier has been demonstrated (de la Puente-Redondo 2007), which is necessary for activity in the emetic center.

Adverse Effects. There are NK-1, -2, and -3 receptors throughout the body. Maropitant has little binding affinity to NK-receptors, other than NK-1; it also does not bind to other CNS receptors such as GABA-, opiate-, adrenergic-, serotonin-, histamine-, muscarinic-, or dopamine-receptors. Although NK-1 receptors are involved in a large number of other physiologic and behavioral responses, at doses used for antiemesis in dogs, there were no adverse effects associated with these other functions.

Compared to other antiemetic drugs, maropitant has had a good safety profile. No clinically significant adverse events have been reported in the clinical trials with maropitant conducted in dogs thus far. Maropitant studies in cats have not been reported.

GASTROINTESTINAL PROKINETIC DRUGS

Prokinetic drugs are drugs that increase gastrointestinal motility. For a review of conditions in which prokinetic drugs are used, see Washabau and Hall (1997).

METOCLOPRAMIDE, (REGLAN®, MAXERAN®). Metoclopramide has multiple actions. It is a dopamine (D_2) antagonist, serotonin (5-HT_4) agonist and serotonin (5-HT_3) antagonist. Among the proposed mechanisms of metoclopramide is an increase in the release of acetylcholine in the GI tract, possibly via a prejunctional mechanism. It also may increase motility of gastric smooth muscle by increasing sensitivity of the cholinergic response. Since it also is a dopamine antagonist, it may antagonize dopamine's (D_2) inhibitory action on GI motility.

Metoclopramide increases gastric emptying, increases the tone of the esophageal sphincter, and stimulates motility of the duodenum. It has less effect on distal segments of the intestine. Metoclopramide acts centrally to inhibit dopamine in the CRTZ, which is responsible for antiemetic effects. In people, metoclopramide also has been used to treat hiccups and lactation deficiency.

Side effects from metoclopramide are related to CNS effects. They can include excitement (seen in horses, for example), anxiety, and involuntary muscle movements. There are also endocrine effects: There is a transient increase in prolactin and aldosterone. *Since some breast cancers are prolactin-dependent, there has been some concern about the carcinogenicity of this drug in women.*

Use in Small Animals. In dogs metoclopramide has been used as an antiemetic more commonly than other

drugs. Although it has been used to promote GI motility as well, this effect is less established than previously thought. For example, it is of little benefit to increase stomach emptying in disorders of gastroparesis or chronic regurgitation. It also has been used to stimulate normal upper motility following surgery (e.g., corrective surgery for gastric dilatation), but one study showed that metoclopramide did *not* change gastric motor activity to promote gastric emptying in dogs with gastric dilatation volvulus (GDV) (Hall et al. 1996). In another study, it reduced, but did not prevent gastroesophageal reflux in anesthetized dogs at a dose of 1 mg/kg (Wilson et al. 2006). Doses are in the range of 0.25 to 0.5 mg/kg, q8–12h, but they have been increased to 1–2 mg/kg.

Use in Large Animals. The clinical use of metoclopramide in large animals has not been as common as in small animals. Metoclopramide has little usefulness in cattle, although it may increase the motility of the rumen in cattle and sheep. It has been used successfully in some cattle with functional pyloric stenosis (Braun et al. 1990), but was not effective in calves (0.1 mg/kg IM). At doses higher than 0.1 mg/kg in calves it caused severe neurologic side effects (Wittek and Constable 2005).

Use in Horses. Some equine surgeons have used infusions of metoclopramide (0.125–0.25 mg/kg/hr) added to IV fluids to reduce postoperative ileus in horses (Gerring and Hunt 1986). It may stimulate small intestine—but not large bowel—motility, but this has little benefit for horses with intestinal ileus (Sojka et al. 1988). Undesirable side effects in horses have been common, and include behavioral changes and abdominal pain. Since this drug transiently increases prolactin secretion, there has been interest in using this drug for treating agalactia in animals, but efficacy has not been determined.

DOMPERIDONE (MOTILIUM, EQUIDONE). Domperidone has been available as a 10 mg tablet outside the U.S. as a prokinetic drug. Its mechanism of action and GI prokinetic effects are similar to metoclopramide, but its efficacy has not been very impressive in animals. A difference between metoclopramide and domperidone is that the latter does not cross the blood-brain barrier. Therefore, adverse CNS effects are not as much of a problem compared to metoclopramaide in horses. It may have antiemetic properties, but only if the receptor blocked is associated with with the CRTZ. The CRTZ in the area postrema of the brain is not protected by the blood-brain barrier.

Use in Small Animals. The use is not reported, but a suggested dose is 2 to 5 mg/animal.

Use in Horses. Domperidone has been investigated for use in horses to treat fescue toxicity and agalactia. Fescue toxicosis is caused by a fungus that produces a toxin that induces reproductive problems in horses. The action of domperidone to increase lactation is through the stimulation of prolactin. Although not yet registered for use by the FDA, the equine formulation of domperidone, Equidone oral gel, 11%, is listed "for prevention and treatment of fescue toxicosis and related agalactia in periparturient mares." The dose administered to horses is 1.1 mg/kg, daily PO, starting 10 days before the scheduled foaling date. (This dose is equivalent to 5 ml per 500 kg—5 ml per horse—daily, PO of the 11% oral gel.) Administration should continue until foaling. If there is not adequate milk production after foaling, continue for 5 additional days. Do not administer with stomach antacids such as omeprazole, cimetidine, or antacids.

CISAPRIDE. In July 2000, cisapride (formerly called Propulsid®) was removed from the market because of serious cardiac adverse events, and some deaths in people. The effect is caused by cardiac arrhythmias. The drug sponsor has no plans to market this drug to veterinarians, but there is continued interest among veterinarians and it is still available via compounding pharmacists. Until other new replacement drugs become available, such as prucalopride, veterinarians will rely on compounded formulations or consider alternative drugs.

The reviews by Washabau and Hall (1995) and Van Neuten (1992) describe the details of its mechanism of action and clinical effects. Cisapride has greater prokinetic effects in comparison to the other drugs discussed thus far. Its mechanism is believed to be as an *agonist* for the 5-hydroxytryptamine (5-HT_4) receptor on myenteric neurons (5-HT_4 ordinarily stimulates cholinergic transmission in the myenteric neurons). (Serotonin and antagonists/agonists are covered in more detail in Chapter 16.) However, cisapride may also be an *antagonist* for the 5-HT_3 receptor. Via these mechanisms—or independently—cisapride may enhance release of acetylcholine at the myenteric plexus. There is evidence that, in cats, cisapride

directly stimulates smooth muscle motility via an unknown noncholinergic mechanism (Washabau and Summarco 1996). Cisapride increases the motility of the stomach, small intestine, and colon. It accelerates the transit of contents in the bowel and intestines.

Pharmacokinetics. Oral absorption is variable because of extensive metabolism. The oral absorption in dogs and cats ranges from 30–60%. In horses, rectal absorption has been attempted, but the amount absorbed systemically is negligible (Cook et al. 1997).

Elimination half-life is variable, but ranges from an average of approximately 5 hours in dogs and cats to a much faster rate in large animals—2 hours or less in horses and ruminants. The volume of distribution is high in small animals (>4 l/kg) and approximately 1.5 l/kg in large animals.

Use in Dogs. In dogs at a dose of 0.1 mg/kg (range 0.08–1.25 mg/kg) orally, it stimulates the esophagus, stomach, small intestine, and colon, with a duration of effect of about 3 hours. Routine clinical doses have ranged from 0.1 to 0.5 mg/kg every 8–12 hours.

Clinical use in dogs has included treatment for gastroesophageal reflux, delayed gastric emptying, and small bowel motility disorders. Although cisapride has been used by some veterinarians for treatment of megaesophagus in dogs, the response is usually poor. The canine esophagus is striated muscle, with no smooth muscle to directly respond to the medication.

Use in Cats. Experiments have shown that cisapride will cause stimulation of the entire GI tract in cats. Of particular interest is the effect of cisapride on colonic smooth muscle. Cisapride will stimulate this motility and has been used for treating chronic constipation. By contrast, metoclopramide has no effect on colonic smooth muscle. The dose of cisapride in cats is approximately 2.5 mg per cat, two or three times daily. Doses as high as 1 mg/kg every 8 hours, or 1.5 mg/kg every 12 hours have been recommended by some investigators (LeGrange et al. 1997).

Use in Horses. In horses cisapride increases the motility of the left dorsal colon and improves ileocecocolonic junction coordination. In contrast to metoclopramide, cisapride has fewer side effects at doses needed to affect the GI tract and greater effects on the jejunum and colon than metoclopramide. Many investigators believe that it has a place in the postoperative management of horses that have undergone abdominal surgery. One dose tested to be effective was 0.1 mg/kg, IV. At this dose, the effects appear to persist for approximately 2 hours. Oral administration is usually not possible in these horses because of gastric reflux and absorption after oral administration in a horse with gastric reflux probably is questionable.

Availability of Formulations. The previously available tablet was a 10 mg tablet from Janssen Pharmaceutica. Although cisapride is insoluble in most aqueous solutions, solubility is possible in acidic solutions. An IV form may be created by preparing a 4 mg/ml solution in tartaric acid by a reputable compounding pharmacist. The preparation of this formulation was described in the publication by Cook et al. (1997). To prepare this solution, 40 mg of cisapride is combined with 1 ml of 0.4 M tartaric acid. After the cisapride is dissolved, dilute with water to obtain a total volume of 10 ml (Cook et al. 1997).

Oral formulations for cats have been prepared from the bulk powder administered in a capsule, via a suspension in a flavored vehicle or dissolved in cod liver oil.

Side Effects and Interactions. Adverse effects have not been reported in animals; however, abdominal discomfort has been observed when animals received high doses. In safety studies, dogs have tolerated high doses (40 mg/kg) for prolonged periods without problems.

In people, high plasma concentrations have caused cardiac arrhythmias. The arrhythmias are caused by prolonged QT intervals, presumably from blockade of potassium channels. This can lead to serious arrhythmias and has been responsible for deaths in people. These reactions have not been reported for animals. Nevertheless, one should be cautious about combining cisapride with drugs such as itraconazole and ketoconazole that may increase plasma concentrations by interfering with metabolism.

TEGASEROD (ZELNORM). Tegaserod use in animals has not been reported. It was removed from the human market in April 2007. It was used as a motility modifying drug to treat irritable bowel syndrome. Its action is believed to be similar to that of cisapride—a partial agonist of serotonin (5-HT_4)—but it has little effect on HT_3 or dopamine receptors. After stimulating 5-HT_4 receptors it stimulates coordinated motility by stimulating other

neurons and release of other mediators. It increases gastric emptying and small bowel transit. The dose in people was 6 mg twice daily.

BETHANECHOL (URECHOLINE). Many of the formulations of bethanechol have been discontinued and are no longer marketed. Some generic forms may still remain and veterinarians have also obtained it through compounding pharmacies. This drug is a cholinergic agonist that has been used to nonspecifically stimulate smooth muscle. It binds to muscarinic receptors and initiates GI smooth muscle contractions, but its actions are nonspecific. In contrast to cisapride or metoclopramide, bethanechol has a more pronounced effect on motility of the ileocecocolic region in cattle (0.7 mg/kg). In horses, bethanechol increases gastric emptying at a dose of 0.025 mg/kg IV (Ringger et al. 1996). One of its other uses has been to stimulate contraction of bladder smooth muscle in animals that have a failure to completely empty their urinary bladder when voiding. Adverse effects are common and include diarrhea and other consequences of cholinergic stimulation.

NEOSTIGMINE (PROSTIGMIN). Neostigmine inactivates the enzyme acetylcholinesterase, which results in inhibition of degradation of acetylcholine at the synapse. It prolongs the action of acetylcholine and may directly stimulate cholinergic receptors. It is short acting. In horses, its use is discouraged because it may actually decrease intestinal propulsive contractions, delay gastric emptying, and cause abdominal discomfort.

One of the other uses of neostigmine in animals is for the treatment of neuromuscular diseases such as myasthenia gravis. Its adverse effects are significant, and include diarrhea, salivation, respiratory difficulty, vomiting, and muscle twitching. (Usually, another anticholinesterase drug, pyridostigmine is preferred for treating myasthenia gravis because it has fewer side effects.)

H_2-RECEPTOR ANTAGONISTS. H_2-receptor blockers such as ranitidine and nizatidine have prokinetic effects on intestinal smooth muscle in animals. These drugs are discussed later in the section on antiulcer drugs.

ERYTHROMYCIN. Erythromycin is a macrolide antibiotic widely used to treat bacterial infections. It has long been associated with vomiting and regurgitation in small animals as an adverse consequence of treatment. This effect on the stomach appears to be caused by stomach contraction and expulsion at high doses. But, at low doses, it can cause nonspecific stimulation of GI motility. Not all macrolide antibiotics exhibit this property because it requires a unique chemical structure that not all drugs in this class possess. In people erythromycin has been used to promote gastric motility and increase emptying in patients with diabetic gastroparesis. It also has been used in conjunction with enteral feeding in critical care patients (Hawkyard and Koerner 2007).

The action of erythromycin appears to be related to an increase in activation of motilin receptors, via release of endogenous motilin, or via cholinergic mechanisms in the upper GI tract (Hall and Washabau 1997; Lester et al. 1998; Hawkyard and Koerner 2007). (Antimicrobial details on erythromycin are covered in detail in Chapter 37.) Because most of the motilin receptors are on the stomach and proximal small intestine, responses to erythromycin may not be as profound in the distal GI tract. The dose that produces this effect in animals is in the range of 1 mg/kg or less—much lower than the antibacterial dose. In calves, doses of 8.8 mg/kg IM increased rumen motility (Wittek and Constable 2005). It was effective for stimulating motility in horses (Ringger et al. 1996) and has been examined for clinical indications, such as stimulating gastric emptying and increasing intestinal motility.

Clinical responses to erythromycin in horses have been somewhat disappointing. One study showed that responses to erythromycin in horses that had undergone surgery were different from horses that were healthy (Roussel et al. 2000). Therefore, clinical responses may not be as great in horses with motility problems as they are in normal horses. There is a concern that erythromycin may cause diarrhea in some horses through the effect on the normal bacterial flora of the intestine. An additional concern is that routine use may promote resistance.

LIDOCAINE. Lidocaine is a well-known local anesthetic. (Local anesthetics are covered in more detail in Chapter 14.) It is used for local infiltration for minor surgical procedures and to treat cardiac arrhythmias. Intravenous infusions of lidocaine also improve intestinal motility in horses (Table 47.5). Lidocaine has been used in horses

TABLE 47.5 Action of lidocaine on GI tract

- Suppresses transmission of sympathetic tone
- Prevents sympathetic reflexive spinal and peritoneal inhibition of sympathetic stimulation
- Produces direct excitatory effects on smooth muscle of intestine
- Suppresses centrally mediated hyperalgesia
- Antiendotoxin and antiinflammatory effects

TABLE 47.6 Antiulcer drugs: Clinical uses

- Gastritis
- Gastric ulcers
- Duodenal ulcers
- GI ulcer prevention
- Esophagitis
- Mast cell tumors
- Hypergastrinemic syndromes

postsurgically to reduce postoperative ileus. Postoperative ileus in horses is a widespread clinical problem that may be caused by 1) sympathetic stimulation, 2) pain, or 3) inflammation. These effects inhibit smooth muscle motility in the intestine and lidocaine may work by suppressing this transmission (see Table 47.5). Yet another view is that lidocaine does not have a direct prokinetic effect, but rather restores motility via other mechanisms (Cook and Bilkslager 2008). These authors presented evidence that in horses lidocaine restores motility by inhibiting intestinal inflammation and re-perfusion injury.

In one study (Malone et al. 2006) lidocaine administration to horses produced less reflux and shorter time of hospitalization. Infusions of lidocaine have decreased postoperative ileus either through a direct effect, or via suppression of painful stimuli. Doses in horses are 1.3 mg/kg loading dose (bolus), followed by 0.05 mg/kg/min IV infusion.

Adverse Effects. As with the other uses of lidocaine, systemic administration may produce adverse events. The most common in horses have been muscle fasciculations, ataxia, and seizures. If signs are observed, decrease rate of infusion.

NEW DRUGS TO PROMOTE INTESTINAL MOTILITY.

Mosapride is a 5-hydroxytryptamine-4 ($5\text{-}HT_4$) receptor agonist. It has been studied in experimental horses and demonstrated to increase motility of the small intestine and cecum at a dose of 1.5–2 mg/kg PO (Sasaki et al. 2005).

Newer approaches to treating postoperative ileus in animals has focused on blocking intestinal opiate receptors (μ-receptors). (Opiate drugs and antagonists are covered in more detail in Chapter 12.) It is well established that activation of opiate μ-receptors in the intestinal smooth muscle decreases propulsive motility. Expression of μ-opiate receptors has been found in the submucosal plexus, myenteric plexus, and longitudinal muscle of the ileum. This effect has been used to treat some forms of diarrhea with opiate-agonists (e.g., loperamide). (The role of opiates to treat diarrhea is discussed later in this chapter.) However, administration of opiate analgesics postoperatively (Boscan et al. 2006; Sojka et al. 1988), or increased levels of endogenous opioids (endorphins) stimulate these receptors to inhibit intestinal motility causing postoperative ileus (DeHaven-Hudkins et al. 2007). Opiate antagonists can restore motility to colonic intestine of ponies (Roger et al. 1985). However, use of naloxone will also cross the blood-brain barrier to diminish the analgesic effect of opioids.

Opioid antagonists are being explored for use, primarily to limit the adverse effects of opioids and pain on gastrointestinal motility. These agents are considered *peripheral* opioid antagonists, rather than *central* opioid antagonists. They do not produce a central effect because they are unable to cross the blood-brain barrier. Such agents include *alvimopan* and *methylnaltrexone*. They are being investigated to be used as therapeutic agents to treat gastrointestinal motility problems associated with opioid analgesic use as well as other stress or pain syndromes that cause a decrease in gastrointestinal motility (for example, postoperative ileus) (DeHaven-Hudkins et al. 2007; Taguchi et al. 2001). These agents are capable of restoring gastrointestinal motility, but preserving opioid-mediated analgesia. Methylnaltrexone is now registered for use in people (Relistor) as an injection. It is administered at a dose of 0.15 mg/kg SC, once every 24–28 hours. Alvimopan has advantages over methylnaltrexone with respect to potency and duration of activity.

DRUGS FOR TREATMENT OF GI ULCERS IN ANIMALS

Histamine H_2-receptor antagonists, sucralfate, proton pump inhibitors (omeprazole), and antacids remain the principal drugs used to manage gastrointestinal ulceration in small and large animals (Table 47.6; Fig. 47.1). The medical management of ulcer diseases will not be covered in this section, but readers are referred to other references for this information: The clinical description and treatment of ulcer disease in horses was thoroughly reviewed

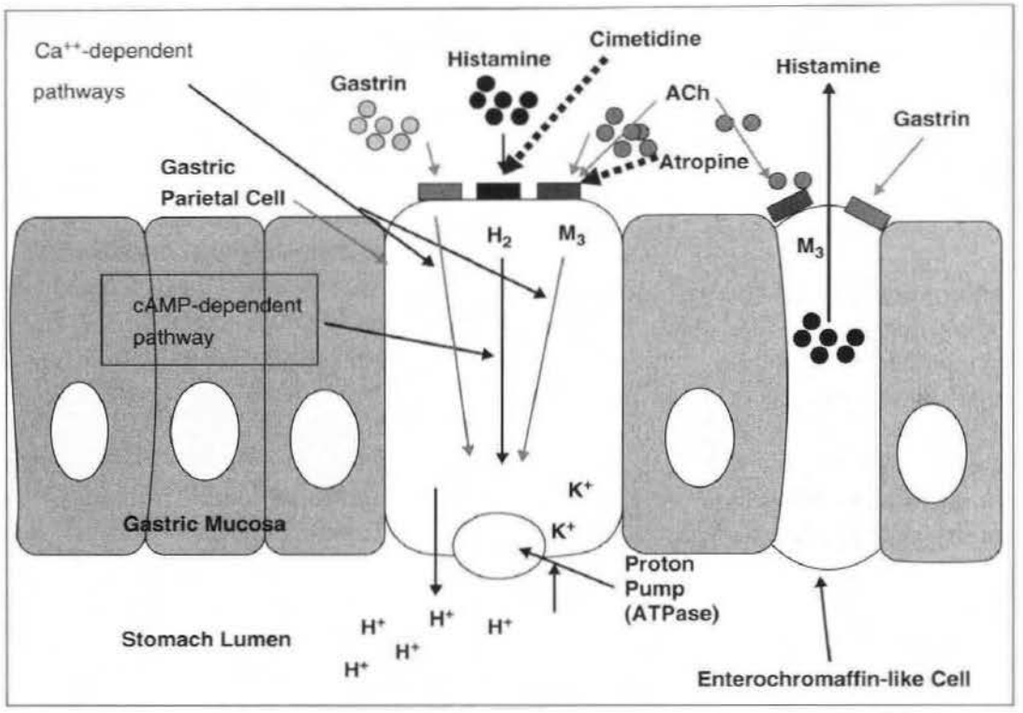

FIG. 47.1 Action of stomach antisecretory drugs. Action of H_2-receptor antagonists and proton pump inhibitors are shown. See text for details.

by Merritt (2003). Treatment in small animals was reviewed by Papich (1993) and Matz (1995). Two recent reviews on gastroprotection and ulcer treatment in dogs are available in the papers by Henderson and Webster (2006). A thorough review of H_2-receptor antagonists is found in the article by Feldman and Burton (1990).

Because many of the ulcerative diseases encountered in veterinary medicine are induced by drugs that inhibit prostaglandin synthesis (NSAIDs), one should be familiar with the role of prostaglandins in the GI tract, how their synthesis is inhibited, and treatments used to maintain the protective effect of prostaglandins in the GI tract. Veterinarians also should be familiar with the normal physiologic role of protective mucus layer in the stomach, the cytoprotective mechanisms, role of bicarbonate secretion, and the normal mechanisms that restore epithelial cells in the stomach and intestine. These factors were reviewed by Allen et al., (1993) several years ago, but are still relevant today. When these protective factors become disrupted or compromised, ulcers can occur in animals. Gastrointestinal ulcers are a major health problem in horses, pigs, dogs, cats, and zoo animals. Conditions that increase the risk of gastrointestinal ulceration are administration of ulcerogenic drugs (NSAIDs, corticosteroids, and stomach irritants), stress, disrupted mucosal blood supply, and inflammatory diseases.

Gastrointestinal ulceration is an important medical problem in horses, in which the prevalence in animals involved in showing and racing has been listed as 81–93% and as high as 100% in some studies. In Thoroughbreds and Standardbreds the prevalence is 80–95%; in show horses it may be as high as 58%. Factors such as stall confinement, intense exercise, diet (high energy concentration in diet), and racing stress may be factors. Location of ulcers in horses is primarily in the squamous epithelium (nonglandular portion). Factors that contribute to ulcers are the intermittent feeding schedule and high stomach acidity. In sick foals, ulcers are common. Factors that contribute to ulcers in foals are NSAIDs, stress, and sepsis.

ANTACIDS. The common antacids are bases of either aluminum, magnesium, or calcium. Examples include aluminum hydroxide, $Al(OH)_3$, magnesium hydroxide, $Mg(OH)_2$, and calcium carbonate, $CaCO_3$ (e.g., Tums). These drugs neutralize stomach acid to form water and a neutral salt. They have no systemic effects. In addition to

their acid-neutralizing ability, antacids may benefit patients by decreasing pepsin activity, binding to bile acids in the stomach, and stimulating local prostaglandin (e.g., PGE_2) synthesis.

Formulations. Commonly available antacid preparations (e.g., Maalox, Mylanta, DiGel) are combinations of magnesium hydroxide and aluminum hydroxide to optimize the buffering abilities of each compound. These combinations balance the adverse effects of constipation from aluminum hydroxide and the laxative effect from magnesium hydroxide.

Adverse Effects. Adverse effects are rare because they are seldom administered long-term. Additionally, antacids are not absorbed and therefore lack serious systemic effects. In animals with renal failure, magnesium accumulation may be a problem. Antacids will interfere with the oral absorption of other drugs (e.g., tetracyclines, fluoroquinolones, and digoxin), if administered concurrently.

Dosing Recommendations. Dose recommendations vary, but empirically, 5–10 ml six times daily for small animals is often cited, regardless of the animal's size or product used. Doses of 180 to 250 ml have been administered to adult horses, but only suppressed acidity for 45 min to 2 hours (Murray 1997). A dose of 30–60 ml for calves and foals has been recommended. For the treatment of acid rumen, magnesium hydroxide has been administered orally at a dose of 225–440 grams per adult cow, or mineral oil at 4 liters per rumen. For the treatment of grain overload, antacids have been administered at a dose of 450 grams per rumen, repeated every 6–8 hr.

HISTAMINE H_2-RECEPTOR ANTAGONISTS.

Blockade of H_2 receptors and subsequent inhibition of gastric acidity correlates with ulcer healing in the stomach and duodenum even though evidence—based on data generated from controlled studies—is lacking. The clinical impression among veterinarians indicates that cimetidine, ranitidine, and famotidine are beneficial for the treatment of gastric and duodenal ulceration, gastric erosions, esophageal reflux disease, and gastritis in animals. Drugs vary in their potency (Table 47.7) but all can effectively suppress stomach acid.

Mechanism of Action. Acid secretion is stimulated by three receptors: 1) gastrin receptor, 2) histamine type-2 (H_2 receptor), and 3) cholinergic (muscarinic) receptor (M_3). Stimulation of acid secretion occurs via stimulation of all three receptors. H_2-receptor antagonists (e.g., cimetidine, Tagamet®; ranitidine, Zantac®) effectively block gastric acid secretion from parietal cells by blocking the H_2-receptor.

TABLE 47.7 Potency of acid-suppressant drugs

Drug	Relative Potency
Cimetidine (Tagamet)	1
Ranitidine (Zantac)	4–10
Nizatidine (Axid)	4–10
Famotidine (Pepcid)	20–50

Use in Small Animals. Cimetidine at doses of 10 mg/kg (IV, IM, or orally) administered to dogs will suppress acid secretion for 3 to 5 hours. Because ranitidine has a longer half-life, it may not have to be administered as often as cimetidine. Ranitidine doses of 2 mg/kg (IV, IM, or orally) will suppress acid secretion for up to 8 hours. Famotidine (Pepcid®) has been used at 0.5 mg/kg every 12–24 hr, but doses of 0.1 to 0.2 mg/kg q12h are probably equally effective. Despite the availability of pharmacokinetic information, a precise dose interval for the drugs listed has not been established because the optimum duration or extent of acid suppression for ulcer healing to occur is not known.

Use in Horses. Suppression of gastric acidity in horses was reviewed by Murray (1997). These drugs are not absorbed orally in horses as well as in dogs (Duran and Ravis 1993), with a systemic availability of only 14 to 30%, and the high oral doses for large animals reflect this difference (Sams et al. 1997). Cimetidine is administered to horses at 40–60 mg/kg/day. Ranitidine is used in horses at a dose of 2.2 to 6.6 mg/kg q6–8h (Holland et al. 1997). In clinically normal foals, ranitidine at 6.6 mg/kg, PO, or 2 mg/kg IV suppresses acid secretion for 8 hours and 4 hours, respectively (Sanchez et al. 1998).

Use in Calves. Cimetidine and ranitidine have been used in calves to maintain the pH of the abomasum >3.5 for 75% of the dosing interval (Ahmed et al. 2001). Recommended oral doses are cimetidine 100 mg/kg q8h, or ranitidine 50 mg/kg q8h.

Adverse Effects. Generally, histamine H_2-receptor antagonists have a good safety record. Adverse effects reported in people include antiandrogenic effects, decreased reproductive performance, central nervous system toxicity, and bacterial overgrowth in the stomach. These effects are rare and have not been cited as a serious problem in veterinary patients. There have been anecdotal reports of famotidine injection producing hemolytic anemia in cats. However, the conclusion from a clinical study was that when administered IV over 5 minutes, there was not a risk (de Brito Galvao & Trepanier, 2008). Drug interactions are possible because cimetidine inhibits the clearance of other drugs via its action as a hepatic oxidation enzyme inhibitor (microsomal enzyme cytochrome P450 inhibitor). Ranitidine and others are less likely to cause such a reaction.

Other Effects of H_2-Receptor Antagonists. Histamine H_2-blocking drugs have been used for other conditions in addition to suppressing stomach acid. Some evidence suggests that cimetidine strengthens the gastric mucosal defenses against ulceration (e.g., increases bicarbonate secretion), and enhances cytoprotection, but the relationship of these effects to ulcer healing are not well understood.

Effects on Smooth Muscle Activity. Acid secretion inhibits stomach contractions. In experimental dogs, administration of cimetidine normalized the stomach contractions that were inhibited by stimulation of acid secretion in the stomach. Therefore, H_2-receptor antagonists may have a role in promoting an emptying of the stomach (Hayashi et al. 1990). In addition, ranitidine and nizatidine, but not cimetidine or famotidine, stimulate motility and increase gastric emptying and colonic motility via an anticholinesterase (AchE) action. Because of these motility effects, ranitidine has been used to stimulate GI motility as a prokinetic agent in animals. This has been more common after the prokinetic drug cisapride was withdrawn from the market. (Cisapride is discussed further earlier in this chapter.)

Immunologic Effects. Cimetidine can block H_2-receptors on suppressor T-lymphocytes, which increases lymphocyte responses to mitogen stimulation (Mavligit 1987). This effect has been applied clinically in the immunologic treatment of patients with tumors (Goetz et al. 1990), but the clinical benefit for most uses has been controversial. In people, the administration of cimetidine may accelerate healing of herpes lesions in immunocompromised patients.

Antiallergic Effects. Histamine H_2-blockers may decrease the effects of histamine on blood vessels, and may alleviate some inflammation due to allergy. However, when used as a sole treatment, the clinical response has not been encouraging. Ordinarily when antihistamine effects are desired for treating allergic conditions, histamine type 1 (H_1) antagonists are administered.

SUCRALFATE (CARAFATE®). Sucralfate dissociates in the acid milieu of the stomach to sucrose octasulfate and aluminum hydroxide (Fig. 47.2). Sucrose octasulfate polymerizes to a viscous, sticky substance that creates a protective effect by binding to ulcerated mucosa. It protects the mucosa by preventing back diffusion of hydrogen

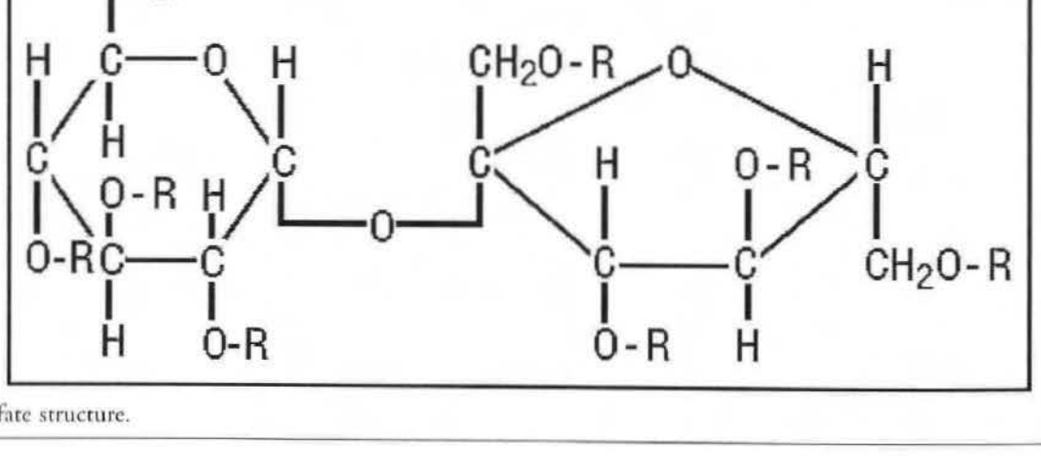

FIG. 47.2 Sucralfate structure.

ions and also inactivates pepsin and adsorbs bile acid. Additionally, sucralfate increases the mucosal synthesis of prostaglandins, which has a cytoprotective role and may promote healing. Increase in the epidermal growth factor may contribute to ulcer healing.

Clinical Use. Sucralfate has been used for the prevention and treatment of gastric and intestinal ulceration and gastritis in both small and large animals. Some veterinarians have used it to prevent or treat ulcers associated with NSAIDs. Despite this common use, there is little evidence of its efficacy for preventing NSAID-induced ulcers. Because sucralfate is not absorbed, it is virtually free of adverse effects. The most common side effect associated with its use in people has been constipation. Dosage regimens for sucralfate have been extrapolated from human dosages. Doses administered are as follows: 250 mg (one-quarter tablet) to cats two to three times daily, 500 mg to 1 gram to dogs, and 4 gm orally to foals.

Drug Interactions. Even though sucralfate has some "coating action," this does not prevent oral absorption of drugs from the intestine. However, sucralfate contains aluminum and may interfere with absorption of some drugs. For example, aluminum will chelate fluoroquinolone and tetracycline drugs and prevent absorption.

PROTON PUMP INHIBITORS (PPI). The proton pump inhibitors (PPI) inhibit the H^+/K^+ proton pump (H^+/K^+ ATP-ase) at the luminal surface of the parietal cell that secretes hydrogen ions into the stomach lumen. The most commonly used drug in this class is omeprazole (Prilosec, GastroGuard, UlcerGuard), which was registered for humans in 1989 and more recently for horses. Other drugs available are listed in Table 47.8. There are no differences in efficacy that have been reported among these drugs.

TABLE 47.8 Proton pump inhibitors (PPI)

- Omeprazole (Prilosec) 20 mg capsule
- Lansoprazole (Prevacid) 20 mg tablet
- Rabeprazole (Aciphex) 20 mg tablet and IV
- Pantoprazole (Protonix) 40 mg tablet
- Esomeprazole (Nexium) 20, 40 mg capsules

Acid Suppression and Efficacy. The proton pump inhibitors are potent acid suppressing drugs (10–20 times more than cimetidine) with effects that persist after plasma concentrations have declined. These drugs are weak bases that favor accumulation in the acidic environment of the parietal cells. After systemic absorption, they become trapped in the acidic parietal cells of the stomach (up to 1000 times) because of ionization inside the acidic parietal cell. The effect of one dose may persist for greater than 24 hours in dogs and 22 hours in foals. However, there may be a delayed onset before they achieve maximal efficacy.

There is evidence in humans that these drugs are superior to other antisecretory drugs such as H_2-antagonists for treatment and prevention of ulcers caused by NSAIDs. In human studies, omeprazole has had better healing rates in comparison to other antiulcer drugs—such as H_2-receptor blockers—for some types of ulcers and esophagitis. In addition, these drugs have an inhibitory effect on the bacteria *Helicobacter pylori*, which is a cause of gastritis and ulcers in people.

Recently, omeprazole has become available without prescription (Prilosec-OTC). There are several new drugs that produce the same action on the proton pump (see Table 47.8). One of the most popular of these drugs in human medicine is esomeprazole magnesium (Nexium). Esomeprazole is simply the S-isomer of omeprazole. Twenty mg of esomeprazole is more effective than 20 mg of omeprazole, because it essentially contains twice as much of the active drug (the S-isomer). Otherwise, there is no difference between these drugs.

Use in Small Animals. Omeprazole has been used in dogs that need potent, long-acting acid suppression, dogs with NSAID-induced ulcers, or dogs that fail to respond to other antiulcer drugs (Jenkins and DeNovo 1991). Omeprazole is available as a 20 mg capsule. A dose of 1 mg/kg q24h maintained the pH in the stomach ≥3, which is the critical range for healing ulcers (Bersenas et al. 2005). Veterinarians have used dosages of 0.7 mg/kg/day, or alternatively: dogs under 5 kg, 5 mg per dog; dogs under 20 kg, 10 mg per dog; and for dogs over 20 kg, 20 mg per dog. Each dose is administered once daily.

Omeprazole is available in capsules containing granules, which protects the drug from acid degradation. If the granules are crushed, the drug can be inactivated by stomach acid. Therefore, if the capsule is opened, one

should ensure that the granules are not crushed, or administer the initial doses together with an H_2-blocker to prevent breakdown by the stomach acid. Once omeprazole has been absorbed, stomach acid will be inhibited to a sufficient extent to allow subsequent administrations.

There has been less reported on the administration to cats compared to dogs. There is no evidence published to indicate that proton pump inhibitors are unsafe in cats. Doses are similar to those used in dogs.

Use in Horses. Omeprazole suppresses acid secretion in horses and is used to treat and prevent ulcers. One mg/kg/day is needed to inhibit acid secretion (Andrews et al. 1999) and 1.4 to 2 mg/kg is needed for a more consistent effect (Baker and Gerring 1993; Murray 1997). Four mg/kg PO suppressed acid secretion in foals for 22 hours. Omeprazole (4 mg/kg PO, q24h) was significantly better than ranitidine (6.6 mg/kg PO, q8h) for healing ulcers (Lester et al. 2005).

Omeprazole is approved for this use as GastroGard®, an oral paste for horses at a dose of 4 mg/kg once daily for 4 weeks, and for prevention of ulcers the dose is 2 mg/kg once daily. Recently, an over-the-counter (OTC) form of this drug for horses has become available (UlcerGuard). The dose and concentration is the same as the prescription drug (GastroGuard). If the dosing formulation is altered by compounding, degradation may occur in the stomach, which renders the drug ineffective (Nieto et al. 2002). Three to five days of administration are required for maximal suppression of acid secretion. To promote ulcer healing in horses, the pH of the stomach should be maintained above 3.5 (Andrews et al. 1999).

Adverse Effects. The proton pump inhibitors can produce complete inhibition of acid secretion. There is no evidence that achlorhydria (lack of stomach acid) is, in itself, harmful. However, decreased stomach acid has been implicated as a cause of bacterial overgrowth in the stomach and intestines. The true cause-and-effect relationship in animals between proton pump inhibitors and gastrointestinal bacterial overgrowth has not been established. Another concern is that if bacteria are allowed to populate in the stomach as a result of stomach acid suppression, this may produce a risk if an animal aspirates stomach contents (aspiration pneumonia). Such a risk is possible if proton pump inhibitors are administered to animals prone to aspiration pneumonia, such as dogs with megaesophagus.

The long-term use (>8 weeks) of proton pump inhibitors is discouraged because of increased gastrin levels. Lack of negative feedback produces higher gastrin levels in animals. This has increased risk of gastric tumors in laboratory animals. However, there is no evidence that long-term use has been detrimental in veterinary patients.

Drug Interactions. Proton pump inhibitors are inhibitors of cytochrome P450 microsomal enzymes. This may be a problem for some drugs used in humans, but the clinical significance in veterinary medicine has not been established. Acid suppression may decrease oral availability of some oral drugs, for example, itraconazole, ketoconazole, and domperidone.

SYNTHETIC PROSTAGLANDINS. Synthetic prostaglandins—administered orally—produce many of the protective effects on the GI mucosa that natural prostaglandins have been known to achieve (Allen et al. 1993; Henderson and Webster 2006). Misoprostol (Cytotec®) is a synthetic PGE-1 analogue that has been used in people to diminish the risk of ulcers associated with NSAID therapy. In dogs, it has been shown to prevent duodenal hemorrhage and ulceration associated with aspirin therapy. Misoprostol is a better drug for preventing GI ulcers than for treating ulcers once they occur. Its use appears to be limited to NSAID therapy. Misoprostol was *not* effective for preventing gastritis, ulcers, and gastrointestinal hemorrhage associated with corticosteroid administration (Hanson et al. 1997).

Use in Small Animals. Misoprostol is available as 0.1 and 0.2 mg tablets. Dosages for dogs range from 2 to 5 µg/kg. It is absorbed and rapidly metabolized to an active metabolite. At high doses (>5 µg/kg) adverse effects of diarrhea have been reported.

Use in Horses. Misoprostol has been shown to decrease stomach acidity in horses. However, misoprostol may cause abdominal discomfort, cramping, and diarrhea. For these reasons, the use has been discouraged in horses.

Nongastrointestinal Uses for Misoprostol. Misoprostol was shown to have modest antiinflammatory effects and has been effective for some dermatoses in dogs. In

these studies, 3–6 µg/kg was administered to dogs with atopic dermatitis three times daily orally. Misoprostol produced a decrease in pruritus and clinical score of 30%. Side effects may prevent more widespread use and higher doses.

Misoprostol is an effective abortifacient. It has been used as a component of medical treatment of abortion in humans—in combination with other drugs. It has not been used for this purpose in animals, but if it is administered inadvertently to a pregnant animal, abortion could occur.

DRUGS USED TO TREAT *HELICOBACTER* GASTRITIS. Treatment of gastritis and ulcers caused by the bacteria *Helicobacter pylori* and *Helicobacter*-like organisms has gained interest in veterinary medicine. This organism has been identified in biopsy specimens from dogs and cats, but its role in gastritis and ulcers has yet to be established (Yamasaki et al. 1998). Some studies have found no association between *Helicobacter* infection and gastritis (Winberg et al. 2005; Haponen et al. 1998). However, in some animals with gastritis, treatment has helped decrease signs when treatment was initiated with ampicillin, metronidazole, and famotidine (AMF). A discussion on the role of *Helicobacter* as a cause of gastritis in animals can be found in the articles by Simpson et al. (2000) and Neiger and Simpson (2000). One of the authors recommends that animals with clinical signs of gastritis and positive for *Helicobacter* or *Helicobacter*-like organisms should be treated. The oral treatment for animals that has been the most widely used is a 2-week course of the combination of metronidazole and/or clarithromycin, plus amoxicillin, and a proton-pump inhibitor, or H_2-receptor antagonist.

In people, *Helicobacter pylori* gastritis has been treated with the simultaneous use of metronidazole, omeprazole, and clarithromycin (Suerbaum and Michetti 2002). One regimen uses clarithromycin (Biaxin®) and omeprazole (Prilosec®). A product called Tritec® combines ranitidine with bismuth citrate and is designed to be administered concurrently with clarithromycin (Biaxin®). Some regimens also use amoxicillin, or metronidazole. Some synergism is achieved with these combinations. For example, H_2-antagonists or omeprazole, enhance the antibacterial activity of metronidazole and perhaps other antibiotics.

TABLE 47.9 Causes of diarrhea in animals

- Osmotic (e.g., dietary indiscretion)
- Secretory (e.g., enterotoxigenic *E. coli*)
- Increased permeability (exudative) (e.g., parvovirus diarrhea)
- Malabsorption (e.g., pancreatic insufficiency)

DRUGS FOR TREATMENT OF DIARRHEA

Therapy for diarrhea should include fluid therapy, electrolyte replenishment, maintaining acid/base balance, and control of discomfort. But drugs such as antimicrobials, motility modifiers, and intestinal protectants are sometimes used. Diarrhea caused by intestinal parasites is covered in Section 10 of this book. Common causes of diarrhea in animals is shown in Table 47.9. Many of these causes do not require drug therapy and the disease is self-limiting. In some instances, treatment may be needed to temporarily relieve clinical signs. Some of these treatments are discussed below.

MUCOSAL PROTECTANTS AND ADSORBENTS

Kaolin-Pectin Formulations. Products that are promoted as mucosal protectants such as mixtures of kaolin and pectin (Kao-Pectate®) have been popular. Kaolin is a form of aluminum silicate and pectin is a carbohydrate that is extracted from the rinds of citrus fruits. The manufacturers claim that kaolin-pectin acts as a demulcent and adsorbent in the treatment of diarrhea. The action of kaolin-pectin is believed to be related to binding of bacterial toxins (endotoxins and enterotoxins) in the GI tract. However, experimental studies have shown that kaolin-pectin is an ineffective binder of *E. coli* enterotoxin and clinical studies have failed to show a benefit from the administration of kaolin-pectin. This product may change the consistency of stools, but it will not decrease fluid or electrolyte loss, nor will it shorten the duration of illness.

Kao-Pectate formulations contain salicylate as one of the active ingredients. There is 8.7 mg/ml in the Regular Strength, and 16 mg/ml in the Extra Strength formulation. Since some animals may be sensitive to salicylates, the salicylate content of the formulation should be considered before administering the product to animals.

Clinical Use of Kaolin-Pectin. Despite the lack of clinical evidence of efficacy, some veterinarians administer

this drug at a dose of 1 to 2 ml/kg, q6h. Kaolin-pectin is not absorbed, but salicylate may be absorbed in most animals (see the next section, on bismuth subsalicylate, and Papich et al. 1987). Drug interactions are also possible. Kaolin-pectin may adsorb or bind other drugs that are administered orally and decrease their effectiveness.

Bismuth Subsalicylate. The most common form of bismuth subsalicylate is Pepto Bismol®. Although other "mucosal protectants" may have questionable efficacy, this product is considered by many gastroenterologists to be the symptomatic treatment of choice for acute diarrhea. Its efficacy has been proven in controlled clinical trials in humans with acute diarrhea, particularly the form caused by enterotoxigenic *E. coli* (also known as traveler's diarrhea) (Bierer 1990). Bismuth may have some ability to adsorb bacterial enterotoxins, and it may produce some gastric or intestinal protective effect. The salicylate component is responsible for the efficacy, because it produces an antiinflammatory action. There are five sources of salicylate in this formulation accounting for approximately 9 mg of salicylate per ml. Two tablespoons (the typical human dose) contains almost 300 mg of salicylate. An "extra-strength" formulation contains twice this amount. Practically all of the salicylate from Pepto Bismol is absorbed systemically when administered to dogs and cats (Papich et al. 1987). Despite the systemic absorption, the amount is unlikely to produce salicylate toxicity. Even in cats—a species sensitive to salicylate toxicity—it is unlikely that enough would be administered from standard dosages to produce a toxic reaction.

Clinical Use of Bismuth Subsalicylate. The dose administered to animals was not derived from clinical studies, but extrapolated from human dosages. One to three ml/kg/day in divided doses have been administered safely (even to cats). Some animals may not like the taste, but otherwise there have not been serious adverse effects reported from administration of Pepto Bismol. Salicylate toxicosis is possible from overdoses, and pet owners should be advised to limit the amount administered, especially in animals with other primary diseases that may have initiated the diarrhea. Pet owners should be warned that Pepto Bismol may turn the stools black. As noted earlier, bismuth also has an anti-*Helicobacter* effect in the stomach. It has been included in many of the regimens for treating *Helicobacter*-gastritis. Therefore some benefits for treating gastritis may have been caused from the action on *Helicobacter* or *Helicobacter*-like organisms.

Pepto Bismol also has been administered for the treatment of acute diarrhea in large animals, especially foals and calves. The presumed benefit is from binding to enterotoxins or from the antiprostaglandin effect.

MOTILITY MODIFIERS FOR TREATMENT OF DIARRHEA

Anticholinergic Drugs (Antimuscarinic Drugs). Anticholinergic drugs significantly decrease intestinal motility and secretions and have been included as ingredients in antidiarrheal preparations. These drugs inhibit muscarinic action via their antagonism of either the muscarinic-M_1 or -M_3 receptor. (M_1 is a ganglionic receptor, and M_3 acts at peripheral sites.) Their parasympatholytic effects decrease segmental and propulsive intestinal smooth muscle contractions. Although they do not alter the course of the disease, anticholinergic drugs may decrease the urgency associated with some forms of diarrhea, decrease the fluid secreted into the bowel, and decrease abdominal discomfort associated with hypermotility. The limitation for the use of anticholinergic drugs lies in the questionable efficacy for most diarrhea seen in veterinary medicine (few cases of diarrhea actually can be classified as "hypermotile"). These drugs are also associated with important side effects. Anticholinergic drugs are discussed in more detail in Chapter 7.

Efficacy. Although the anticholinergic agents clearly decrease intestinal motility, there is no clear evidence that a decrease in motility is always beneficial. Intestinal motility is already impaired in many patients with some forms of diarrhea and these drugs may actually worsen the diarrhea by creating a "stovepipe" effect. The use of these drugs should be avoided if the diarrhea is infectious (e.g., caused by *Salmonella*).

Adverse Effects. Anticholinergic drugs have profound systemic pharmacological effects. If they are administered in sufficient doses to affect the bowel, side effects are possible, which include ileus, xerostomia, urine retention, cycloplegia, tachycardia, and CNS excitement. Chronic administration can lead to serious bowel atony. In addition to decreasing bowel motility, anticholinergic drugs decrease stomach emptying, which can lead to stomach distention and discomfort. This is certainly contraindicated in a

TABLE 47.10 Anticholinergic drugs used for treatment of diarrhea

Tertiary amines
• atropine
• scopolamine
Quaternary amines
• methscopolamine
• isopropamide
• propantheline
• glycopyrrolate

patient that has gastritis and is vomiting. Rumen atony is possible in cattle.

Examples of Drugs. Atropine is the best known anticholinergic drug, but because it has many other systemic effects, it is not ordinarily used for its antidiarrheal properties (Table 47.10). To avoid CNS effects, it is desirable to administer drugs that are quaternary amines. Because these drugs are charged, their lipophilicity is reduced and they do not cross the blood-brain barrier as readily as tertiary amines (see Table 47.10).

Quaternary amines used in veterinary medicine include methscopolamine, propantheline (Pro-Banthine®), and isopropamide (Darbid®). Darbazine, an old combination rarely available today, contains both isopropamide and prochlorperazine. Anticholinergic drugs have been included in formulations such as aminopentamide in Centrine® and diphemanil in Diathal®. Combination products such as Donnatal® contain scopolamine, atropine, and hyoscyamine (in addition to phenobarbital). Some of these formulations are outdated and unavailable today.

N-Butylscopolammonium Bromide (Buscopan). N-butylscopolammonium bromide is an anticholinergic drug used to treat colic in horses (0.3 mg/kg IV). Although anticholinergic drugs are not ordinarily indicated for treatment of colic in horses, this drug has FDA approval for this indication. N-butylscopolammonium bromide is considered an antispasmodic drug registered for treatment of colic associated with spasm of the intestine in horses. Within 5–10 minutes of IV injection, spasm of intestinal smooth muscle is reportedly relieved. Adverse effects from N-butylscopolammonium include other anticholinergic effects such as transient increase in heart rate lasting for approximately 30 minutes. It should not be used in horses with an impaction or in horses with ileus.

OPIOIDS. Opioids can have both antisecretory and antimotility actions as they act on the μ (mu)-opiate receptors of the GI tract. They decrease propulsive intestinal contractions and increase segmentation (an overall constipating effect) (DeHaven-Hudkins et al. 2007). They also increase the tone of GI sphincters. In addition to affecting motility, opiates have an antisecretory effect and stimulate absorption of fluid, electrolytes, and glucose. Their effects on secretory diarrhea are probably caused by inhibition of calcium influx and decreased calmodulin activity (Hedner and Cassuto 1987). These drugs can affect large animals as well as small animals. Opiates have been documented to inhibit colonic motor activity in horses (Roger et al. 1985; Boscan et al. 2006). Opiates are discussed in more detail in Chapter 12.

Examples of Drugs. The constipating effects of morphine and other opioids are well known. However, it would be irrational to administer morphine repeatedly to animals simply for the antidiarrhea effect. Instead, opioids are used that produce little systemic effect. Two synthetic opioids are known for their specificity of action on the GI tract and their effect on secretory diarrhea. They are primarily active locally on the opiate μ-receptors and they produce GI effects without other systemic side effects. Two such compounds are *diphenoxylate* (Lomotil®) and *loperamide* (Imodium®) (Johnson 1989). Diphenoxylate is a derivative of meperidine and not commonly used.

Loperamide is the most often used and is available OTC in capsules (Imodium) of 2 mg and an oral solution of 0.2 mg/ml (for dosages, see Table 47.11). The typical dose for small animals is 0.1 mg/kg, q12h, PO. Paregoric is an older compound (tincture of opium), found in many antidiarrheal products. *5 ml of paregoric corresponds to approximately 2 mg of morphine.*

Adverse Effects. Opiates can have potent effects on the GI tract and should be used cautiously. Loperamide is an over-the-counter drug available for people, often administered to animals. These drugs are generally contraindicated in infectious diarrhea because opiates may significantly slow GI transit and increase the absorption of bacterial toxins. Diphenoxylate (Lomotil) contains 25 μg of atropine per 2.5 mg tablet. The amount of atropine contained in this mixture may contribute to some inhibition of intestinal smooth muscle, but is present in the formulation primarily to discourage abuse by people.

TABLE 47.11 Antidiarrhea drugs and doses

Drug	Dose
OPIATES	
codeine	0.5–1.0 mg/kg, PO, q8–12h
morphine	0.05–0.1 mg/kg, IM, SC, q8–12h
diphenoxylate (Lomotil)	0.1–0.2 mg/kg, PO (dog), q8–12h or 0.05–0.1 mg/kg, PO (cat), q12h
loperamide (Imodium)	0.1–0.2 mg/kg, PO, q8–12h
paregoric	0.05–0.06 mg/kg, PO, q12h
ANTICHOLINERGIC DRUGS	
propantheline (Pro-Banthine)	0.25–0.5 mg/kg, PO, q8–12h
aminopentamide (Centrine)	0.01–0.03 mg/kg, q8–12h or 0.1 mg/cat PO,IM,SC, q8–12h
diphemanil (Diathal)	1.8 mg/kg, IM, q12h

Loperamide does not cause central nervous system opiate-related effects because the membrane transporter p-glycoprotein (p-gp) helps to remove this drug from the central nervous system. Dogs deficient in p-gp (e.g., Collie dogs and other herding breeds) may be prone to toxicity (Mealey 2004).

ANTIMICROBIAL THERAPY FOR TREATMENT OF DIARRHEA. The routine use of antimicrobials to treat diarrhea has been questioned by gastroenterologists. In most cases of diarrhea in small animals, a bacterial etiology cannot be identified. In large animals diarrhea is often caused by bacteria (*E. coli*, for example), but antibiotic therapy may not alter the course of the disease and there is a lack of well-controlled studies to demonstrate efficacy. Oral, nonabsorbed antibiotics are sometimes combined with motility modifiers, adsorbents, and intestinal protectants in commercial preparations, but some of these are irrational combinations. Sometimes administration of oral antibiotics can be a *cause* of diarrhea (Bartlett 2002).

For the few indications where antimicrobial therapy may be an important treatment for diarrhea, protocols are listed below. Discussions about specific drugs are provided in Chapters 33–38 of this book.

Campylobacter Enteritis. This disease is caused by *Campylobacter jejuni*, which may be transmitted to people. This organism is the most common cause of food-borne infectious diarrhea in people. The treatment is aimed primarily at maintaining fluid and electrolyte balance. If antimicrobials are considered the following have been used: erythromycin (10 to 15 mg/kg, q8h x 5 d), fluoroquinolones, tylosin, clindamycin, tetracycline, or chloramphenicol (35–45 mg/kg, q8h). Although erythromycin usually is cited as the treatment of choice, bacterial shedding may resume once therapy is stopped. (Monfort et al. 1990).

Intestinal Bacterial Overgrowth Caused by *E. coli* or *Clostridium* spp. Treatments that have been used include antimicrobial treatment and administration of probiotics. Using probiotics entails administration of bacteria that will restore a healthy population of bacteria in the intestine. When antibiotics are considered, one should administer an oral drug that is effective in the GI lumen and has activity against anaerobic bacteria. For *E. coli*, fluoroquinolones are recommended. For *C. difficile*, metronidazole or vancomycin is recommended. Other drugs to consider include amoxicillin, ampicillin, tylosin, clindamycin, or tetracyclines.

Tylosin-Responsive Diarrhea. Because some forms of chronic diarrhea in animals have been responsive to the antimicrobial tylosin (Tylan), they have been characterized as "Tylosin-Responsive Chronic Diarrhea in Dogs" (Westermarck et al. 2005). This disease, affecting both large and small bowel, is most likely caused by a bacterial pathogen, but the specific etiology has not been identified. *Campylobacter jejuni* and *Clostridium perfringens* have been identified in some animals, however. In these animals, tylosin has been effective at improving clinical signs that occur with or without organisms being identified. When administered at 12 mg/kg/day (average dose) response was prompt. Some dogs respond within 24 hours; others respond within 3 days. Other studies by the same investigators showed that a dose of 20 mg/kg/day was effective, but other drugs (metronidazole, trimethoprim-sulfonamides, doxycycline, or prednisolone) were not (Westermarck et al. 2005).

Sources of Tylosin. The powdered form for livestock (Tylan) has been mixed with the animal's food at a dosage of 40–80 mg/kg/day. One teaspoon contains approximately 3 grams (3,000 mg); therefore, 1/4 teaspoon contains 750 mg, enough for many dogs. Some animals may find the bitter taste unpleasant and refuse their food,

however. Tablets for small animals are available in other countries.

METRONIDAZOLE (FLAGYL®)-RESPONSIVE DISEASES. Metronidazole is active against the protozoan *Giardia,* and it is for this use that metronidazole was first administered to treat diarrhea in small animals. (Antiprotozoan drugs are discussed in Chapter 43.) Veterinarians discovered that metronidazole also was effective in patients that did not have giardiasis. Bowel inflammation may be caused by metronidazole-sensitive bacteria, which act as a chemoattractant for neutrophils. The efficacy of metronidazole may be related to this antibacterial activity. Oral administration of metronidazole at 20 mg/kg to cats decreased the number of anaerobic and aerobic bacteria and altered the indigenous bacterial population (Johnston et al. 2000). In addition, it may have an immunosuppressive effect on the GI mucosa (decreased cell-mediated response). Metronidazole (alone and in combination with ampicillin) has been effective for histiocytic ulcerative colitis in dogs (Hostutler et al. 2004). Doses have been as high 60 mg/kg/day for 2 to 4 weeks, but many animals will respond to low doses of 30 mg/kg/day (in divided doses). Cats can receive one-quarter of a 250 mg/tablet two to three times daily (10 to 25 mg/kg). *Caution pet owners that when the tablet is broken, the exposed tablet may cause an unpleasant taste for cats.*

Adverse effects from metronidazole are primarily seen as CNS effects. Tremors, seizures, and other CNS disturbances have been documented. CNS problems are caused by inhibition of GABA. Avoid high doses to prevent the CNS adverse effects.

Salmonella. The primary goal when treating *Salmonella* is to maintain fluid balance and prevent electrolyte losses. The patients should be isolated to prevent spreading of infection, and strict containment procedures should be instituted in the hospital. Antibiotics are discouraged unless absolutely necessary for patients with salmonella. Antibiotic therapy may prolong shedding. In horses, if there is fever and neutropenia, gentamicin IV should be considered. In animals in which oral therapy is possible, drug choices include the following: fluoroquinolones, chloramphenicol, or florfenicol (depending on the species), ampicillin or amoxicillin or amoxicillin-clavulanate, trimethoprim-sulfonamide, or a cephalosporin (higher activity with third-generation cephalosporin).

Antibiotic Treatment in Calves with Diarrhea. Use of antibiotics to treat diarrhea is probably most often practiced in young ruminants. A review of this practice has summarized the relevant literature (Constable 2004). This author points out that the following antimicrobials are approved for treatment of calf diarrhea: amoxicillin, chlortetracycline, neomycin, oxytetracycline, streptomycin, sulfachloropyridazine, sulfamethazine, and tetracycline—*all* administered orally. Some of these drugs were approved many (approximately 50) years ago, before evidence was required for registration. Of all these drugs listed, only amoxicillin has been shown to be effective in well-controlled studies. Other drugs shown to be effective, (fluoroquinolones, chloramphenicol, nitrofurazone) are illegal to use for this indication in calves. If bacteremia develops as a complication of bacterial diarrhea in calves, systemic therapy is needed. Drugs most often given systemically (IM, SC, or IV) for this indication include ceftiofur and ampicillin.

Bacterial Septicemia Secondary to Diarrhea. When it is suspected that there may be a loss of the protective epithelial barrier, the intestine mucosal integrity is compromised. In these cases, bacteremia and septicemia can occur due to translocation of bacteria. Signs accompanying septicemia include a severe, bloody diarrhea, fever, and leukocytosis. This may progress to signs of endotoxic shock. If septicemia is suspected, systemic antibiotics are clearly warranted.

The choice of antibiotics will vary depending on the species and the animal's age. Some drugs are restricted in food animals. Neonates with diarrhea will deteriorate rapidly, and treatment cannot wait for culture and sensitivity results when prescribing antimicrobial therapy. Therefore, broad-spectrum antimicrobials often are used.

Recommended antibiotics include ampicillin or amoxicillin, (combined with a β-lactamase inhibitor), combination of a β-lactam (penicillin, aminopenicillin, or cephalosporin) with an aminoglycoside (gentamicin or amikacin), aminoglycoside alone, cephalosporin (extended-spectrum cephalosporin), carbapenem (meropenem or imipenem), or fluoroquinolones (enrofloxacin, marbofloxacin, difloxacin, orbifloxacin).

If the animal shows signs of sepsis, systemic antimicrobials should be used. Antibiotics that are poorly absorbed and confined to the GI lumen may be of little benefit (e.g., neomycin, ampicillin).

***Lawsonia intracellularis* (Pigs and Horses).** In horses 3–6 months old, a disease characterized as *proliferative enteropathy* is caused by the organism *Lawsonia intracellularis*. Affected animals show signs of lethargy, anorexia, depression, weight loss, colic, diarrhea, and hypoproteinemia. Treatment in horses has included erythromycin, azithromycin, chloramphenicol, clarithromycin, and doxycycline.

In pigs, *Lawsonia intracellularis* also causes intestinal disease. The recommended treatment is tetracyclines and tylosin, added to feed.

DRUGS FOR TREATMENT OF INFLAMMATORY INTESTINAL DISEASES

Intestinal inflammatory diseases cover a wide range of etiologies grouped together because they may have similar clinical signs. Among the diseases that may be included in this group are those caused by parasites, bacteria, food hypersensitivity, or immune-mediated diseases. Inflammatory bowel disease (IBD) may involve the small intestine or large intestine. There are similarities to intestinal diseases in people, which were reviewed by Hanauer (1996). For a thorough discussion of these diseases in small animals, consult reviews in clinical textbooks (Washabau & Holt 2005; Hall & German, 2005), read the chapters by Hall and German (small intestine) and Washabau and Holt (large intestine) in Ettinger and Feldman (editors, *Textbook of Veterinary Internal Medicine, 6th Edition,* Elsevier Saunders 2005; Chapter 222, page 1332, and Chapter 223, page 1378).

Inflammatory bowel disease is a collective term that describes a group of disorders characterized by persistent or recurrent signs and histologic evidence of inflammation. Inflammation may be characterized by the cells infiltrating the mucosa (lymphocytic, plasmacytic, eosinophilic, neutrophilic). In the large intestine, the disease is often referred to simply as *colitis* but also may be associated with many etiologies.

Initial therapy for inflammatory intestinal disease is aimed at managing the underlying cause. Therefore, antiparasitic therapy and dietary therapy are usually pursued initially. When these treatments have failed, or a specific etiology has not been identified, drug therapy, usually consisting of antiinflammatory drugs, is used, or added to existing treatment. Dietary management will not be discussed here. You are encouraged to consult dietary and nutrition veterinary textbooks for guidelines on diet management. Antiparasitic drugs are discussed in Section 10.

SULFASALAZINE (AZULFIDINE®). Sulfasalazine is used as an initial drug therapy for treatment of colitis. It is not as effective for inflammatory diseases of the small intestine. Sulfasalazine is a combination of sulfapyridine and 5-aminosalicylic acid (mesalamine) joined by an azo bond. The bond is broken by bacteria in the colon to release the two drugs. The sulfonamide component is absorbed into the circulation while the salicylic acid component remains active in the GI tract. Less than half of the salicylate component is absorbed systemically.

Clinical Use. Many veterinarians consider sulfasalazine to be the drug of choice for the initial treatment of ulcerative or idiopathic colitis, or plasmacytic-lymphocytic colitis after dietary therapy has been attempted. Clinical efficacy is attributed to a local antiinflammatory action from the salicylate component. There is also evidence for antilipooxygenase (LOX) activity, decreased IL-1, decreased prostaglandin synthesis, and oxygen radical scavenging activity.

Dosage recommendations start at 10–25 mg/kg q8h, PO, but have been as high as 40 mg/kg, two to three times per day. The dose is then reduced after there is an initial response to treatment.

Adverse Effects. The salicylate component is absorbed only minimally. The sulfonamide component is absorbed and can produce adverse effects in some animals, such as keratoconjunctivitis sicca in dogs (Morgan and Bachrach 1982). This drug cannot be used in patients that have allergic reactions to sulfonamides.

Other Sources of 5-Aminosalicylic Acid (Mesalamine). In people, the adverse effects associated with sulfasalazine therapy are primarily due to the sulfonamide component; therefore, drugs have been formulated to contain mesalamine (5-aminosalicylic acid) without the sulfonamide. These formulations are listed in Table 47.12. Some formulations are designed to release the active drug at the high pH of the distal intestine (Table 47.13).

ANTICHOLINERGIC DRUGS (ANTIMUSCARINIC DRUGS). As discussed previously, anticholinergic drugs (atropinelike drugs) inhibit smooth muscle and glandular secretions of the GI tract. Anticholinergic drugs occasionally have been used for the treatment of colitis. However, colitis is not ordinarily associated with hypermotility and

TABLE 47.12 Mesalamine (5-aminosalicylic acid) formulations

- Asacol®: Asacol is a tablet coated with an acrylic-based resin. The resin dissolves at a pH of 7.0 and is designed to release 5-aminosalicylic acid in the colon. It is available as a 400 mg tablet.
- Mesasal®: Mesasal is a tablet coated with an acrylic-based resin that dissolves at a pH of >6.0. It is designed to release 5-aminosalicylic acid in the terminal ileum and colon. Approximately 35% of the salicylate is absorbed systemically. It is available in 250 and 500 mg tablets. The dose in people is 1 to 1.5 g/day.
- Olsalazine sodium (Dipentum®): Olsalazine is a dimer of 2 molecules of 5-aminosalicylic acid linked by an azo bond. It is used in people who cannot tolerate sulfasalazine. Only 2% of the salicylate from this compound is absorbed systemically. It is available in 500 mg tablets. The most common adverse effect in people from this preparation has been a watery diarrhea.
- Pentasa: This formulation contains microgranules of mesalamine coated with ethyl cellulose, which releases 5-aminosalicylic acid into the small and large intestine gradually, regardless of pH.

TABLE 47.13 pH values of GI tract in small animals

	Stomach (Fasted)	Proximal S. Intestine	Distal S. Intestine	Cecum	Colon	Feces
Dog	3.4–5.5	6.2	7.5	6.4	6.5	6.2
Cat	4.2–5.0	6.2	7.6	6.0	6.2	7.0

the rationale of anticholinergic drugs should be questioned. Patients with a hypermotile or spastic bowel may have a limited benefit from these drugs.

Anticholinergic drugs also may have a role for reducing straining during the postoperative management of rectal and/or anal surgical procedures. A common drug for these indications is propantheline (Pro-Banthine®) at a dosage of 0.25 mg/kg, orally, two or three times daily.

GLUCOCORTICOIDS. The effects of glucocorticoids for treating inflammatory bowel diseases are probably related to their antiinflammatory and immunosuppressive ability (Dillon 1989). It is believed that colitis is the result of autoantibodies and T-lymphocytes directed against the colonic epithelial cells. Corticosteroids, via their ability to suppress cytokine synthesis, leukocyte migration, and lymphocyte activation suppress the activity responsible for inflammatory bowel disease clinical signs. Glucocorticoids have been used when a biopsy suggests eosinophilic colitis or lymphocytic-plasmacytic colitis (Washabau and Holt 2005; Leib et al. 1989). They are often employed when other forms of therapy (including dietary) have failed. The pharmacology of the corticosteroids was discussed in more detail in Chapter 30.

Clinical Use and Dosages. The dose of prednisolone initially is in the immunosuppressive range of 2 to 4 mg/kg per day in divided doses for dogs and cats. Although there are no comparisons between prednisone and prednisolone, it is advised to use prednisolone. Prednisone is an inactive drug that relies on the conversion to the active drug prednisolone. If a local (topical) effect is desired from an oral dose, prednisolone is preferred over prednisone. Moreover, there is evidence—at least in cats—that some animals do not convert prednisone to the active drug.

After initial response is observed, the doses are tapered to approximately 1 mg/kg every other day if there is a positive treatment response. Prednisolone may be administered with azathioprine (see next section). The magnitude of the dosage depends on the severity of the disease. Cats with severe inflammatory bowel disease have required prednisolone dosages as high as 4 mg/kg/day. Injections of corticosteroids (for example, methylprednisolone acetate DepoMedrol® at 20 mg/cat) for the control of inflammatory bowel disease has not been as successful as oral therapy. *Veterinarians should be aware that some animals develop diarrhea when treated with glucocorticoid therapy.*

Local Treatment with Budesonide (Entocort EC). Budesonide is a locally acting corticosteroid. It has been used in people, but there has been only limited use in small animals. Budesonide granules are contained in an ethylcellulose matrix that is coated with methacrylic acid polymer. This coating does not release the drug until the pH >5.5. In the proximal intestine the pH is low and it gradually increases in the distal intestine to attain a pH

above 7 (see Table 47.13). Therefore, the drug is not released until it reaches the distal GI tract. If a portion of the drug is absorbed, 80–90% is inactivated by metabolism first-pass effects. Therefore, systemic glucocorticoid effects are minimized. In humans it has been as effective as other drugs for treatment of Crohn's disease. It is available in a 3 mg capsule and is used in people at a dose of 9 mg/day.

Use of Budesonide in Animals. There is only limited experience with budesonide in dogs and cats, but some animals have benefited from its administration. There is some systemic absorption as evidenced by decreased response to ACTH after 30 days of treatment to dogs at 3 mg/m^2, but other side effects were not observed (Tumulty et al. 2004).

IMMUNOSUPPRESSIVE DRUGS. Immunosuppressive drugs also have been used to manage some forms of inflammatory bowel diseases. These drugs were discussed in more detail in Chapter 46. The most commonly used immunosuppressive drug for intestinal disease is azathioprine. The use of other drugs, such as cyclosporine, has been more limited.

Azathioprine is metabolized to 6-mercaptopurine (6-MP), which inhibits de novo synthesis of purine nucleotides in activated lymphocytes thereby suppressing lymphocyte response. Azathioprine (Imuran®) has been used at dosages of 2 mg/kg once daily, to 40 mg/m^2 once daily in dogs with severe inflammatory bowel disease. The dose may be decreased to 0.5 mg/kg every other day if there is a positive initial response. Cats are more sensitive to the adverse effects than dogs. Azathioprine dosages of 2.2 mg/kg/day have produced bone marrow suppression in cats (Beale et al. 1992), but lower doses may be safe—for example 0.3 mg/kg. In one report, cats with inflammatory bowel disease responded to azathioprine at a dose of 3 mg per cat (one-eighth of a 25 mg tablet), every other day.

N-3 FATTY ACIDS FOR COLITIS. In people omega-fatty acids (n-3 fatty acids) such as eicosapentanoic acid are beneficial for the treatment of colitis. These compounds are available in veterinary medicine in products such as DermCaps®, Pet-Derm®, and others for the purpose of treating pruritic skin disease. In studies performed in people with ulcerative colitis, supplementation for 4 months with omega fatty acids reduced leukotriene levels in the colon, and improved clinical signs. The clinical efficacy of these compounds for treating small animals with colitis has not been reported.

CYCLOSPORINE. Cyclosporine (Neoral, Atopic) has been used to treat perianal fistulas, which are a component of ulcerative colitis (see Chapter 46). The treatment for this disease has been very successful. In addition, cyclosporine has been used to treat diarrhea caused by inflammatory bowel disease (Allenspach et al. 2006). At a dose of 5 mg/kg PO, q24h, ×10 weeks there was improvement in 78% of dogs. The success is attributed to the ability of cyclosporine to suppress T-cell mediated activity in the bowel, and to suppression of inflammatory cytokines.

LAXATIVES AND CATHARTICS

Laxatives and cathartics are drugs that increase the motility of bowel and change the character of the stool. Uses of these drugs are listed in Table 47.14. These drugs promote the elimination of soft-formed stool or increase fluid content of stool, which increases the bulk. Laxatives and cathartics can be divided into 1) bulk-forming laxatives, 2) stool softeners, 3) lubricants, 4) saline hyperosmotic agents, and 5) stimulants. They also may be categorized by their onset of action: The osmotic (saline) laxatives act in 1–3 hours; the direct stimulants act in 6–8 hours; the bulk laxatives and surfactants act in 1–3 days.

STIMULANT (IRRITANT) LAXATIVES. The exact mechanism of action for this group of laxatives is uncertain, but they appear to cause electrolyte loss by inhibiting Na^+/K^+-ATPase in the intestine and increasing electrolyte loss through intestinal tight junctions. These drugs are

TABLE 47.14 Use of laxatives and cathartics in veterinary medicine

- Promotes the elimination of a soft-formed stool
- Increases passage of intestinal contents to relieve an impaction (equine)
- Cleanses bowel prior to radiography or endoscopy
- Promotes the elimination of a toxin from the intestine
- Softens stools following intestinal or anal surgery (decreases straining)

among the most rapidly acting of the laxatives, with action within 6–8 hours. They can have potent effects and excessive fluid and electrolyte loss can result from overdoses. Adverse effects can result from damage to enterocytes from chronic use and abuse:

- *Diphenylmethane*: Use is not documented in veterinary medicine.
- *Phenolphthalein*: This was once an ingredient found in over-the-counter laxative preparations such as ExLax®, but is no longer available. (Other natural ingredients are used in ExLax.)
- *Anthraquinone:* These are glycoside derivatives found in bisacodyl (Dulcolax), senna (Senokot), and cascara sagrada (Nature's Remedy).

HYPEROSMOTIC CATHARTICS (SALINE CATHARTICS). The saline cathartics are nonabsorbed electrolytes that draw fluid into the bowel via osmosis. These are the most rapidly acting of the cathartics, with onset of action in 1–3 hours. The fluid content of the stool increases, which causes intestinal distention and promotes increased normal peristalsis. These have been some of the most commonly used cathartics in veterinary medicine. Most often they are dissolved in an aqueous solution (water) and administered via gastric gavage (stomach tube). These drugs have been used to prepare animals for an endoscopic procedure (*bowel cleansing)* or for cathartic treatment of poisoning. They are relatively safe drugs, but overdoses can cause fluid loss in a patient. Examples of these drugs are shown in Table 47.15.

TABLE 47.15 Saline cathartics

- Sodium sulfate (Glauber's salt)
- Magnesium salts such as magnesium sulfate (Epsom Salts), magnesium hydroxide (Milk of Magnesia), and magnesium citrate (Citro-Mag)
- Nonabsorbed sugars: Lactulose, Mannitol, Polyethylene glycol (PEG)
- Lactulose also is used to treat hepatic encephalopathy. Its action lowers the bowel pH and decreases ammonia absorption by converting to NH^{+3}. The ionized form of the compound is less absorbed systemically.
- Combination products: Golytely is a strong osmotic cathartic that is a combination of sodium sulfate, potassium chloride, sodium chloride, sodium bicarbonate, and polyethylene glycol (PEG 3350). The dose is 250 ml to one liter per animal (depending on the size) and has a rapid onset of action. The most common use of this product is for bowel cleansing prior to an endoscopic procedure.

HYDROPHILIC COLLOIDS ("BULK LAXATIVES"). These agents are mostly natural products and dietary plant fibers. They are composed of nonabsorbed synthetic or natural polysaccharide and cellulose derivatives. These fibers are resistant to digestion and attract water into the intestine. By imbibing water, they increase the mass of nondigestible material in bowel and motility is increased through the stimulation of mechanoreceptors. They are more slowly acting than other drugs with an onset of action of 24 hours, or longer. They are relatively safe drugs with few side effects. Examples are included in Table 47.16.

TABLE 47.16 Bulk laxatives

- Carboxymethylcellulose
- Methylcellulose
- Psyllium (Metamucil) powder
- Prunes and wheat bran and other attempts to increase "fiber" in the diet
- For cats, canned pumpkin is a source of fiber that most cats eat readily

LUBRICANT LAXATIVES (MINERAL OIL AND LIQUID PETROLATUM). The lubricants act by coating the surface of the stool with a water-immiscible film and increasing the water content of the stool. They also produce a lubricant action to ease passage of the stool. Lubricant laxatives usually contain mineral oil (liquid petrolatum) or white petrolatum. Many of the nonprescription products contain white petrolatum (Vaseline) as their ingredient. Administration of glycerin also has been used as a lubricant laxative. The lubricant laxatives are relatively safe because they are absorbed from the GI tract only to a small extent. The worst adverse effect is that they may possibly elicit a foreign body reaction. Chronic use may decrease the intestinal absorption of fat-soluble vitamins.

Use in Large Animals. These drugs, particularly mineral oil, are popular for several nonspecific GI problems in horses and cattle.

Use in Small Animals. Products such as Laxatone®, Felaxin®, and Kat-a-Lax® are promoted for increasing the passage of trichobezoars (hair balls) in cats. These products

TABLE 47.17 Other uses for ursodeoxycholic acid

Although listed with the laxatives, most of the use of ursodeoxycholic acid (ursodiol), in veterinary medicine is for the management of liver disease in animals, rather than for its laxative action. Ursodeoxycholic acid has an important effect in slowing progression, or improving, liver disease (Lindor 2007). Because ursodiol is a water-soluble bile acid, administration may alter the circulating pool of bile acids to replace some of the more toxic, hydrophobic bile acids from accumulating in animals with liver disease.

contain white petrolatum (Vaseline) as their active ingredient with additional flavorings.

STOOL SOFTENERS (SURFACTANTS). These drugs act to decrease surface tension and allow more water to accumulate in the stool. Their onset of action is usually 24–48 hours. They are relatively safe, except cramping pains are reported in people if they ingest high dosages.

Docusates: Dioctyl Sodium Sulfosuccinate (DSS, Colace), and Dioctyl Calcium Sulfosuccinate (Surfak, Doxidan). Also known as docusate sodium and docusate calcium, these compounds are used when there is a need to soften the stool. Efficacy in animals has not been tested.

Bile Acids. Bile acids include dehydrocholic acid and ursodeoxycholic acid (Ursodiol, Actigall). Bile acids can produce both a choleretic (increase bile flow) and laxative effect. Other uses are listed in Table 47.17.

Castor Oil. Castor oil is hydrolyzed in the bowel to release ricinoleic acid, which causes an increased secretion of water in the small intestine.

Dermatotherapy: Atopic Dermatitis	1291

A large number of cases seen in the everyday practice of small- and large-animal veterinary medicine involve lesions of the skin or its appendages. This chapter reviews the salient features of the general anatomy, histology, and biochemistry of skin relevant to the treatment of dermatologic disease; acquaints the practitioner with the features of percutaneous drug absorption relevant to the treatment of skin disease; and discusses the categories of pharmacologic preparations available on the veterinary market to treat skin diseases in domestic animals. The specific drugs used to treat skin diseases are well covered in other chapters of this text. Chapters that should be consulted for application to skin disease include those on antimicrobials, analgesics, and antiinflammatory drugs; antipruretics and antihistamines; glucocorticoids; immunosuppressives (cyclosporine); and ectoparasiticides.

Only in the last few decades have scientists begun to understand how the skin functions in normal and diseased states, to understand the skin's barrier function in terms of water loss and drug delivery, and that attempts have been made to improve the delivery of pharmaceutical agents through the skin by temporarily adjusting that barrier to deliver the drug. In order to successfully minimize the skin's ability to block the absorption of drugs to

treat dermatologic disease in domestic animals, it is imperative to understand the normal functional anatomy and biochemistry of the skin. In veterinary medicine, transdermal delivery is widely employed when pesticides are applied monthly to a single area of skin for the control of fleas and ticks over the entire body. Transdermal fentanyl patches are also widely used for postsurgical analgesia. This topical port of drug delivery will see increased use for other therapeutic indications. However, most drugs applied to the skin are not intended to be absorbed systemically but are used to elicit a local therapeutic effect in the treated skin.

The characteristic that separates dermatologic therapy from other components of veterinary pharmacology is this use of topical dosage formulations to treat surface conditions or to target the underlying skin. The drugs are not different from those used in other diseases, but they are different in the vehicles employed and mode of administration. A full understanding of the biological factors that modulate absorption and of the pharmaceutical composition of dermatologic formulations (e.g., vehicles) is essential to a proper understanding of dermatopharmacology. It must be stressed that the drugs incorporated into these formulations are the same as those used to treat diseases of other systems and thus, their descriptions will not be repeated in this chapter.

ANATOMY AND HISTOLOGY

The skin is the largest organ of the body, with the integument accounting for 24% of the overall body weight in the puppy and 12% in the adult dog (Pavletic 1991). The skin has the function of protecting the internal organs of the body from extremes in temperature fluctuations, allergens, pollutants, toxic chemicals, and organisms such as bacteria, fungi, parasites, and viruses found ubiquitously in the environment.

The skin of domestic animals is quite similar in gross and histologic morphology across species lines and is usually thickest over the head, dorsum of the neck, back, and sacrum and on the plantar and palmar surfaces of the feet. It is thinner on the ventral abdomen, the medial surfaces of the limbs, and the inner pinnae, and thinnest over the scrotum of male animals and the earlobe of the human. Perforating the skin are several types of appendages (depending on the species), such as hair follicles, sebaceous and sweat glands, spines, quills, scales, spurs, horns, claws, nails, and hooves (Montagna 1967). The specific anatomy of skin and hair has been reviewed extensively elsewhere (Monteiro-Riviere 2006; Blackburn 1965; Lloyd et al. 1979a,b; Sar and Calhoun 1966; Kozlowski and Calhoun 1969; Strickland and Calhoun 1963; Talukdar et al. 1972; Pavletic 1991; Montagna 1967; Amakiri 1973).

THE EPIDERMIS. On the histological level, the skin can be divided into two distinct units: the epidermis and the dermis. The epidermis consists of stratified squamous keratinized epithelium that undergoes a programmed proliferation and differentiation that will eventually result in the formation of the major barrier to drug penetration: the stratum corneum. Two primary cell types exist in the epidermis: those of keratinocyte origin and those of nonkeratinocyte origin.

Five distinct layers of keratinocytes can be present in the epidermis as shown in Figure 48.1. Listed from the deepest layer of the epidermis to the most superficial, they are 1) stratum basale (basal layer), 2) stratum spinosum (prickle layer), 3) stratum granulosum (granular layer), 4) stratum lucidum (clear layer), and 5) the stratum corneum (horny layer). Each cell layer has its point of origin at the stratum basale. The stratum basale is a single layer of cuboidal or columnar cells that rest on the basal lamina. These cells are attached to the basal lamina by hemidesmasomes, and to each other and to the cells of the stratum spinosum by desmasomes. The stratum basale cells continuously divide, with some remaining as basal cells and others beginning to move more superficially and mature by changing their intracellular content through the process called *keratinization*. This viable and dividing epidermal cell layer is the target for transformation into cancerous cells.

The next more superficial layer next to the stratum basale, the stratum spinosum, is composed of irregularly shaped polyhedral cells that make up much of the bulk thickness of the epidermis. The next layer composes the stratum granulosum, which consists of several layers of cells that begin to flatten horizontally. Of primary interest are the lamellated granules within these cells, which contain polar phospholipids, such as glycosphingolipids and free steroids, and numerous hydrolytic enzymes, including acid phosphatase, proteases, lipases, and glycosidases. As these intracellular products accumulate, these cells will exocytose their intracellular products and fill in the intercellular spaces, eventually forming the extracellular lipid matrix of the stratum corneum that forms the penetration

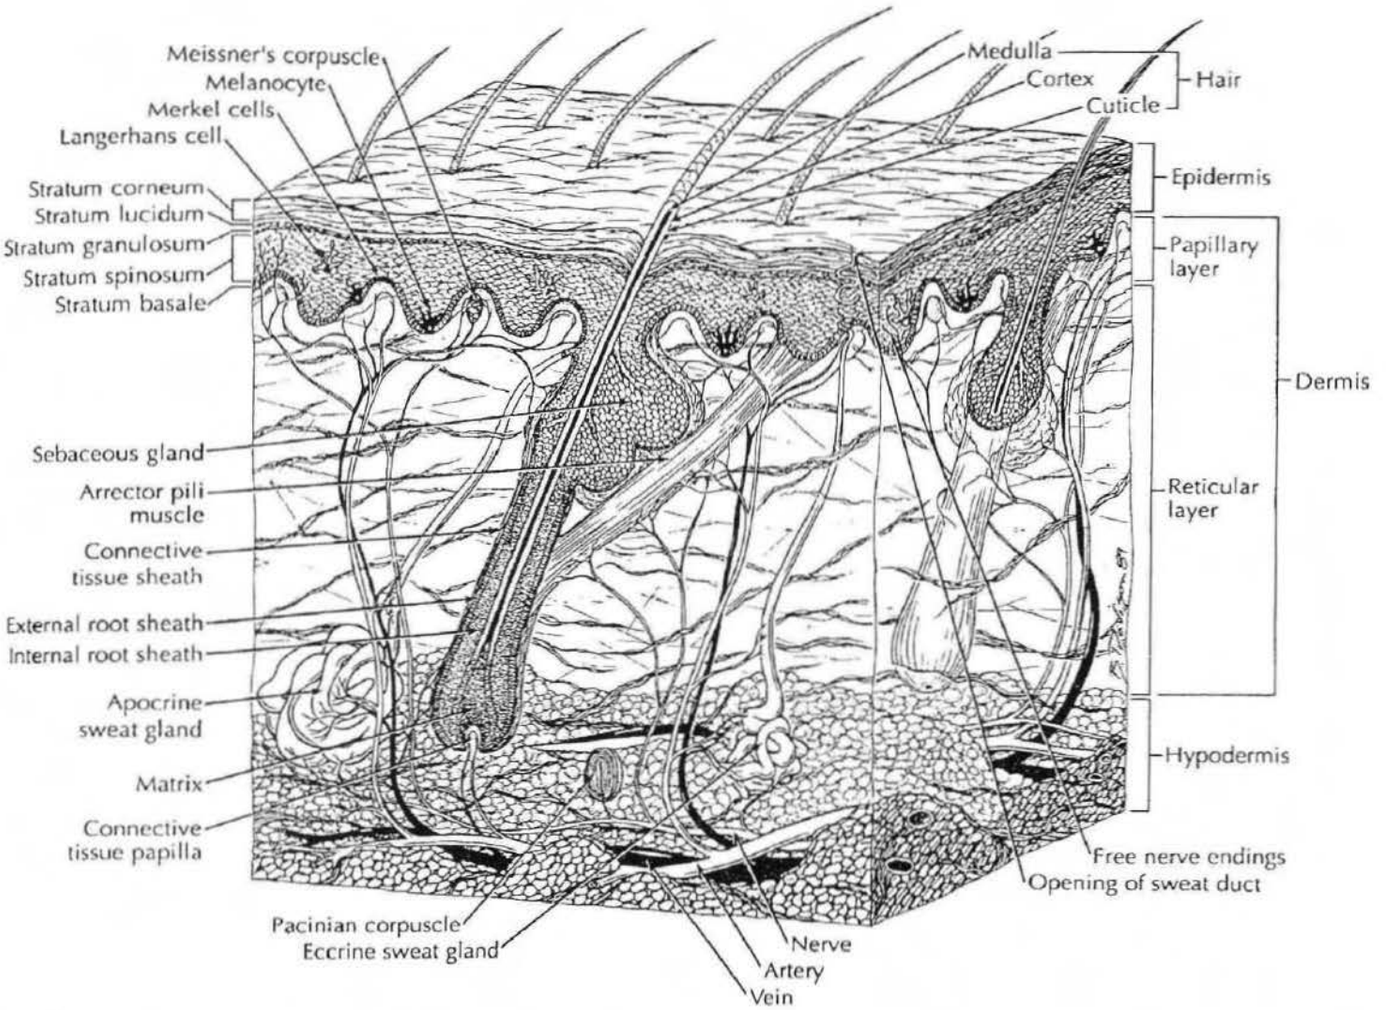

FIG. 48.1 A schematic view of the epidermis and dermis of the skin (Monteiro-Riviere 1991).

barrier of the stratum corneum. As these epidermal cells continue their migration, they form the stratum lucidum, a translucent line of cells found only in areas having very thick skin, such as plantar and palmar surfaces (footpads) and the planum nasale. These cells are translucent because both nuclei and cytoplasmic organelles are missing (Monteiro-Riviere 1991, 2006; Idsen 1975; Montagna 1967).

The stratum corneum is the final and most superficial layer of the epidermis and is its most important when considering the feasibility of topical drug therapy since it is the primary barrier to percutaneous absorption. In addition to the barrier function for xenobiotics trying to enter the body from the environment, the stratum corneum also provides a barrier to insensible water loss, an evolutionary adaptation that allows terrestial animals to exist in a nonaquatic environment. In fact, most veterinary dermatologic vehicles are targeted at this action. This layer consists of several dead layers of cells, organized into vertical columns in a tetrakaidecahedral (14-sided) configuration, the thickness of which varies depending on location (Monteiro-Riviere 1991). This particular cell shape provides a minimal surface-to-volume ratio and also minimizes systemic water loss through the skin (transepidermal water loss). Each cell is ingrained in the lipid matrix produced by the lamellated granules when the cells were still in the stratum granulosum layer. These dead cells are also surrounded by a thick plasma membrane with a submembranous layer of involucrin, also produced earlier in development. With intracellular and intercellular barriers firmly in place, the

stratum corneum has the ability to constrain the passage of unwanted chemicals and toxins from the environment. Unfortunately, the stratum corneum does not discriminate between these unwanted substances and the pharmaceuticals the veterinarian may wish to penetrate the skin for topical drug therapy for the treatment of dermatologic disease.

Melanocytes are cells located in the basal layer of the epidermis and contain dark cytoplasmic granules called melanosomes. These cells impart color to the skin, the color and intensity determined by the number, size, distribution, and degree of melanization of the melanosomes. Merkel cells are also located in the basal region of the epidermis and are thought to function as slow-adapting mechanoreceptors for touch. Langerhans cells are located in the stratum spinosum but can also be present in dermal lymph vessels, lymph nodes, and dermis. The Langerhans cells' primary function is to present antigen to lymphocytes; they may also be the initial receptors for cutaneous immune responses.

THE DERMIS. The dermis is composed of connective tissue consisting of collagen, elastin, and reticular fibers dispersed in an amorphous ground substance and can be divided into two rather poorly demarcated areas. The papillary layer consists of loose connective tissue and connects the epidermis (stratum basale/basal lamina) to the deeper reticular layer of the dermis. The reticular layer consists of dense connective tissue connected to the hypodermis, which is composed mostly of fat.

Dispersed throughout both layers of the dermis is a network of arterial and venous blood vessels needed to nourish the cells of the epidermis and dermis as well as take part in the last stages of the percutaneous absorption of compounds. Lymph vessels, nerves, apocrine and eccrine sweat glands, sebaceous glands, Pacinian (pressoreceptor), Meissner's (touch receptor), and Ruffini (mechanical receptor) corpuscles, hair follicles, and smooth muscles (arrector pili) are the other major structures found in the dermis. Two types of arteries, musculocutaneous and direct cutaneous, supply the needed nutrients to the epidermis. Direct cutaneous arteries run parallel to the skin, directly supplying the skin with blood, while musculocutaneous arteries supply both the skin and underlying musculature and run perpendicular to the skin. Cutaneous blood supply by each type of artery varies with species and location. Cutaneous blood flow rates may be one of the factors affecting the passive percutaneous absorption of chemicals. Table 48.1 clearly demonstrates this by comparing laser Doppler cutaneous blood flow parameters in nine species of domestic animals (Monteiro-Riviere et al. 1990).

SPECIES DIFFERENCES. As a general rule, skin structure and function are similar across species lines. However, some minor differences are apparent.

Avian integument possesses the most profound differences in skin morphology from other domestic species. The four layers of the epidermis are, from the deepest to the most superficial, the stratum basale, the stratum intermedium (stratum spinosum), the stratum transitivum (stratum granulosum), and the stratum corneum (stratum germinativum). Unlike mammals, avians possess no skin glands (Monteiro-Riviere 2006). The skin of aquatic mammals has a very thick stratum corneum resembling

parakeratosis and there is no stratum granulosum (Montagna 1967).

Pigskin is similar histologically to human skin (Monteiro-Riviere and Stromberg 1985) and has been used experimentally to reliably predict the percutaneous absorption of chemicals in humans (Riviere 2006). With respect to cutaneous circulation, musculocutaneous arteries are the primary vascular supply to the skin of humans, apes, and swine. Loose-skinned animals (canines and felines) lack musculocutaneous arteries; all vessels involved in cutaneous circulation travel parallel to the skin (Pavletic 1991). Recent studies of piroxicam (a nonsteroidal antiinflammatory drug) in pigs suggest that the type of cutaneous circulation may affect the local tissue concentrations of topically applied drug (Monteiro-Riviere et al. 1993). Little work has been done directly comparing the absorption of drugs and topical pesticides across veterinary species (Riviere and Papich 2001).

BIOCHEMISTRY

ENERGY PRODUCTION AND UTILIZATION. The skin, specifically the epidermis, is mostly an anaerobic organ. The absence of capillaries directly feeding oxygen to the epidermal cells makes the epidermal cells relatively oxygen poor in the normal state when compared to other tissues with a more direct blood supply. Due to this low oxygen tension, the epidermis produces 70–80% of its total energy requirements (adenosine triphosphate) through the anaerobic metabolic pathway (glycolysis), with lactic acid being the end product of glucose utilization. The epidermal cells, the most active of which are those in the single layer of the stratum basale, are the primary cells involved in this energy production, with the lactic acid end product passively diffusing into the dermis and then into the blood vasculature, eventually recycled by the liver back into glucose. Although the glycolytic pathway produces most of the energy requirements of the epidermis, other energy pathways (tricarboxylic acid cycle and pentose phosphate shunt) are also utilized to lesser degrees in some phases of epidermal growth (Freinkel 1983).

Some topically applied drugs may have an effect on energy production pathways within the epidermis. One study (Spoo et al. 1993) showed that in vitro weanling porcine skin flaps had large increases in epidermal cell glucose utilization when the skin was dosed with benzoyl peroxide. In addition to drugs, vehicles (discussed in more detail later) may also have similar effects.

DRUG BIOTRANSFORMATION. The stratum corneum is the primary line of defense to prevent percutaneous absorption of drugs. However, any drug passing through the stratum corneum may face a metabolic, rather than a physical, barrier. The skin has a remarkable ability to metabolize xenobiotics. These metabolic reactions consist mainly of oxidation, reduction, hydrolysis, and the phase I and II conjugation reactions. Enzymes present within the extracellular lipid matrix include acid lipase, phospholipase A, sphingomyelinase, glycosidases, acid phosphatases, cathepsins, and carboxypeptidases (Elias 1992). Some of these reactions are major pathways for the metabolism of topical steroids as well as other drugs such as norepinephrine, benzoyl peroxide, and benzo(a)pyrene.

Skin has been shown to metabolize organophosphate parasiticides. When parathion is topically applied to the skin and penetration through the stratum corneum occurs, it undergoes significant metabolism within the epidermis to the bioactive metabolite paraoxon and/or *p*-nitro phenol, both of which will enter the systemic circulation to possibly affect other organ systems (Riviere and Chang 1992). Additional studies have demonstrated the metabolic capabilities of skin when topically exposed to caffeine, testosterone, butylated hydroxytoluene, salicylic acid, norepinephrine, benzo(a)pyrene, and benzoyl peroxide—to name only a few—in many species of laboratory animals, as well as in human skin. Benzoyl peroxide, a popular veterinary drug used as a keratolytic and degreasing agent, is metabolized almost 100% to benzoic acid within the epidermis. In addition, the cytochrome P450 enzyme system, most commonly associated with the liver, is present and is inducible in skin (depending on the compound that was applied topically) and is the pathway that is responsible for the conversion of parathion into paraoxon in porcine skin (Riviere and Chang 1992; Mukhtar 1992; Bashir and Maibach 2005). Glutathione S-transferase, aryl hydrocarbon hydroxylase, and 7-ethoxycoumarin have also been demonstrated to exist in rat and mice epidermal cell homogenates (Raza et al. 1992). These studies all show that the skin has formidable metabolic functions as well as the traditional barrier functions.

LIPID METABOLISM. In addition to its metabolic activities, skin also has a marked ability to synthesize lipid,

which is used to construct the extracellular epidermal barrier. Epidermal cells manufacture a variety of neutral lipids, ceramides, glycosylceramides, gangliosides, sterol esters, fatty acids, alkanes, and phospholipids, which are largely found in the extracellular barrier of the stratum corneum. Some of these lipids tend to be site-specific, with phospholipids and sterols residing mostly in the basal cell layers and some sterols and neutral lipids occupying the upper regions of the epidermis, mainly the stratum corneum. The effects on percutaneous absorption by the intercellular lipid structure have been discussed in greater detail elsewhere (Wertz 1992; Potts and Francoeur 1992; Hadgraft et al. 1992; Swartzendruber 1992; Elias and Feingold 1992; Monteiro-Riviere at al. 2001). It is now accepted that this complex intercellular lipid matrix provides the primary barrier to drug penetration. It is important to realize that in some skin disease states, the overall production of lipids by the epidermal cells may be altered due to altered intracellular metabolism, subsequently followed by some alterations in the percutaneous absorption patterns of many drugs. Alterations in the epidermal cells' plasma membrane (primarily composed of lipid)—whether due directly to a drug(s), by the vehicle a drug was delivered in, or due to a disease process—may incite inflammatory reactions due to the release of inflammatory mediators (eicosanoids) from the epidermal cells or from the underlying cutaneous vasculature. Eicosanoids are a group of biologically active compounds derived enzymatically from eicosatetraenoic acid (arachidonic acid). Prostaglandins, leukotrienes, thromboxanes, and hydroxyeicosatetraenoic acids can be produced in minute quantities from arachidonic acid and have powerful proinflammatory effects on skin and the surrounding tissues. Eicosanoids are found in nearly every tissue in the mammalian body (Spannhake et al. 1981; Dunn and Hood 1977; Goldyne 1986), with some cells specializing in a certain type of eicosanoid. Skin produces several prostaglandins, including PGE_2, $PGF_{2\alpha}$, and PGI_2, as well as the lipoxygenase product leukotriene B_4.

PGE_2 induces vasodilation by elevating cyclic adenosine monophosphate in vascular smooth muscle cells, while $PGF_{2\alpha}$ causes vasoconstriction of the cutaneous vasculature by elevating cyclic guanosine monophosphate levels in vascular smooth muscle cells. In contrast to PGE_2, increased $PGF_{2\alpha}$ concentrations in skin enhance the leukocytes' response to chemotactic stimuli. $PGF_{2\alpha}$ has many effects on organs other than the skin, most notably in the reproductive tract of both humans and domestic animals. PGI_2 is a potent vasodilator produced mainly by vascular endothelial cells; it also inhibits vascular platelet aggregation. PGI_2 can be released from skin in response to some vehicles—namely, alcohols such as methanol, ethanol, and 2-propanol (Landolfi and Steiner 1984; Karanian et al. 1985). Cutaneous vasodilation has been observed in humans orally consuming alcohol (ethanol), presumably due to release of PGI_2 from vascular endothelial cells in contact with the alcohol-containing blood (Landolfi and Steiner 1984).

Leukotriene B_4 (LTB_4) is an inflammatory mediator produced from arachidonic acid via 5-lipoxygenase enzyme activity (Ford-Hutchinson 1985). As with $PGF_{2\alpha}$, LTB_4 is a potent chemotactic agent (Paulissen et al. 1990; Van de Kerkhof et al. 1991) and may also be a potent vasodilator and cause significant increases in vascular permeability when coadministered with PGE_2 (Ford-Hutchinson 1985). Although LTB_4 is most commonly produced by leukocytes, skin contains some inherent 5-lipoxygenase activity as determined from studies using stimulated human keratinocytes in culture as well as human and murine epidermal homogenates (Ruzicka 1990). These inflammatory mediator-induced changes in cutaneous blood flow may impact on the absorption and cutaneous distribution of topically applied drugs.

PROTEIN METABOLISM. The primary protein product of the skin is keratin, which is the main intracellular component of the stratum corneum. In tandem with extracellular lipid, keratin forms the major component of the epidermal barrier. Keratin primarily consists of cystine, serine, glutamic acid, arginine, aspartic acid, and glycine amino acid residues. Of significance within the keratin molecule structure is the intrachain cystine disulfide bridging that further strengthens the overall keratin macrostructure. Keratin is the major protein foundation of hair (Monteiro-Riviere 1991, 2006).

PRINCIPLES OF PERCUTANEOUS ABSORPTION: SKIN PERMEABILITY

Prior to the 20th century, many scientists believed that skin was an impermeable barrier to all substances, except possibly gases. The science of dermatology has since advanced to reveal that many substances can enter the systemic circulation via the skin. Four pathways by which

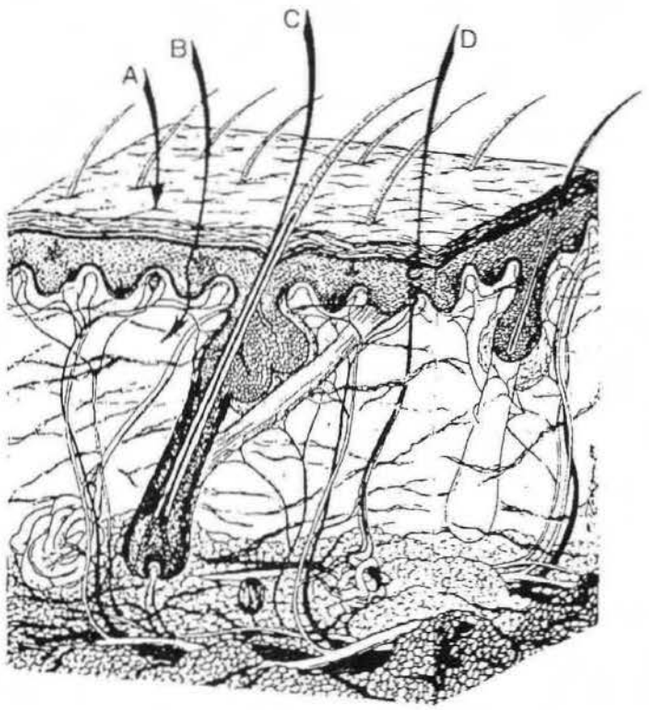

FIG. 48.2 A schematic view of the skin and the four routes of drug penetration. Drugs can penetrate through the stratum corneocytes (A), between the stratum corneocytes (B), transfollicularly via any hair follicle (C), or via an eccrine sweat gland or sebaceous gland (D).

substances can gain this access to the rest of the body have been postulated and are schematically shown in Figure 48.2.

The percutaneous absorption of drugs is important from two perspectives. Veterinary clinicians should be concerned about how much of a drug actually penetrates the skin to achieve a pharmacologic effect in treating diseases of the skin. This can be a function of several factors including vehicle selection, hydration state of the stratum corneum, partition coefficient of the drug from vehicle into the stratum corneum lipids, the integrity of the stratum corneum, and cutaneous blood flow. The other need for knowing the extent of percutaneous absorption lies in the field of public health and food consumption. Many compounds used in food animals are applied to and absorbed through the skin and enter the systemic circulation. Many of these compounds are stored in edible tissues (fat, muscle) for long periods of time, causing concern about residues in these tissues (Baynes et al. 1997; Riviere 1992).

The stratum corneum is accepted to be the major barrier, but not the only barrier, to percutaneous penetration in most species of animals. Passive diffusion is defined here as the movement of matter from one space to another space by random molecular motion. No known active transport processes are used by stratum corneum to modulate percutaneous absorption. To better understand how substances diffuse through the stratum corneum, it is convenient to think of the stratum corneum as a wall in a "brick and mortar" configuration (Elias 1983), with the bricks representing the stratum corneocytes and the mortar representing the lipid matrix around them, as shown in Figure 48.3. In this context, permeation through the stratum corneum might occur via two routes. The first involves the drug traversing through the stratum corneocytes ("bricks") and extracellular lipid matrix ("mortar"), through the cells of the deeper epidermal cells, and then into the systemic circulation. The second route involves the chemical maneuvering its way through the stratum corneum via the intercellular lipid matrix only. It is generally accepted that the primary route of penetration is via the intercellular pathway. Because of the structure of the stratum corneum and the metabolic capabilities of the lower epidermal cells, the veterinarian must be aware that only a small percentage of the drug that is topically applied is going to actually penetrate the stratum corneum. This small fraction of the total dose will need to be able to affect the disease process occurring in the underlying layers of the epidermis.

The molecular structure of the intercellular lipid matrix throughout the epidermis is in a liquid crystalline configuration, consisting of fatty acids, ceramides, triglycerides, sterols, sterol esters, cholesterol sulfate, and miscellaneous alkanes. As epidermal cells migrate superficially and transform into the cells of the stratum corneum, the lipid content surrounding these cells changes from polar to more neutral in nature. Specifically, phospholipids and triglycerides tend to decrease while fatty acids, cholesterol, cholesterol sulfate, ceramides, and sphingolipids increase as the epidermal cells differentiate (Elias 1992). Enzymes are also present within this matrix of lipid. These lipids organize themselves into a lipid bilayer structure, with the hydrophobic ends of the molecules orienting themselves with other hydrophobic ends, and the hydrophilic ends orienting themselves in a similar fashion. More than one lipid bilayer can be formed within the intercellular matrix, leading to the formation of hydrophilic and hydrophobic channels, as illustrated in Figure 48.4. One might assume

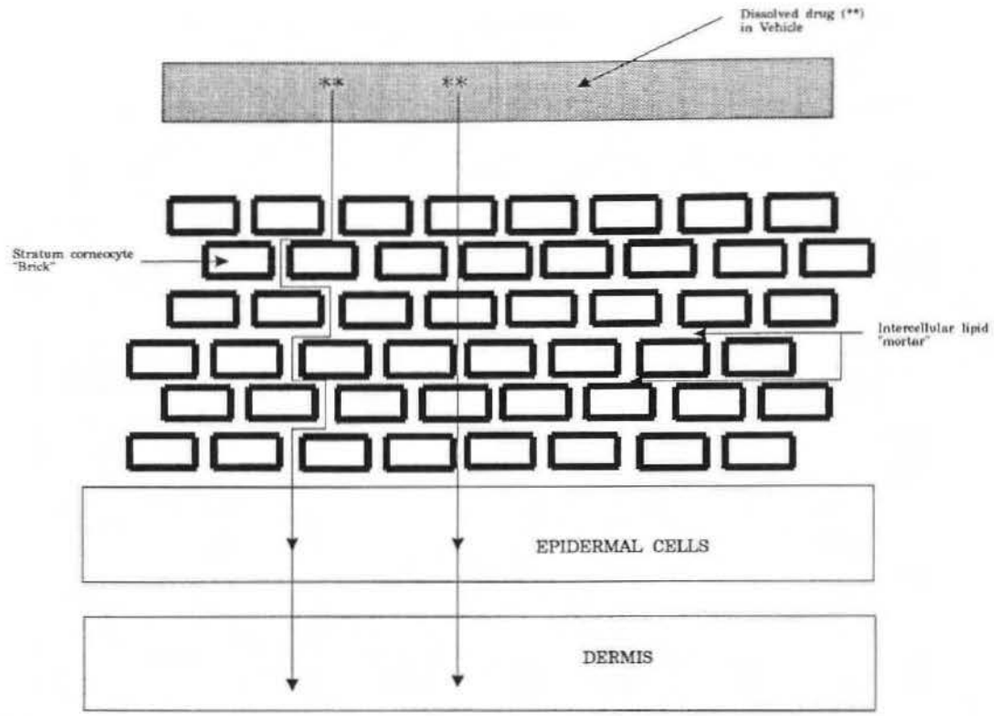

FIG. 48.3 Simplistic "brick and mortar" model of the skin. Drugs can penetrate by traveling around the stratum corneocytes through the lipid matrix, or drugs can pass through each corneocyte via the lipid matrix.

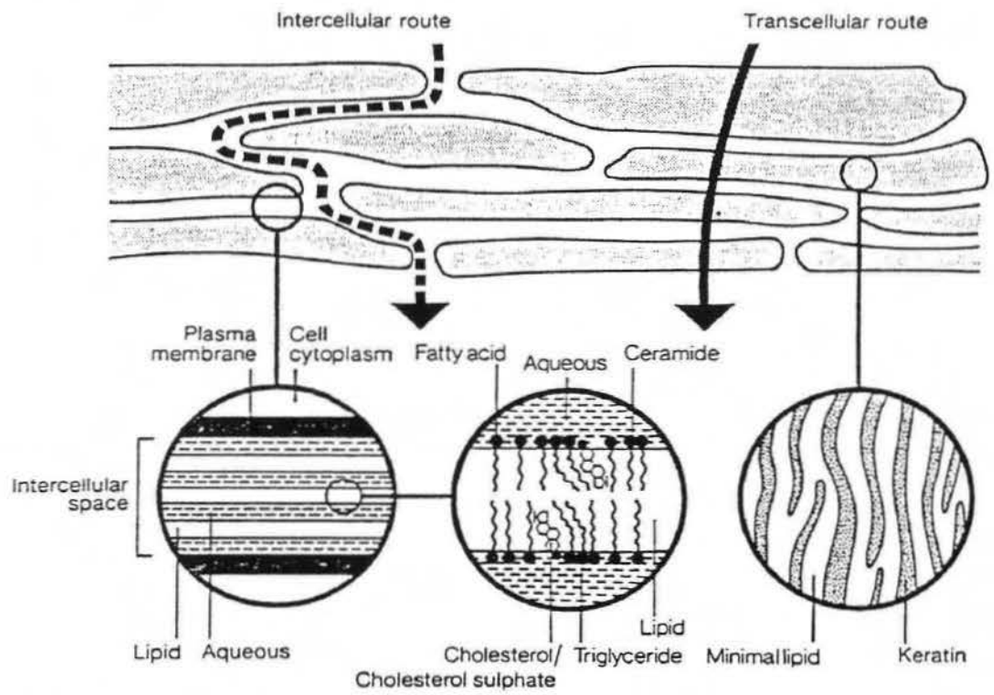

FIG. 48.4 The lipid bilayer model of the stratum corneum.

that this complex lipid barrier would result in very low absorption profiles for hydrophilic (water soluble) compounds since these molecules would have difficulty crossing a hydrophobic barrier, but some studies have shown that many hydrophilic compounds penetrate the epidermis in much higher quantities than predicted, implying that there are other mechanisms whereby hydrophilic compounds permeate the stratum corneum. The primary mechanism by which this is accomplished is for hydrophilic molecules to penetrate through fluctuations, or "kinks," in the lipid alkyl chains (Potts and Francoeur 1992; Potts et al. 1992). Further, the permeation of hydrophilic molecules (such as water, methanol, ethanol, etc.) through the lipid matrix is due to their small size and molecular weight, which aid them in traveling through the lipid matrix through passages established by the lipid alkyl chains. This view is supported by the observation that larger hydrophilic molecules have lower percutaneous absorptions than their smaller molecular weight counterparts. Alternatively, penetration may also occur through the aqueous channels formed between the polar head groups of the lipid layers.

Chemicals may also permeate the skin using the skin appendageal route, mostly by way of hair follicles and sweat ducts. The importance of the transappendageal route on percutaneous absorption is controversial, but some studies indicate that the importance of this route tends to be species-specific (Pitman and Rostas 1981). Generally, those animals possessing a sparse number of hair follicles per area of skin (humans, pigs) are considered to have little, if any, absorption of topically applied compounds via this route when compared to those animals having a high density of hair follicles (cattle, sheep). In these latter animals, the stratum corneum barrier is just as impermeable to drugs as that of their less-haired counterparts, but the drug permeates the skin barrier via the hair follicles, sweat ducts, or other openings in the stratum corneum, increasing the percutaneous absorption of the chemical. It has been demonstrated that transappendageal absorption is high initially, then becomes insignificant, due to the small surface area of follicles and glands in relation to the total surface area of the stratum corneum. Topical delivery of pesticides to domestic livestock has been used for many years for the control of external as well as internal parasites of these animals, indicating that enough of the pesticide is absorbed systemically to kill some internal parasites while not harming the host animal (Riviere 1992).

Two events must occur for a drug to be successfully delivered to the epidermis under the stratum corneum: 1) the drug must diffuse out of the vehicle and onto the surface of the stratum corneum and 2) the drug must be able to penetrate the stratum corneum (Idson 1983). Restated, the vehicle in which the topical drug is being delivered should have significantly less affinity for that drug than for the stratum corneum. In actuality, many factors enter into the release of drug from the vehicle and its penetration through the stratum corneum. These factors have been mathematically described for steady-state kinetics in Fick's first law of diffusion (Idson 1983):

$$dQ/dt = (PC)C_v\mathrm{DA}/h$$

where dQ/dt is a steady rate of penetration, PC is the drug's partition coefficient between the vehicle and the stratum corneum, C_v is the concentration of the drug dissolved in the vehicle, D is the diffusion coefficient, A is the area of skin to which the drug is applied, and h is the diffusion path length through the stratum corneum. In short, Fick's law states that the driving force causing the transfer of a drug from regions of high concentration to areas of low concentration is proportional to the concentration gradient (Idsen 1975). The diffusion coefficient is primarily correlated to the partiton coefficient of the penetrant, and can also be predicted from a knowledge of the drug's molecular volume and hydrogen bond activity (Potts and Guy 1995).

Only the nonionized moiety of a weak acid or base is available for diffusion across the stratum corneum. The pH of skin is variable and sensitive to hydration state. The typical pH of skin ranges from 4.2 to 7.3. For drugs with pK_a values within this range, the ionized fraction may vary according according to the principles governed by the Hendersen-Hasselbalch equation, which would alter the amount of drug available for absorption. This is usually controlled for in the dermatologic formulation by use of buffering systems. Theoretically, vehicles with different pH may have species-specific absorption for drugs with pKa values in this range.

TOPICAL VEHICLES

A vehicle is defined as the medium in which a medicinally active agent is topically administered. It is a gross misconception that the vehicle in which topical drugs are dissolved is inert and has little effect on the skin; in fact, the physical and chemical properties of the vehicle will largely

determine how successfully the drug will penetrate the skin. This has been clearly demonstrated with the pesticide carbaryl in pigs (Baynes and Riviere 1998). The vehicle may penetrate the stratum corneum to some extent and change the solubility of the intercellular lipid matrix. A simplistic view of the fate of topically applied drugs has been outlined in Figure 48.5.

The partition coefficient is a unitless measure of the relative affinity of a compound between a highly hydrophobic phase (usually octanol) and a hydrophilic phase (water), and is a physicochemical factor that has a major role in determining the percutaneous absorption of a chemical. As the partition coefficient increases, the compound has a greater affinity for the lipid phase and less affinity for the water phase. As discussed earlier, the intercellular matrix of the skin consists of several different types of lipid, the ratios of which may vary from site to site.

Skin penetration of many chemicals has often been correlated to the partition coefficient of the penetrant. Generally, as the log of the partition coefficient increases, lipid solubility increases and there is an overall increase in the percutaneous absorption of the compound through the skin. This scenario is not always the case, however; some poorly lipid soluble compounds (i.e., low partition coefficients) sometimes penetrate the skin much more easily than compounds with higher partition coefficients. Once penetration into the skin occurs, the molecule must eventually leave the lipid phase to be able to reach the systemic circulation. Compounds with high partition coefficients tend to remain within the lipid of the skin and form a reservoir rather than pass through; this is a well-documented phenomenon in skin (Muhammad et al. 2005). It has been shown that a log partition coefficient of 1–4 is desirable for skin penetration of most compounds.

Absorption of the vehicle into the stratum corneum is another factor to consider, since the vehicle may cause some disruptions in the composition and orientation of the intercellular lipid matrix. Partition coefficients for use in predicting the percutaneous absorption of topically applied drugs should ideally measure the index of affinity of a drug between the vehicle the drug is being delivered in and the lipid/vehicle composition of the stratum corneum. Unfortunately, few measurements of this kind are in existence because interaction of the vehicle with the stratum corneum lipids invalidates its determination. The role of partition coefficients in skin has been extensively reviewed elsewhere (Surber et al. 1990a,b; Sloan et al. 1986; Aungst et al. 1990).

The optimal vehicle is one in which the drug is soluble enough to enter into solution, but has less affinity for the vehicle than the stratum corneum lipids thereby favoring partitioning from the vehicle into the epidermis. Optimal delivery for a polar drug may thus be a relatively hydrophobic vehicle that has sufficient solubility to dissolve the drug. However, if a drug is too soluble in a vehicle relative to the stratum corneum, the drug may persist in the vehicle and only slowly release drug into the skin for as long as the vehicle stays on the skin.

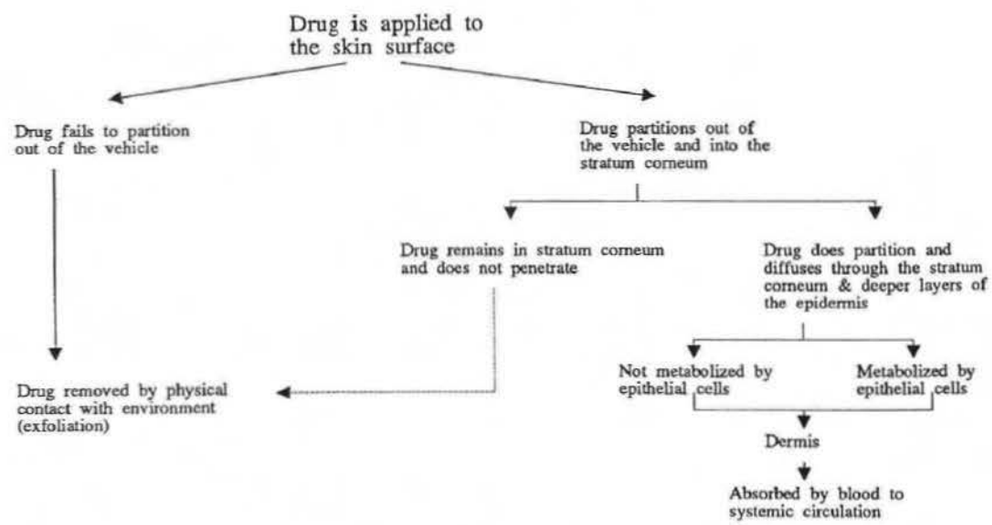

FIG. 48.5 Schematic representation of the fate of topically applied drugs.

The effect of the vehicle on chemical absorption has recently been quantitated based on competing physical chemical interactions of the drug and the vehicle versus the skin, using quantitative structure activity relationship principles (Riviere and Brooks 2005, 2007). This approach has the potential for rationally designing topical drug formulations based on physical chemical principles.

The ability of the vehicle to stay on the skin surface long enough to allow passive absorption of the drug to occur is an important factor in passive drug absorption. The vehicle can be removed by three mechanisms: 1) absorption of the vehicle through the stratum corneum, 2) evaporation from the skin surface into the surrounding air, or 3) physical removal (rubbing, licking, scratching, etc.). If the vehicle penetrates the stratum corneum more quickly than the drug, the concentration of the drug in the vehicle left on the surface of the stratum corneum will increase, which would increase the concentration of drug driving absorption, but would also have the potential of inducing precipitation of the drug onto the skin's surface. The vehicle may also change the permeability of the lipid matrix (e.g., function as an enhancer). Evaporation of the vehicle will result in a similar scenario.

Vehicles may also affect the hydration state of the stratum corneum, which in turn may affect the rate at which topically applied compounds can penetrate the stratum corneum. Occlusion of the skin significantly increases the penetration of parathion (Chang and Riviere 1993) and other compounds. The vehicle can accomplish this by modulating insensible cutaneous water loss or skin transpiration. "Transpiration" is the term used to describe the passage of water vapor from the body, through the epidermis, and out to the surrounding environment. The act of transpiration is an important factor in determining percutaneous absorption of chemicals. In the normal state, the epidermal cells below the stratum corneum are highly hydrated compared to the stratum corneum. The water in and around these epidermal cells tends to slowly "percolate" upward, following the decreasing concentration gradient of water toward the less hydrated stratum corneum, eventually passing through the stratum corneum and into the environment. This phenomenon can be noninvasively assessed by measuring transepidermal water loss (TEWL) and has been correlated to the stratum corneum permeability of hydrophilic drugs. The stratum corneum normally maintains a 10–20% hydration state. When hydration of the stratum corneum occurs, which may reach 60–80% of the total stratum corneum's mass, this water "opens" the compact substance of the stratum corneum and reduces the density of the intracellular structures, thereby decreasing the cells' resistance to passive diffusion and allowing substances to permeate more readily than in the normal, dehydrated state. Hydration of the stratum corneum can be accomplished by slowing the rate of epidermal water loss to the environment by applying occlusive emollients to the skin (petrolatum, lanolin, etc.), by applying a non–water-permeable membrane (patch), by soaking the skin in water, or by increasing the relative humidity of the air surrounding the skin (Blank et al. 1984). An increase in percent hydration from 10 to 50% in the stratum corneum can result in as much as a tenfold increase in diffusion constants (Idson 1983). This effect of environmental humidity and occlusion of the absorption of parathion through pig skin was clearly demonstrated (Chang and Riviere 1993).

Even when fully hydrated, the stratum corneum is one of the most water-impermeable biological membranes found in nature (Idsen 1975). Similarly, decreasing the hydration of the stratum corneum can decrease percutaneous absorption of substances. Dehydration of stratum corneum cells below the normal 10–15% usually results in "dry skin" and is a secondary symptom of many dermatologic diseases. Decreased stratum corneum hydration often results in a rugged and rough feeling to the skin, along with cracking, increased desquamation of the stratum corneum, and possible secondary septic or aseptic dermatitis. Dry skin can be treated by 1) treating the underlying condition causing the disease and/or 2) applying agents that will increase the hydration of the stratum corneum by slowing transepidermal water loss. Applying keratolytics (discussed later in this chapter) is also of use. This discussion should point out that selecting a vehicle that increases the amount of water in the stratum corneum will most likely result in more permeation of drug to the underlying affected tissues, an important factor in successful dermatologic therapy. In diseases involving dry skin, returning the stratum corneum to its normal hydration state should also be a goal of dermatologic therapy.

In summary, the vehicle, not just the choice of drug, plays a crucial role in determining the success or failure of dermatologic therapy. No "ideal vehicle" exists; the veterinary clinician must evaluate the patient's skin lesion and should determine what drug is indicated and which vehicle would best augment that therapy. Both factors may markedly influence the success of therapy. Pharmaceutical

classifications of topical vehicles are covered at the end of this chapter.

OTHER FACTORS AFFECTING PERCUTANEOUS ABSORPTION. Other factors that may enhance or hinder percutaneous absorption are the molecular weight of the chemical, temperature, blood flow, and skin age. Increasing the blood flow through the dermis would suggest a more rapid removal of drugs absorbed from the epidermis (Riviere and Williams 1992). Vasoconstriction of these vessels has been shown to significantly decrease percutaneous absorption of 6-methylprednisolone and testosterone (Malkinson 1958). The temperature of the air surrounding the skin plays a role in blood flow, with warmer environmental temperatures or skin showing one of the cardinal signs of inflammation (heat) increasing the blood flow to the skin and cooler temperatures decreasing cutaneous blood flow. An inverse relationship appears to exist between absorption rate and the molecular weight of the drug (Idsen 1975). Although smaller molecules tend to increase total topical dose absorbed through the skin, there is considerable variability in the amounts percutaneously absorbed among compounds of similar molecular weights (Idsen 1975; Tregear 1966).

PENETRATION ENHANCERS. The stratum corneum has been portrayed as a formidable and almost impenetrable barrier to the absorption of lipophilic, hydrophilic, and amphoteric xenobiotics. Many efforts have been made to adjust the barrier of the stratum corneum to increase the percutaneous absorption of topically applied xenobiotics, for the most part with only limited success. The barrier function of the stratum corneum can be structurally modified using a relatively small class of compounds, collectively known as penetration enhancers or penetration accelerants, that increase the percutaneous absorption of many compounds.

Many reports exist in the human and veterinary literature of various agents that have been shown to accelerate penetration of compounds through the skin, but few describe the precise mechanism by which an individual penetration enhancer performs this function. One theory, the lipid-protein–partitioning concept, has been proposed for the mechanism of action of all the known penetration enhancers, including penetration via the intercellular as well as the intracellular routes (Barry 1991). For both routes, this theory acknowledges that polar (hydrophilic) molecules permeate the skin via polar channels (either by aqueous pores or by alkyl group modulation), which are different from the channels used by nonpolar (hydrophobic) molecules. After application to the skin surface, the drug molecules diffuse out of the vehicle and into the stratum corneum and begin to traverse the many aqueous and lipid barriers found in the intercellular matrix (see Fig. 48.4) in order to reach the rest of the body via the systemic circulatory system. Penetration enhancers are hypothesized to modify these lipid and aqueous bilayers of the intercellular lipid matrix and allow topically applied compounds to penetrate the stratum corneum more readily by disrupting the normally very organized structure of the lipid layers.

It is convenient to organize the known penetration enhancers into four common subgroups: azone and its derivatives, urea and its derivatives (1-dodecylurea, 1,3 didodecylurea, 1,3 diphenyl urea, propylene glycol, dimethylisosorbide), the terpenes (carvone, pulegone, piperitone, menthone, cyclohenene oxide, terpinen-4-ol, and others), and the aprotic solvents (dimethylsulfoxide, demethyl formamide, decylmethyl sulfoxide, 2-pyrrolidone, and others). At the present time, the first three groups are used almost exclusively in human pharmaceutical products and research and will not be discussed here. The most extensively used penetration enhancer in veterinary medicine is dimethylsulfoxide (DMSO).

DMSO is a product from the processing of wood pulp and is a dipolar and aprotic solvent. DMSO is also produced by phytoplankton and is present in many foods (Herschler 1982). DMSO has been used to treat a myriad of skin ailments, including otitis externa, interdigital cysts, lick granulomas, superficial burns, skin grafts, and snakebites; and to reduce the engorgement of the mammary glands of the nursing bitch (Knowles 1982). Other less common veterinary uses for DMSO have also been described (Jacob et al. 1965; Jacob 1982; Knowles 1982). In addition to penetration enhancement, DMSO is also bacteriostatic, vasodilatory, fibrinolytic, antiinflammatory, and produces some degree of topical analgesia. DMSO produces a thermal effect after direct application to the skin, which may function to alleviate pain in the skin and in the underlying muscle and bone. The transient erythema that is induced after topical administration of DMSO is due to the release of histamine (Jacob et al. 1965). These effects are considered transient and reversible and will not generally increase in severity after multiple

treatments, indicating no need to discontinue therapy. Potential skin irritation occurs at concentrations of greater than 70% (see previous editons of this text for more information on DMSO).

DMSO has the potential to enhance the percutaneous absorption of a number of topically applied compounds. The exact mechanism of this percutaneous absorption enhancement has not been clearly elucidated. DMSO appears to produce only minor morphological changes in the skin. Penetration enhancement of topically applied chemicals dissolved in DMSO does not appear significant until the DMSO concentrations approach 50–60%, with overall permeability of the compound tending to increase as the concentration of DMSO applied to the skin approaches 100% (Kurihara-Bergstrom et al. 1987). Many mechanisms have been proposed to attempt to explain why DMSO enhances the percutaneous absorption of such a wide variety of compounds. Possible mechanisms include elution of stratum corneum lipids and delamination of the horny layer by stress resulting from crosscurrents of highly water interactive DMSO and water (Kurihara-Bergstrom et al. 1986). Sharata and Burnette (1988) determined that in nude mice skin, DMSO transformed the highly compact cell contents of the basal stratum corneum (keratin) into a looser meshwork of filamentous bundles, resulting in much more porous intracellular structure with an increase in intracellular surface areas, which they believed might increase percutaneous transport. Whatever the mechanism, DMSO has been shown to enhance the percutaneous absorption of many compounds, including water, hydrocortisone, salicylic acid, tubocurarine HCl, multiple glucocorticosteroids and antibiotics, estradiol, hexachlorophene, phenylbutazone, and a host of other topically applied chemicals.

Finally, recall that there is no universal penetration enhancer or vehicle, e.g., pluronic lecithin organogel (PLO) gel, that would be optimal for the delivery of all classes of topical drugs across the skin of all species. Carefully controlled studies have begun to show lack of transdermal delivery of drugs via this approach (Hoffman et al. 2002; Mealey et al. 2004). Selection of an optimal vehicle for transdermal delivery of a drug requires a close match between the physical chemical properties of the drug, vehicle, and skin lipids.

ELECTRICALLY ASSISTED TRANSDERMAL DRUG DELIVERY. An alternate approach to overcome the stratum corneum permeability barrier is by using electrical (iontophoresis) or ultrasonic (phonophoresis) energy, rather than the concentration gradient of diffusion, to drive drug through the skin (Riviere and Heit 1997). These techniques hold the most promise for delivering large drugs such as peptides and oligonucleotides that now can be administered only by intravascular injection. With these techniques, dose is based on the application surface area and the amount of energy required to actively deliver drug across the skin. In iontophoresis, this amounts to a dose being expressed in mAmps/cm^2. Formulation factors are also very different, since many of the components used are also delivered by the applied electrical current in direct molar proportion to the active drug. Finally, a recent but related strategy is to employ very short-duration high-voltage electrical pulses (electroporation) to reversibly break down the stratum corneum barrier, allowing larger peptides, and even small proteins, to be delivered systemically (Riviere et al. 1995). These approaches, if applied to veterinary medicine, could have implications for the use of controlled transdermal delivery as a viable method of drug delivery.

CLASSIFICATION OF DERMATOLOGIC VEHICLES

As discussed in the introduction to this chapter, the defining difference between dermatologic and other treatment areas of veterinary pharmacology is the topical route of administration coupled with the overriding influence that the dosage vehicle exerts on absorption and activity of the applied drug. The vehicles used as veterinary dermatologics have been historically classified into seven broad categories (Harvey 1985a,b; Block 1985; Rippie 1985; Swinyard 1985; Swinyard and Lowenthal 1985; Nairn 1985).

ADSORBENTS AND PROTECTIVES. Adsorbents and protectives are used extensively in many veterinary pharmaceutical preparations. Adsorbents act by binding gases, toxins, and some organisms (such as bacteria) to prevent exposure to the damaged skin surface. Protectives function by providing an occlusive layer of protection from the external environment or by providing mechanical support to the affected area. Protectives and adsorbents can be further subdivided into two subclasses: dusting powders and mechanical protectives.

Dusting powders are generally inert and innocuous substances. They include starch, calcium carbonate, talc, titanium dioxide, zinc oxide, and boric acid. Many are used in drug formulations alone or as a vehicle for the delivery of other drugs. If the powder particle has a smooth surface, it will act mainly to prevent friction, thus protecting abraded and raw skin surfaces; powder particles with rough or porous surfaces act on the skin by absorbing moisture. Water-absorbing powders tend to coalesce and eventually occlude the skin's surface when wetted and therefore should not be used on wet, moist, or highly exudative skin surfaces. Powders that also contain starch or other carbohydrates that are allowed to cake onto these moist skin surfaces give bacteria and fungi (mainly *Candida* spp.) a source of energy, allowing them to proliferate. This may lead to a secondary bacterial and/or fungal skin infection or exacerbation of an existing microbial skin infection. Powders should not be used within body cavities (thorax, abdomen) or in skin abscesses, especially those powders containing talc. Talc has been shown to promote severe granulomatous reactions when used in these areas but is relatively innocuous when used on intact skin surfaces.

Mechanical protectives provide an occlusive film that protects the underlying skin from irritants present in the external environment (ultraviolet radiation, contact irritants, toxins), provide mechanical support, and are popular vehicles for many drugs. Many members of this subgroup are used to treat cutaneous ulcers and other hard-to-heal cutaneous wounds. Compounds in this group include kaolin, lanolin, anhydrous lanolin, mineral oil, olive oil, peanut oil, petrolatum, zinc stearate, and recently a number of synthetic polymers.

DEMULCENTS. Demulcents are generally high molecular weight compounds that are water-soluble and function by alleviating irritation (*demulcere,* "to smooth"). Like the compounds listed in the protectives group, demulcents can coat the surface of damaged skin and protect the stratum corneum and underlying cellular structure of the epidermis by forming a protective barrier against the surrounding environment. They differ from protectives in that they inherently reduce the irritation from these external stimuli. This group comprises a large and diverse number of chemicals, including mucilages, gums, dextrins, starches, polymeric polyhydric glycols, glycerin, gelatin, hydroxypropyl cellulose, hydroxypropyl methylcellulose, hydroxyethyl cellulose, methyl cellulose, polyvinyl alcohol, and recently silicone-based polymers such as dimethicone. The dried gum extracts from the acacia and tragacanth plants can readily dissolve in water to form mucilages (see previous editions of this text for more detail). The most commonly used demulcents in veterinary dermatology today are glycerin, propylene glycol, and the polyethylene glycols.

Glycerin is a hygroscopic, trihydric alcohol prepared from propylene and has been used for many years as a suppository, with high concentrations of this vehicle relieving constipation by drawing water from the body and into the colon. Glycerin is a clear, colorless liquid that is miscible with water and alcohol and has been used neat to reduce corneal edema and to facilitate ophthalmoscopic examinations. Used in high concentrations topically on the skin, glycerin may dehydrate and irritate the skin, thereby increasing transepidermal water loss. Lower concentrations of glycerin absorbed into the skin hydrate the stratum corneum because of glycerin's hygroscopic nature. Despite its side effects, glycerin makes an excellent vehicle for topical drug delivery when used at lower concentrations.

Propylene glycol (1,2 propanediol) is a hygroscopic, colorless, odorless water-soluble liquid that is miscible with many compounds (water, alcohols, acetone, many volatile oils) and is also bacteriostatic, fungistatic, and nonocclusive. It was first considered for use in 1932 to be used with a drug to treat human syphilis and has since been used as a nontoxic antifreeze in dairies and beer breweries (Catanzaro and Smith 1991). Propylene glycol is an ideal medium for the topical delivery of many drugs in animals and humans, as well as for many oral and parenteral drug formulations, such as antitussives and shampoos. Propylene glycol spreads evenly onto the skin's surface and has a very low evaporation rate; it is not greasy to the touch, does not stain clothing or hair, and has some effect on slowing transepidermal water loss, thereby hydrating the stratum corneum to some extent. Topical hypersensitization and other toxicities are rare but have been reported (Catanzaro and Smith 1991).

Polyethylene glycols are a group of structurally similar compounds that differ in molecular weight. The larger the number, the higher the molecular weight and the more viscous the formulation becomes. At ambient temperature, polyethylene glycols 200, 300, 400, and 600 are clear

viscous liquids; polyethylene glycols 900 to 9000 are semihard waxy solids at room temperature. As a group, the polyethylene glycols do not easily hydrolyze and are nontoxic, bland, highly water soluble, and nonvolatile.

EMOLLIENTS. Emollients are bland, fatty materials often used to soften or moisten the skin. Emollients are particularly useful when treating skin conditions resulting from water-soluble irritants and airborne bacteria because of their ability to act as a protectant, sequestering the damaged skin away from these noxious stimuli. When used topically, emollients soften skin by decreasing transepidermal water loss, or transpiration (discussed earlier), and increasing the hydration of the stratum corneum. Therefore, this is a useful group of compounds for treating dermatologic conditions involving dry, crusty, or flaky lesions of the epidermis. Emollients are used today as vehicles for many lipid-soluble drugs. Examples of commonly used emollients are listed in Table 48.2.

ASTRINGENTS. Astringents precipitate protein, toughen the skin, promote healing, and dry the skin when applied topically. When used to coagulate blood, astringents are said to be styptic and elicit a mildly uncomfortable sensation when applied to small open wounds. Most of the chemicals in this group are inorganic salts of aluminum, zinc, potassium, and silver, and include aluminum chloride, aluminum sulfate, calamine (a combination of Fe_2O_3 and ZnO_2), potassium permanganate, silver nitrate, zinc chloride, zinc oxide, zirconium chlorhydrate, and tannic acid. There are many germicidal agents that also have astringent activity. Other astringents are of vegetable origin, most of these preparations owing their activity to tannic acid (gallotannic acid). Astringents in the vegetable-derivative group include gallic acid, kino, krameria, and rubus (blackberry) (see previous editions of this text for more detail). Astringents have limited uses in veterinary medicine today.

RUBEFACIENTS, IRRITANTS, AND VESICANTS. Chemicals in this class are used to induce hyperemia (rubefacients), hyperemia and inflammation (irritants), or cutaneous blisters (vesicants). Heat applied to the skin via a hot-water bottle, heat lamp, moist hot pack, or an electric heating pad are acceptable rubefacients and are extensively used in human medicine. Chemical rubefacients are more commonly used in veterinary medicine, mainly due to the difficulty in applying the heat sources listed above for extended lengths of time. An abbreviated list of chemicals that are known rubefacients, irritants, or vesicants includes anthralin, camphor, coal tar, cresote, ichthamnol, menthol, methyl salicylate, resorcinol, cantharidin, black mustard, iodine, mercuric iodide, capsicum, chloroform, alcohols, turpentine, thymol, and pine tar. With the exception of coal tar, most members of the chemical group are not commonly used in modern veterinary practice because of their potential toxicity. Coal tar is a component found in many veterinary dermatology preparations (especially shampoos) and is a by-product of the distillation of bituminous coal. Photosensitization has been reported to occur. Coal tar should not be used on cats, because of frequent irritant or allergic reactions. Camphor is a rubefacient that has been used in some topical preparations and has some mild analgesic activity. It is of limited use in the treatment of mild pruritus. Similarly, menthol stimulates sensory nerve endings, inducing a feeling of coolness, induces mild analgesia, and is also a mild antipruritic (Harvey 1985).

TABLE 48.2 Emollients in use today

Official Vegetable Oils	Animal Fats	Hydrocarbons
Olive oil	Lanolin (wool fat with water added)	Paraffin
Cottonseed oil	Anhydrous wool fat (no water added)	Petrolatum
Corn oil	Lard	White petrolatum (vasoline)
Almond oil	Whale oil	Mineral oil
Peanut oil		White/yellow waxes (beeswax)
Persic oil		Spermaceti
Cocoa butter		

CAUSTICS AND ESCHAROTICS. Caustics (also known as *corrosives*) are agents that will destroy tissue after one or more applications. Escharotics are corrosive and will also precipitate proteins, leading to the formation of a scab and eventually a permanent scar. As with the rubefacient, irritant, and vesicant group, many of the caustics and escharotics have few uses in veterinary dermatology today. Historically, caustics have been used to induce desquamation of the stratum corneum (keratolytic) and to treat warts, keratoses, and other hyperplastic skin diseases. Escharotics have also been used to seal cutaneous ulcers and wounds. Examples of this group include glacial acetic acid, alum, aluminum chloride, gentian violet, phenol, potassium hydroxide, salicylic acid, and silver nitrate.

KERATOLYTICS, KERATOPLASTICS, AND ANTISEBORRHEICS. Keratolytics function by loosening keratin, which facilitates the desquamation of the stratum corneum, whereas keratoplastics attempt to "normalize" keratinization by slowing basal cell proliferation through inhibition of DNA synthesis. Other mechanisms may also contribute to this effect. Antiseborrheics attempt to modulate sebum production in the skin. Many of the keratolytics available today are also keratoplastic and/or antiseborrheic; therefore, these functions are discussed together. Most keratolytics and antiseborrheics are also cutaneous irritants, which may, in some cases, preclude their use on diseased skin in some animals (Shanley 1990). Several keratolytics and antiseborrheics used in veterinary dermatology are discussed below.

Salicylic acid (2-hydroxybenzoic acid) is used topically as a keratolytic, keratoplastic, and antiseborrheic agent and has some mild antibacterial and antifungal actions. Salicylic acid (2–10%) causes the dead or dying cells of the stratum corneum to hydrate, swell, and soften, thereby hastening their desquamation, and solubilizes the intercellular lipid layer, releasing the cells of the stratum corneum from each other. Salicylic acid is used extensively in veterinary dermatology to treat many keratoproliferative diseases. Topical use of salicylic acid may cause an irritant dermatitis in animals and has been studied extensively in both humans and many animal models (Weirich 1975; Nook 1987; deMare et al. 1988; Sloan et al. 1986; Roberts and Horlock 1978).

Benzoyl peroxide is a keratolytic and antiseborrheic agent that is also a strong oxidizer, free-radical generator, and antimicrobial and has been used in veterinary and human dermatology for many years. The majority of topically applied benzoyl peroxide is metabolized to benzoic acid by the viable epidermal cells during penetration through the skin (Holzmann et al. 1979; Nacht et al. 1981). Benzoyl peroxide in high concentrations can cause skin irritation and was identified as being a skin tumor promoter in SENCAR mice if used in tandem with 7,12-dimethylbenz(a)-anthracene (Slaga et al. 1981; Epstein 1988; Schweizer et al. 1987). The bactericidal activity associated with benzoyl peroxide comes from its ability to generate free radicals, which disrupt bacterial cell membranes. Due to its bactericidal activities, benzoyl peroxide is indicated in the treatment of pyodermas (Ihrke 1980a,b) as well as in diseases that cause keratosis. Transient stinging or burning sensations after application to the affected site have been reported in humans.

Resorcinol (*m*-dihydroxybenzene) is a keratolytic agent that also has bactericidal and fungicidal properties. Like urea (discussed below), it acts as a protein precipitant and promotes hydration of the keratin, resulting in its keratolytic function. Resorcinol may be used alone or compounded with other mild keratolytic agents, such as sulfur or salicylic acid.

Sulfur is a keratolytic, keratoplastic, and antiseborrheic agent used in a variety of topical agents. Sulfur is also antibacterial and antipruritic and has a mild follicular flushing action. The keratolytic activity of elemental sulfur is thought to be related to an inflammatory process that ultimately causes a sloughing of the stratum corneum. The formation of hydrogen sulfide and pentathionic acid is responsible for some of its keratolytic and antibacterial properties. The keratoplastic effect is most likely similar to that of the coal tars, being cytostatic (Miller 1986).

Retinoids are a class of naturally occurring or synthetically manufactured compounds that have vitamin A-like (retinoic acid) activity. Retinol (vitamin A alcohol) is the most potent analog and is metabolized to two other retinols, retinal and retinoic acid. In the early 20th century, researchers documented the importance of vitamin A in reproduction, vision, and epidermal cell growth promotion, along with its functions in differentiation and maintenance of epithelial cell surface structure, including that of the skin (Kwochka 1989). It was also found that *some* dyskeratotic skin diseases could be correlated to low levels of vitamin A, which eventually led to the therapeutic use of vitamin A to treat these skin diseases. The use of vitamin A was limited, however, as the levels needed to induce a clinical improvement of the lesions often induced signs of

hypervitaminosis A. This side-effect dilemma prompted research into vitamin A substitutes, which led to the discovery and testing of over 1,500 retinoids. Three retinoids—tretinoin, isotretinoin, and etretinate—are available for clinical use today.

The retinoids, like vitamin A, act as growth and differentiation regulators in the skin when administered orally or topically. Although the exact mechanism by which the retinoids exert these effects is not completely understood, it is theorized that retinoids alter RNA synthesis within the cell, in turn altering protein synthesis and prostaglandin production, and also affecting some enzymes, such as ornithine decarboxylase and collagenase (Power and Ihrke 1990). The overall effect of the retinoids is to "normalize" the epithelium in those diseases responsive to these drugs.

In humans, the retinoids are used to treat severe recalcitrant cystic acne, psoriasis, Darier's disease, pityriasis rubra pilaris, and various other disorders of keratinization. Retinoids also have an ability to control malignant transformations in some tissues that are caused by chemical carcinogens, ionizing radiation, growth factors, and viruses. Naturally occurring retinoids have been shown to protect animals against skin papillomas and carcinomas of the skin and other organs (Griffiths and Vorhees 1994; Kwochka 1989). Numerous side effects have been associated with retinoid use in humans, including cheilitis, xerosis of the skin, pruritus, dryness of mucous membranes, epistaxis, thinning of the hair, palmoplantar desquamation, conjunctivitis, headache, ataxia, fatigue, psychologic changes, and visual disturbances. Tetragenicity is a serious problem in women who take isotretinoin during pregnancy. Symptoms of hypervitaminosis A may also occur, which is characterized by demineralization and thinning of the long bones, cortical hyperostosis, periostitis, and premature closure of the epiphyses (Kwochka 1989).

Retinoids are not used to a great extent in veterinary medicine (Werner and Power 1994). Reported uses of any of the retinoids in dogs and cats are few, and the recommendations for use and possible toxicities and side effects are based on a very small number of animals. Indications for veterinary use remain rather vague, in part because the skin diseases that retinoids may be efficacious in treating in humans do not have exact analogs in domestic animals. There is also a lack of formal studies conducted on large populations of dogs or cats. Reported uses for the retinoids in domestic animals are in disorders of keratinization, which may include primary idiopathic seborrhea in Cocker Spaniels, sebaceous adenitis, canine lamellar ichthyosis, Schnauzer comedo syndrome, and epidermal inclusion cysts, among others (Power and Ihrke 1990; Kwochka 1989). The use of retinoids in cats with neoplastic disorders, specifically squamous cell carcinoma and epidermal dysplasia, has been investigated and found to be of limited value (Evans et al. 1985). Toxicities to the retinoids in animals seem to be few, but it should be made clear that the reported side effects and toxicities are based on a small population of clinically ill animals treated for short periods of time with these compounds and these observations may prove to be inaccurate if the use of these compounds increases. Out of 29 dogs treated with isotretinoin in one study (Kwochka 1989), four dogs developed conjunctivitis that was observed to be reversible after treatments ended. There is no formal information available as to the existence of skeletal anomalies in dogs given retinoids for long periods of time (Power and Ihrke 1990). Birth defects involving the central nervous system, skeleton, thymus, and heart do occur, as seen with high doses of vitamin A during pregnancy. Cats appear to have a higher incidence of side effects associated with retinoid treatment. Cats treated with isotretinoin were observed to develop periocular erythema, periocular crusting, epiphora, and blepharospasm (Kwochka 1989).

Isotretinoin (Accutane, Roche; 13-*cis*-retinoic acid) and etretinate (Tegison, Roche) are two systemically used retinoids that also have potential veterinary applications. Power and Ihrke (1990) describe several cases where these two retinoids have been used to treat several skin diseases in dogs, with variable success. Isotretinoin is the most effective inhibitor of sebum production known (Kwochka 1989), making it potentially useful in treating primary idiopathic seborrhea and comedo syndromes. Although retinoids are associated with less toxicity than vitamin A, toxicities can occur. Etretinate may be associated with fewer toxic side effects than isotretinoin. Insufficient data are available for dogs or cats to determine its efficacy or toxicity.

Coal tar is another pharmaceutical that has keratolytic as well as keratoplastic and antiseborrheic activity. Its mechanism of action and general uses have been discussed previously. Coal tar products should not be used in the feline due to frequent irritant and allergic reactions.

Urea is a product of protein metabolism that, when used topically, acts as a protein denaturant, promoting the hydration of keratin. Once the treated areas of keratin swell, mild keratolysis ensues. The use of urea alone as a

keratolytic agent is not common in veterinary dermatology today.

Selenium sulfide is an externally applied antiseborrheic, keratolytic, and keratoplastic compound that also has some antidandruff activities. Selenium sulfide exerts these actions by its antimitotic activity, slowing cell proliferation and sebum production, and tends to be irritating (especially if used in long-term treatment protocols) and also stains hair. It also causes irritation of the mucous membranes, so care should be taken to avoid contact with these tissues. Percutaneous absorption is minimal if applied to intact skin.

CLASSES OF MEDICATED APPLICATIONS

Pharmaceuticals can also be classified by the type of base in which they are formulated. There are eight classes of medicated applications (Harvey 1985; Block 1985; Rippie 1985; Swinyard 1985; Swinyard and Lowenthal 1985; Nairn 1985).

OINTMENTS. Ointments are semisolid preparations that usually (but not always) contain drugs used to treat dermatologic diseases. There are five classes of ointments commonly used in veterinary medicine.

Hydrocarbon Bases. These emollient ointment bases usually are composed of vegetable oils and animal fats. Common members of this subset include spermaceti, cetyl esters wax ("synthetic spermaceti"), oleic acid, olive oil, paraffin, petrolatum, white petrolatum, white wax, and yellow wax. Hydrocarbon base ointments are emollient and generally hydrophobic and occlusive, causing an increase in the hydration of the stratum corneum and underlying epidermal cell structure by decreasing transepidermal water loss, making them useful in rehydrating or softening the skin. Disadvantages include greasiness and their ability to stain clothing; also, they cannot be washed off in water, making them difficult to completely remove from the skin.

Anhydrous Absorption Bases. This type of ointment base contains very little (if any) water after preparation but differs from the hydrocarbon bases in that it will readily accept any water molecules it comes in contact with. Absorbent ointment bases can absorb large quantities of water and still keep their thick consistency. Examples of this subgroup include hydrophilic petrolatum and anhydrous lanolin, both of which are emollient, occlusive, and greasy.

Water-Oil Emulsion Bases. Emulsions, by definition, are oil and water combinations. Water-in-oil emulsion bases ("creams") are water-washable bases that are easily removed from the skin surface and contain more oil than water on a percentage basis. The oil phase usually consists of petrolatum or liquid petrolatum and perhaps an alcohol (cetyl or stearyl alcohol). The aqueous phase may consist of water; however, other aqueous vehicles may be used, such as propylene glycol, polyethylene glycol, or glycerin, to which various preservatives (such as paraben derivatives) are usually added. Water-in-oil bases are emollient (due to the higher percentage of oil than aqueous phase), occlusive, greasy, and may absorb some water, but not to the same degree as the anhydrous absorption bases. Other common components of water-in-oil emulsion bases include glyceryl monosterate and stearic acid.

Oil-Water Emulsion Bases. Oil-in-water emulsions are manufactured in the same manner as the water-in-oil bases, with the exception that the aqueous phase is in a higher percentage than the oil component. The same ingredients are also used to make the oil-in-water bases. Because of the higher water (or other aqueous phase) content, oil-in-water bases are water-washable, nongreasy, and nonocclusive.

Water-Soluble Bases. As the name implies, these bases have lost their hydrophobic lipid base components. These demulcent bases are primarily composed of polymers that are completely water soluble and usually anhydrous, do not easily hydrolyze, do not support mold growth, and are nongreasy, nonocclusive, and nonvolatile. If the components of a preparation contain water-soluble bases in a gelled medium, they are referred to as *gels*. Gels are a combination of propylene glycol, propylene gallate, disodium EDTA, and carboxypolymethylene that results in a clear, water-miscible, and relatively greaseless formulation. A commonly used drug in a gel formulation is DMSO (Domoso, Diamond). Glucocorticosteroids may also be formulated in this way.

POULTICES. A poultice (or cataplasm) is a soft moist mass of materials applied locally to an affected area and

was historically composed of roots, herbs, seeds, and even mud in a gruellike base. The poultice was intended to be a topical wound treatment serving as a counterirritant and absorptive/adsorptive sink. Poultices are rarely used in veterinary medicine today.

PASTES. Pastes are absorptive powders placed in a gelatinous base, usually petrolatum or hydrophilic petrolatum. Pastes have been used to adhere to the skin and thereby act as a "sponge" to absorb exudates and moisture and also as a physical barrier to protect the skin from the external environment. Pastes are easily removed from the skin and can be used on moist lesions of the skin.

POWDERS. Powders have been discussed earlier in this chapter as a class of vehicle for the delivery of topical drugs to the skin. Powders are commonly used in veterinary medicine to deliver pesticides (carbaryl, permethrins, etc.) for the control of external parasites (mainly fleas) and in-large animal veterinary dermatology to deliver antibiotics, such as nitrofurazone, to wounds.

DRESSINGS. Dressings are external applications of some previously discussed compounds (petrolatum, ointments) on an application device such as plastic wrap or sterile gauze and are placed over wound sites to protect the skin lesion from external environmental trauma. Dressings may also contain antimicrobial agents, such as nitrofurazone.

PLASTERS. Plasters are similar to dressings; however, they are attached to the skin via some adhesive material. They protect skin lesions from the external environment and provide an occlusive environment. Plasters have limited use in veterinary medicine today.

SUSPENSIONS. A suspension is a two-phase system composed of a finely divided solid that is dispersed in a liquid, usually water. Suspensions are not utilized to any great degree in veterinary dermatology today. They are more commonly used in oral drug preparation schemes. The most common type of suspension currently used topically is captan (Orthocide, Chevron Chemical), which is used to treat some types of superficial fungal infections and which also has some limited bacteriostatic properties.

LOTIONS. Lotions are powders dissolved in a liquid, usually water or an alcohol. Lotions, like powders, tend to be cooling, drying, and somewhat mildly antipruritic. Lotions have limited applications in veterinary medicine but are used extensively in human over-the-counter skin-care products.

DERMATOTHERAPY: ATOPIC DERMATITIS

One dermatologic disease—atopic dermatitis—deserves specific mention: because it is a common clinical syndrome with various stages of presentation and potential initiating etiologies. Olivry et al. (2003) have summarized an analysis of some 40 clinical trials published in peer review journals that assessed the efficacy of 41 different drug interventions for treatment of canine atopic dermatitis. Fatty acid supplementation and allergen-specific immunotherapy were not assessed.

This analysis suggests that there was good evidence for using oral glucocorticoids and cyclosporine and fair evidence for the use of topical triamcinolone spray, topical tacrolimus lotion, oral pentoxifylline, or oral misoprostol in the treatment of canine atopy. Insufficient evidence exists for the remainder of other therapies often recommended (e.g., antihistamines, tricyclic antidepressants, etc.). However, there is evidence against the efficacy of oral arofylline, leukotriene synthesis inhibitors, and cysteinyl leukotriene receptor antagonists.

ANTITUSSIVE DRUGS

COUGH REFLEX. The afferent arc of the cough reflex receives input from sensory nerves in the bronchial and tracheal airways. Airway irritation and inflammation stimulate the afferent nerves, which in turn activate the cough center located in the medulla oblongata.

MECHANISM OF ACTION OF ANTITUSSIVE DRUGS. The mechanism of action of antitussive drugs is not completely understood. There are both opiate and nonopiate antitussive drugs. However, there is growing evidence that the nonopiate drugs (for example, dextromethorphan) are not as effective as once thought.

The most commonly used antitussives—and apparently the most effective—are derivatives of opiate drugs. They directly depress the cough center in the medulla. The site of action may be either μ- or κ-opiate receptors. Evidence for either receptor being responsible is that both butorphanol (κ-receptor agonist) and codeine or morphine (μ-receptor agonists) can suppress cough (Takahama and Shirasaki 2007; Gingerich et al. 1983; Christie et al. 1980), and naloxone is capable of antagonizing this effect.

There may be a nonopiate mechanism for some antitussives as well. For example, dextromethorphan is an opiate derivative, but does not have activity at opiate receptors. It continues to be marketed as an over-the-counter (OTC) medication with antitussive activity for people—apparently based on early clinical trials. Its mechanism is unknown. The neurokinin receptor (NK) may play a role in antitussive activity of nonopiates, but this mechanism has not been characterized well (Takahama and Shirasaki 2007).

Beta-2 receptor agonists (β_2) will suppress cough in some animals. The effect of these drugs is mediated via bronchodilation. These drugs will be discussed in another section.

MORPHINE. Morphine and derivatives have opiate-receptor–mediated effects, but also are effective as antitussives. Morphine is a natural derivative of one of the alkaloids of opium. (Pharmacology of opiates is discussed in more detail in Chapter 12.) Morphine is the prototype of an opiate (narcotic) analgesic with good binding affinity for the μ- and κ-opiate receptors. Morphine can be administered at low doses that produce antitussive effects without causing analgesia and sedation. The antitussive dose has been reported to be approximately 0.1 mg/kg, q 6–8 h. Morphine is not regularly used as an antitussive because of the side effects and potential for abuse and addiction. Oral formulations of morphine do not have good systemic absorption in dogs.

CODEINE (METHYLMORPHINE). Codeine phosphate and codeine sulfate are found in many preparations including, tablets, liquids, and syrups. There are over 50 different combinations and preparations of codeine. Codeine oral absorption in dogs is low and inconsistent.

Codeine has analgesic effects that are approximately 1/10 that of morphine. By contrast, the antitussive potency is similar to morphine. Although codeine administered orally to dogs attains low systemic levels, other metabolites may be responsible for the antitussive effect. Its usefulness as an oral antitussive in small animals has not been measured. It is available as 15, 30, and 60 mg tablets and oral syrups (2 mg/ml). In some states (regulated by local pharmacy acts), and some countries, codeine in antitussive formulations may be obtained without prescription.

In people, the side effects of codeine at antitussive doses are significantly less than those experienced with morphine. The potential for addiction and abuse is considerably lower. Important side effects include sedation and constipation.

HYDROCODONE. Hydrocodone is similar to codeine in action, but it is more potent. Hydrocodone is combined with an anticholinergic drug (homatropine) in the preparation Hycodan®, which has been prescribed for small animals. The anticholinergic drug is added to discourage abuse rather than for a respiratory indication. In some countries (Canada) it may be obtained without the ingredient homatropine. Some veterinarians consider hydrocodone the first drug of choice for symptomatic treatment of cough in dogs.

Availability of hydrocodone tablets in the United States has diminished. Tablets are difficult to obtain, but there is an oral syrup that contains hydrocodone plus homatropine (1 mg/ml hydrocodone + 0.3 mg/ml homatropine). Although systemic availability after oral administration has not been reported, oral doses administered to dogs are approximately 0.25 mg/kg, q 6–8 h (approx. 1 tablet per 20 kg).

Hycodan bitartrate is formulated as 5 mg of hydrocodone + 1.5 mg homatropine. Only in Canada is hydrocodone available without an anticholinergic (5 mg). Hydrocodone (5 mg) + acetaminophen (500 mg) is combined in a tablet and used for analgesia (Vicodin).

DEXTROMETHORPHAN. Dextromethorphan is not a true opiate, because it does not bind μ- or κ-opiate receptors, but studies in people have supported its antitussive effects. More recent investigations have questioned the antitussive properties of over-the-counter (OTC) formulations.

Dextromethorphan is the D-isomer of levorphan (the L-isomer, levorphan is an opiate with addictive properties, but the D-isomer is not). Dextromethorphan produces mild analgesia and modulates pain via its ability to act as an NMDA (n-methyl D-aspartate) antagonist, but this is unrelated to the antitussive action (Pozzi et al. 2006).

Clinical Use. Dextromethorphan has been administered to dogs and cats, but recent pharmacokinetic studies in dogs indicated that dextromethorphan does not attain effective concentrations after oral administration (KuKanich and Papich 2004). After injections IV it produced adverse effects in dogs (vomiting after oral doses, and CNS reactions after IV administration). Even after IV administration, concentrations of the parent drug and active metabolite persisted for only a short time after dosing. Therefore, routine use in dogs is not recommended until more data are available to establish safe and effective doses.

Formulations. There are many preparations available without a prescription (over-the-counter, OTC) in liquid and tablet form. For example, *Vicks Formula 44* and *Robitussin* contain dextromethorphan as their active antitussive ingredient. OTC formulations may vary in concentration, but most contain 2 mg/ml, or 15 or 20 mg per tablet. Pet owners should be cautioned that many OTC preparations contain other drugs that may produce significant side effects. For example, some combinations also contain acetaminophen, which can be toxic to cats. Some preparations also contain a decongestant, such as pseudoephedrine, which can cause excitement and other side effects.

BUTORPHANOL (TORBUTROL®, TORBUGESIC®). Butorphanol is an opioid agonist-antagonist that has been used both as an analgesic and antitussive. It has been a potent antitussive with clinical studies that support its use in dogs (Gingerich et al. 1983; Christie et al. 1980). High doses may induce side effects such as sedation.

Butorphanol is poorly bioavailable because of oral first-pass metabolism. Therefore, in dogs the oral dose is higher (0.55 to 1.1 mg/kg) than the IV or SC dose (0.05 to 0.1 mg/kg). It is administered as frequently as needed to control cough—usually every 6 to 12 hours. In clinical studies the peak effect was rapid after the injectable formulation. After oral administration, the maximum effects were observed for 4 hours but persisted for up to 10 hours in dogs (Gingerich et al. 1983). By contrast, codeine's effect in dogs is much shorter. It is available as 1, 5, and 10 mg tablets and an injectable solution.

TRAMADOL (ULTRAM). Tramadol is an inexpensive oral drug used for analgesia. It produces opiate, serotonin, and alpha-2 activity. (The pharmacology of tramadol is discussed in more detail in Chapter 12.) The active metabolite has opiate activity and is believed to be responsible for most of the analgesia. This drug also has antitussive properties and appears to be well-tolerated in dogs and it is not a controlled substance. However, efficacy for treating cough in dogs has not been evaluated. Recommended oral dose is 5 mg/kg, every 6 hours (KuKanich and Papich 2004).

BRONCHODILATOR DRUGS (BETA-ADRENERGIC RECEPTOR AGONISTS)

The β-adrenergic receptor agonists have a beneficial effect in the treatment of some airway diseases. They are used commonly in people for the treatment of asthma. In animals, they are used for airway disease, allergic bronchitis, and similar diseases such as feline "asthma," and recurrent airway obstruction (formerly called *chronic obstructive pulmonary disease* or "*heaves*") in horses. A review of the pharmacology of this group of drugs is in the article by Nelson (1995) and the autonomic properties are discussed in more detail in Chapter 6 of this textbook.

MECHANISM OF ACTION. Bronchial smooth muscle is innervated by β_2-adrenergic receptors. Stimulation of β_2-receptors leads to increased activity of the enzyme

TABLE 49.1 Response of various organs to adrenergic receptor stimulation

Receptor Type	Organ	Response
α_1	Pilomotor smooth muscle	Contracts
α_1	Liver	Gluconeogenesis
α_1 & α_2	Peripheral and splanchnic vessels	Constricts
α_1	Sweat glands	Secretion
α_1	Urinary tract	Increases sphincter tone
$\beta 4_2$	Skeletal muscle vessels	Dilates
$\beta 4_2$	Bronchial smooth muscle	Relaxes
$\beta 4_2$	Respiratory mast cells	Stabilizes
$\beta 4 \beta_1$	Heart rate	Increases
$\beta 4_1$	Heart contraction	Increases

TABLE 49.2 Relative effects of catecholamines on adrenergic receptors

Drug	α_1	β_1	β_2	DA
Norepinephrine (Noradrenaline)	+++	1	0	0
Epinephrine (Adrenaline)	+++	+++	++	0
Ephedrine	+++	+++	+++	0
Dopamine (Intropin®)	+++	+++	+	++++
Dobutamine (Dobutrex®)	+	+++	+	0
Isoproterenol (Isuprel®)	0	+++	++++	0
Isoetharine (Bronkosol®)	0	+	+++	0
Metaproterenol (Alupent®)	0	+	++	0
Terbutaline (Bricanyl®)	0	+	+++	0
Albuterol, Salbutamol (Ventolin®)	0	+	+++	0
Clenbuterol (Ventipulmin®)	0	+	+++	0

*DA = dopamine.

adenylate cyclase, increased intracellular cyclic-adenosine monophosphate (cyclic-AMP), and relaxation of bronchial smooth muscle (Table 49.1).

Stabilize Mast Cells. Stimulation of β-receptor activity on mast cells decreases release of inflammatory mediators. The β-receptor on mast cells produces a stabilizing effect (inhibition of mediator release) (Chong et al. 2002). There is little effect on other inflammatory cells. The clinical significance of this effect has not been established.

Increased Mucociliary Clearance. There is some evidence that β-adrenergic receptor agonists increase mucociliary clearance in the respiratory tract. The clinical significance of this effect has not been established.

SHORT-ACTING NONSPECIFIC BRONCHODILATORS

Epinephrine (Adrenaline). Epinephrine stimulates α- and β-adrenergic receptors (Table 49.2). It produces pronounced vasopressive and cardiac effects. Epinephrine is considered the drug of choice for the emergency treatment of life-threatening bronchoconstriction. The nonspecific stimulation of other receptors and its short duration make it unsuitable for long-term use. The dose used in animals is 10 µg/kg IM, IV, administered as a one-time treatment, or repeated in 15 minutes. Formulations are available in either 1:10,000 concentration (0.01%, 0.1 mg/ml) or 1:1,000 concentration (0.1%, 1 mg/ml). Duration of action is short (less than 1 hr).

Norepinephrine (Levarterenol). This drug has similar β_1 effects as epinephrine but fewer α_1 and β_2 effects, and therefore is not suitable for respiratory therapy.

Isoproterenol (Isuprel). Isoproterenol is a potent β receptor agonist. It is selective for β receptors with little α-receptor–mediated effects, but the cardiac (β_1) effects make it unsuitable for long-term use. It has been administered by inhalation or injection. It has a short duration of action (<1 hr).

LONGER-ACTING β_2–SPECIFIC DRUGS. To avoid the adverse cardiac effects of β-adrenergic agonists, drugs have been developed that are more specific for the β_2-receptor. These drugs are preferred for repeated use or long-term use. These drugs are also incorporated in some of the metered-dose inhalers used to treat bronchoconstriction.

Terbutaline (Brethine, Bricanyl). Terbutaline is similar to isoproterenol for its β_2 activity, but it is longer acting (6 to 8 hours). It may be injected subcutaneously to relieve an acute episode of bronchoconstriction. (The dose in people is approx. 3.5 µg/kg, repeated once/hour.) The oral dose is 2.5 mg/dog q8h for dogs, and 0.625 mg (one-quarter of a 2.5 mg tablet) q12h for cats (e.g., cats with feline "asthma"). It is available as 2.5 and 5 mg tablets and 0.8 mg/ml (820 µ/ml) injection. The dose for injection in cats is 0.01 mg/kg IV or IM. Terbutaline has been used in horses to treat recurrent airway obstruction (RAO) (formerly called *chronic obstructive pulmonary disease, COPD*),

which is a bronchoconstrictive disease in horses analogous to asthma in people. It is not absorbed after oral administration in horses; therefore, injectable preparations must be used.

Metaproterenol (Alupent®, Metaprel®). Metaproterenol is similar to terbutaline, but the duration of action is shorter (4 hours). It is available as 10 and 20 mg tablets and 2 mg/ml oral syrup. The dose in small animals is 0.325 to 0.65 mg/kg.

Albuterol (Salbutamol) (Proventil®, Ventolin®). Albuterol is similar to terbutaline and metaproterenol in its action. Doses used in small animals are 20–50 µg/kg up to 4 times/day. (Dose in people is 100–200 µg/kg 4 times daily.) It is available as 2, 4, and 5 mg tablets and 2 mg/5 ml syrup. The use of formulations for horses is discussed in another section on inhalant products (discussed with the topical agents). Levalbuterol is the R-isomer of albuterol, and is used in some products, but it has no advantage over albuterol.

Clenbuterol (Ventipulmin). Clenbuterol was approved by the FDA in 1998 for use in horses. Its use in food animals is illegal, which is discussed in a later section. Its use has not been reported in small animals. Clenbuterol has been used for the treatment of recurrent airway obstruction (RAO) (formerly called *chronic obstructive pulmonary disease, COPD*) (Table 49.3) in horses and some studies have demonstrated efficacy (Shapland et al. 1981). However, its bronchodilating ability has been questioned. Compared to other β-agonists, such as terbutaline, clenbuterol has lower clinical efficacy because it is only a partial agonist and has lower intrinsic activity (Törneke et al. 1998; Derksen et al. 1987).

TABLE 49.3 Recurrent airway obstruction (RAO) in horses

- Formerly called chronic obstructive airway disease (COPD)
- Characterized by
  - Chronic airway inflammation
  - Labored breathing
  - Bronchospasm
  - Mucus plugs
  - Tissue remodeling in airways
  - Neutrophilic inflammation in airways
  - Bronchial hyper-responsiveness
- Treatments:
  - Bronchodilators (beta-2 agonists)
  - Corticosteroids
  - Inhalant medications
  - Cromoglycate
  - Phosphodiesterase inhibitors

Clenbuterol is available as a syrup (Ventipulmin syrup, 100 ml and 33 ml bottles, 72.5 µg/ml) for horses for oral administration. The dose is 0.8 µg/kg twice daily, but can be increased to 2x, 3x, and then 4x (up to 3.2 µg/kg) if the initial dose is not effective. The duration of effect is 6–8 hours. Adverse effects in horses include sweating, muscle tremor, restlessness, and tachycardia.

Compounding of clenbuterol, especially from bulk drugs of unapproved sources, has become popular in equine medicine. Unless the source of clenbuterol for the compounding meets the criteria of the AMDUCA (FDA's Animal Medicinal Drug Use Clarification Act), this is strictly illegal.

In livestock, β_2-agonists have been used illegally as repartitioning agents. (A repartitioning agent repartitions nutrients away from adipose tissue in favor of muscle [Peters 1989].) The result is increased carcass weight, and an increased ratio of muscle to fat, while reducing the feed required per kg of gain. Because clenbuterol has not been approved for food animal use, and residues pose a threat to people (e.g. pregnant women and people with heart conditions), a "zero tolerance" level has been established for these residues. The illegal use of clenbuterol in food animals has been a concern of the FDA. Deaths in humans have been reported as a result of eating beef liver contaminated with clenbuterol residue. In the U.S., clenbuterol residues have been highest in "show animals." *There also is evidence that clenbuterol has been used for "muscle-building" in human athletes.*

Salmeterol and Formoterol. These drugs are long-acting β-agonists that have been used in human medicine, but their use in veterinary medicine has not been reported.

INHALANT FORMULATIONS: NEBULIZED β-AGONISTS. Inhaled aerosols of β_2-agonists are important drugs for treatment of acute bronchospasm in human patients with asthma or allergic bronchitis. Nebulization is the process of creating small droplets of a drug that can be inhaled into the airways. Nebulized agents are delivered via jet nebulizers, ultrasonic nebulizers, and metered-dose inhalers. Several metered-dose inhalers are marketed for this use in people, such as albuterol (Ventolin®), bitolterol

(Tornalate®), terbutaline (Brethaire®), and pirbuterol (Maxair®).

The use of these aerosols has become more common in animals because adapters are available to allow for use by animal owners. In horses, masks are available that allow a metered-dose inhaler to be used (Derksen et al. 1996; Tesarowski et al. 1994). The AeroMask (Trudell Medical International) and Equine Haler (Equine Health Care) are two such masks. For cats, the AeroKat chamber has also been used to deliver these medications.

Albuterol (Torpex). In 2002, albuterol sulfate was approved by the US-FDA for horses, indicated for relief of bronchospasm and bronchoconstriction associated with recurrent airway obstruction (RAO). It is an aerosol formulation in a pressurized canister and delivered via a specialized nasal delivery bulb. The nasal bulb is inserted into the horse's nostril and when the horse inhales, the device is activated. Masks that fit over the horse's nose (discussed in the previous paragragh) also have been used.

In horses, doses of 360 or 720 µg delivered by aerosolization caused significant bronchodilation (Derksen et al. 1999). The same author also administered pirbuterol at 600 µg/horse with good results.

For small animals, the metered dose inhaler to deliver albuterol in people has been adapted for use. An inhalation chamber is used to deliver the drug. The use of small animal inhalers is discussed in more detail in the corticosteroid section.

ADVERSE EFFECTS FROM β-AGONISTS. The most common adverse effects from β-agonists affect the cardiovascular system (tachycardia) and skeletal muscles (muscle tremors) (Fox and Papich 1989). Cardiac effects (rapid heart rate, palpitations, tremor) can be prominent with β_1-agonists and can be produced by β_2-agonists at high doses. When high doses of β-agonists have been nebulized to horses, they produced muscle twitching, sweating, and excitement. β_2-receptor agonists also inhibit uterine motility and should not be used late in pregnancy. (However, these drugs have been used therapeutically for this purpose in situations in which it may be desirable to inhibit uterine contractions to delay labor.) High doses of β_2-agonists also can produce hypokalemia.

As noted above in the clenbuterol section, these drugs also have properties that affect skeletal muscle. These drugs have been abused in humans and animals for their muscle-building properties. High doses can cause muscle twitching and hyperthermia.

TOLERANCE WITH CHRONIC USE. Regular administration of β-agonists can produce drug tolerance, which is a loss in the sensitivity of β-adrenergic receptors owing to down-regulation of receptors. This effect occurs when β-adrenergic drugs are administered regularly for several weeks. Therefore, it is best to rely on these drugs intermittently and allow drug-free breaks in treatment. The most common use of these drugs is for short-term treatment for acute exacerbations of bronchoconstriction.

CROMOLYN (SODIUM CROMOGLYCATE) (INTAL®)

Cromoglycate is used occasionally to stabilize mast cells in animals with hypersensitive airways. It is usually administered as a 2% solution for nebulization in the treatment of bronchoconstrictive diseases. It has been used in people to treat asthma and nebulized to horses via a special mask to treat recurrent airway obstruction (RAO).

MECHANISM OF ACTION. Cromolyn inhibits mast cell release of histamine, leukotrienes, and other substances from sensitized mast cells that cause hypersensitivity reactions, probably by interfering with calcium transport across the mast cell membrane. It has no intrinsic bronchodilator action.

CLINICAL USE. Cromolyn has been used as an aerosol for treating recurrent airway obstruction (RAO) in horses (Thomson and McPherson 1981). It is administered via inhalation once daily for 1 to 4 days, which will provide a therapeutic effect for several days. In one report, nebulization of 80 mg once daily for 1–4 days prevented signs of heaves in horses for up to 3 weeks. However, other studies have produced conflicting results. The primary drawback is the route of administration and timing. To be effective, it *must* be administered before the horse is exposed to the allergen (prophylactically).

Nedocromil Sodium. Nedocromil sodium (Tilade) is a chemically unrelated drug, but has an antiinflammatory effect via a similar mechanism to chromolyn. It is approved for use in treating asthma in people but use in veterinary patients has not been reported.

METHYLXANTHINES (XANTHINES)

The methylxanthines include theobromine, caffeine, and theophylline. Pentoxifylline also is a methylxanthine, but is used for conditions other than asthma. The methylxanthines—particularly theophylline—have been used as bronchodilators, although their exact action is not understood. Once a mainstay in the therapy of human asthma, theophylline use has diminished because of a high incidence of side effects in people and because there are better-tolerated and more effective drugs available. But, in animals—particularly small animals—theophylline continues to be used because it is tolerated well and oral dosing is convenient. There are no clinical studies that have documented efficacy in small animals; the use is purely anecdotal.

PHARMACOLOGIC EFFECTS. The pharmacology of theophylline was reviewed by Weinberger and Hendeles (1996). The methylxanthines are classified as CNS stimulants, but they have a variety of pharmacological effects on various organ systems. The methylxanthines relax bronchial smooth muscle and produce antiinflammatory effects that are unrelated to the bronchodilating properties. In addition, there are nonrespiratory effects of methylxanthines, which include CNS stimulation, urinary diuresis (mild), and cardiac stimulant (mild).

Cellular Basis of Action. The cellular basis of action of the methylxanthines is still not completely understood. The effect that persists in the literature is the action to inhibit phosphodiesterase types 3 and 4. Phosphodiesterase is the enzyme that catalyzes cyclic-AMP to inactive products. Inhibition of the phosphodiesterase enzyme increases intracellular concentrations of the cyclic nucleotide cAMP. Cyclic-AMP inhibits the release of inflammatory mediators from mast cells, has antiinflammatory effects, and produces bronchial smooth muscle relaxation. More detail on the molecular mechanisms of drugs for treating asthma were discussed by Barnes (2003).

Another mechanism of action that may explain the benefits for respiratory disease is via antagonism of *adenosine* receptors. Adenosine causes bronchoconstriction in asthmatic patients, but blocking this receptor also may contribute to the adverse effects.

ANTIINFLAMMATORY EFFECTS. The antiinflammatory effects of theophylline may occur separately—and at lower concentrations—than the bronchodilating effects (Barnes 2003). This may occur by decreasing the expression of inflammatory genes. Treatment with theophylline has induced a decreased response to histamine and other inflammatory mediators in the airways. Theophylline's antiinflammatory effects include diminished activity of inflammatory and immune cells—especially eosinophils—in the airways. Eosinophils are important in the bronchial response to inhaled allergens, and they release inflammatory mediators that induce bronchoconstriction and inflammatory changes in the airways.

FORMULATIONS. Theophylline has been available in several formulations, including, injectable, aqueous solutions, elixirs, tablets, and capsules. However, the most convenient for small animal use are extended-release forms that allow for twice daily treatment in dogs and once-daily or once-every-48-hr treatment in cats. These are discussed in more detail in the section on clinical use.

Examples of other forms of theophylline are presented in Table 49.4. These salts are designed to improve solubility and decrease stomach irritation. The theophylline content of these salts must be considered when calculating a dosage regimen.

TABLE 49.4 Formulations of theophylline

	Brand Name	Percent Theophylline
Theophylline base	Many	100
Theophylline elixir	Many	100
Theophylline monohydrate		90
Theophylline ethylenediamine (aminophylline)	Many	80
Choline theophyllinate (oxtriphylline)	Choledyl	65
Theophylline sodium glycinate	Asbron	50
Theophylline calcium salicylate	Quadrinal	48

TABLE 49.5 Theophylline pharmacokinetics and doses

Species	$t^1/_2$ (Hours)	V_D (l/kg)	%F*	Suggested Dose
People	6-8	0.5	90	4 mg/kg q6h
Dog	5.7	0.82	91	9 mg/kg q6-8h, or 10 mg/kg q12h of the extended release formulations
Cat	7.8,11.7 (IV)14–18 (oral)	0.46, 0.86	96–100	4 mg/kg q8-12h or extended-release at 15 mg/kg (tab) and 19 mg/kg (cap) q24h (q48h may be possible in some cats)
Cattle	6.4	0.815	93	20 mg/kg q12h
Horse	12–15	0.85–1.02	100	5 mg/kg q12h

* %F = percent absorbed from oral administration.

PHARMACOKINETICS. After oral administration, theophylline is rapidly and completely absorbed. Systemic availability is 91%, 96–100% and 100% in dogs, cats, and horses, respectively. Theophylline is metabolized primarily by the liver in all species; only 10% of the dose is eliminated unchanged in the urine. The pharmacokinetics have been studied in several veterinary species and are listed in Table 49.5 with comparisons to people.

PLASMA CONCENTRATIONS AND CLINICAL MONITORING. Theophylline drug plasma assays are available in many laboratories. When theophylline is used long-term, monitoring is recommended to establish the optimum dose. In dogs and cats, the accepted therapeutic plasma concentration is 10 to 20 μg/kg, but these values were extrapolated from human studies. In animals, we aim for plasma concentration greater than 10 μg/ml (usually 10 to 20 μg/ml) for clinical effects. Plasma concentrations greater than 15 μg/ml have been reported to cause clinical adverse effects in horses.

Antiinflammatory action may occur in patients at concentrations that are below the concentrations usually considered for bronchodilation. For example in people, a concentration of 6.6 μg/ml theophylline caused a reduction in activated eosinophils (Sullivan et al. 1994). In the review by Barnes (2003) the antiinflammatory effects are reported to occur in people at concentrations of 5 to 10 μg/ml, which is approximately half of the concentration needed to produce bronchodilation.

SIDE EFFECTS AND ADVERSE EFFECTS. Mild adverse effects include gastrointestinal signs. Theophylline can be nauseating. The nonspecific inhibition of phosphodiesterase also can produce vomiting.

The most important side effects of theophylline are attributed to the cardiac stimulation. In this regard, theophylline is more potent than either caffeine or theobromine. The cardiac effects may be summarized as increased heart rate, increase in myocardial contractility (mild), improved right and left systolic function, vasodilation (mild), and diuretic (weak). At high doses, cardiac arrhythmias are possible.

CNS stimulation is more likely from caffeine than theophylline or theobromine. However, at high doses, theophylline also can affect the CNS. These are reported less frequently from theophylline use in small animals than in humans, but they can be common in horses. The CNS effects can be characterized by increased alertness, agitation, nervousness, increased activity, and convulsions at high doses. At high doses there is decreased cerebral blood flow (26%), which may be related to the incidence of seizures at toxic doses.

The most serious adverse effects are concentration-dependent. Caution is advised if administration is performed rapidly intravenously. These adverse effects have been described when theophylline is administered rapidly intravenously in horses and dogs. If the drug is administered orally, high peak plasma concentrations are less likely (Munsiff et al. 1988).

DRUG INTERACTIONS. Theophylline relies on hepatic metabolism by cytochrome P450 enzymes for clearance. Therefore, interactions are possible when other drugs are administered that affect these enzyme systems. The metabolism of theophylline may be inhibited by erythromycin, fluoroquinolone antibiotics (for example, enrofloxacin), and cimetidine. The metabolism may be induced by rifampin and phenobarbital, which may necessitate increasing the dose if these drugs are used together. Activated

charcoal will increase the clearance of theophylline and other methylxanthines and is useful for treatment of a toxic overdose.

CLINICAL USE IN DOGS AND CATS. Theophylline has been used for the treatment of both cardiac and respiratory diseases in dogs. Some veterinarians have included theophylline in regimens for the management of congestive heart failure, although this is becoming an outdated treatment because of availability of newer cardiac drugs. Theophylline is also employed for the management of intrathoracic collapsing trachea and various forms of bronchitis.

Older sustained-release tablets have been studied in dogs and cats (Koritz et al. 1986; Dye et al. 1989). However, these formulations were recently discontinued and the dose recommendations no longer apply.

Availability of Newer Formulations. Decreased availability of older sustained-release formulations led to the use of new tablets and capsules (TheoChron 100, 200, or 300 mg tablets; or TheoCap 125 or 250 mg capsules, Inwood Laboratories). Oral administration of sustained-release formulations in dogs at a dose of 10 mg/kg, q12h will produce concentrations in dogs within a range considered to be therapeutic (Bach et al. 2004). Studies in cats (Guenther-Yenke et al. 2007), showed that a dose of 100 mg per cat of the tablet, or 125 mg/cat of the capsule (approximately 15 or 19 mg/kg, respectively) every 24–48 hours maintained plasma concentrations in a range considered to be therapeutic. (*Recently these capsule formulations have become less available, but one may continue to use the tablet form.*)

CLINICAL USE IN HORSES. Administration of theophylline to horses has a narrow therapeutic index and it is considered less effective than β-adrenergic agonists. Adverse effects have prevented more common use. Some evidence indicates that phosphodiesterase inhibitors are not effective in horses with recurrent airway obstruction (RAO) (Lavoie et al. 2006).

Despite the risk of adverse effects and questionable efficacy, theophylline has been used in the management of recurrent airway obstruction, RAO (formerly called *COPD*) in horses. Studies cited (Button et al. 1985; Errecalde et al. 1984; Ayres et al. 1985; Ingvast-Larsson et al. 1989; and Kowalczyk et al. 1984) summarize the pharmacokinetics and effects of theophylline in horses. Oral doses usually are used to avoid the high concentrations from injections. A loading dose of 12 mg/kg has been followed by maintenance doses of 5 mg/kg, every 12 hours. One study demonstrated that affected horses showed decreased wheezing, decreased respiratory effort, and an improvement in pCO_2 and blood pH following theophylline administration. However, none of the horses returned to normal. In horses there is also a positive cardiac chronotropic effect and a weak diuretic effect. Toxicosis can occur from large doses and doses administrated rapidly intravenously. Toxic signs include tremors, excitement, tachycardia, and sweating.

CLINICAL USE IN CATTLE. Although there is little clinical experience with the use of theophylline in cattle, experimental evidence suggests that it is a poor bronchodilator in this species (McKenna et al. 1989).

ANTICHOLINERGIC DRUGS

Anticholinergic (parasympatholytic/antimuscarinic) drugs such as atropine and glycopyrrolate are effective bronchodilators. (The pharmacology of anticholinergic agents was provided in more detail in Chapter 7.) Cholinergic stimulation causes bronchoconstriction. Anticholinergic drugs inhibit vagal-mediated cholinergic smooth muscle tone in the respiratory tract. Some studies suggest that asthmatic individuals have excessive stimulation of cholinergic receptors. In some people, COPD can be more effectively treated with anticholinergic drugs than by β-agonists (Barnes 2000). Although atropine will provide relief from these effects in many patients, the side effects are unacceptable for long-term use. Side effects involve the CNS and GI systems.

USE OF ANTICHOLINERGIC DRUGS IN HORSES. Pearson and Riebold (1989) compared the effects of atropine, isoproterenol, and theophylline in horses with recurrent airway obstruction (RAO, also known as *chronic obstructive pulmonary disease, COPD,* or "*heaves*"). Atropine at doses of 0.02 mg/kg, IV was better at relieving some signs of RAO (reduction in intrathoracic pressure for example) than either theophylline or isoproterenol. Isoproterenol was more effective in this study than theophylline.

DRUG CHOICES. If anticholinergic drugs are administered, the quaternary amines such as glycopyrrolate (Robinul-V®), propantheline, (ProBanthine®), and isopropamide should be used instead of atropine because quaternary amines are less likely to cross the blood-brain barrier and CNS side effects will be minimized. However, atropine is acceptable for short-term use and a 5 mg IV dose has been used as a response test in horses suspected of presenting with RAO.

Ipratropium bromide (Atrovent®) is a quaternary amine that is an effective bronchodilator in human asthmatic patients. It is administered as an aerosol and is the first anticholinergic drug to be approved as a bronchodilator. Since ipratropium is not absorbed from the airways, it is described as a "topical form of atropine." It has been administered to horses for treatment of RAO and produced effects for 6 hours at a dose of 2 μg/kg.

ADVERSE EFFECTS. The cardiac effects and inhibition of gastrointestinal function prohibit long-term use of atropine. The topical drugs (e.g., ipratropium) have less systemic effects. Anticholinergic drugs may decrease mucociliary clearance. In horses, atropine at 0.02 mg/kg decreased tracheal mucus transport rate.

GLUCOCORTICOIDS

Glucocorticoids decrease inflammation associated with inflammatory pulmonary diseases. Prednisolone has been effective for treatment of feline tracheobronchitis ("feline asthma"), nonseptic pulmonary diseases associated with pulmonary infiltrates of leukocytes (noninfectious bronchitis), allergic bronchitis, and recurrent airway obstruction (RAO) in horses. For treatment of asthma in people, inhaled corticosteroids are recognized as the most effective therapy available (Barnes 1995, 2006). In one article, they were called the "drugs to beat" (Barnes 2006).

MECHANISM OF ACTION. The pharmacology of the glucocorticoids was discussed in more detail in Chapter 30. In patients with inflammatory airway diseases, glucocorticoids have potent antiinflammatory effects on the bronchial mucosa. Glucocorticoids bind to receptors on cells and inhibit the transcription of genes for the production of mediators (cytokines, chemokines, adhesion molecules) involved in airway inflammation (Rhen and Cidlowski 2005). In horses with RAO, administration of oral dexamethasone in combination with feeding changes, decreased the gene expression of proinflammatory cytokines in bronchoalveolar cells (deLuca et al. 2008). A decrease in the synthesis of inflammatory mediators such as prostaglandins, leukotrienes, and platelet-activating factor caused by glucocorticoids also may be important (Barnes 1995a, 1989, 2006). Mast cells are not affected by glucocorticoids as much as other inflammatory cells. Glucocorticoids also enhance the action of adrenergic agonists on β_2-receptors in the bronchial smooth muscle, either by modifying the receptor or augmenting muscle relaxation after a receptor has been bound. In addition, corticosteroids may prevent down-regulation of β_2-receptors. Glucocorticoids and theophylline used together appear to be synergistic (Barnes 2003).

CLINICAL USE

Dogs. Oral prednisolone or prednisone is usually the drug of choice. A typical antiinflammatory dosage is 0.5 to 1.0 mg/kg. After an initial course of treatment many patients can be managed by administering this dose on an every-other-day (EOD) basis.

Cats. Because cats are somewhat resistant to glucocorticoids, higher doses have been used compared to doses administered to dogs. Oral prednisolone initial dosages of 2 to 4 mg/kg/day have been used for 10–14 days, followed by chronic doses of 1.0 mg/kg/day for the treatment of feline asthma (Padrid 2000). For cats, prednisolone should be used instead of prednisone because of an absorption/conversion problem similar to horses (see below) (Graham-Mize and Rosser 2004). Some veterinarians have administered 20 mg per cat of a long-acting formulation, methylprednisolone acetate (Depo Medrol®) intramuscularly. The effects of one injection may persist for 3 weeks.

Adverse effects in cats are a concern with long-term treatment (Table 49.6). Among the concerns are that corticosteroids may exacerbate or increase the risk of congestive

TABLE 49.6 Adverse effects of corticosteroids in cats

- Behavior changes
- Increased appetite
- Weight gain
- Hyperglycemia
- Increased plasma volume (secondary to hyperglycemia)
- Increased risk of heart disease (secondary to increased plasma volume)
- Hepatomegaly

heart failure in cats (Smith et al. 2004; Ployngam et al. 2006). The proposed mechanism for increasing this risk is increase in plasma glucose, volume expansion, and increase in plasma volume. The vascular volume increase may lead to an overload. To avoid systemic adverse effects, topical (inhaled) formulations have been used (see below).

Horses. In horses, corticosteroids are important for management of recurrent airway obstruction (RAO). Oral corticosteroids have been used, but there are no convenient dose formulations. In some cases tablets have been crushed and added to a drug vehicle or mixed with feed (grain). In horses, one should be cognizant of the dose form administered. Prednisone in horses is either not absorbed, and/or not converted to the active prednisolone after absorption (Peroni et al. 2002). Therefore, prednisolone tablets are the preferred drug for oral administration. The dose used initially is approximately 2 mg/kg oral, once or twice a day. Oral dexamethasone, added to the horse's feed, also can be used. In a study in which dexamethasone was effective for decreasing inflammatory cytokine expression in RAO horses, a decreasing oral dexamethasone dose of 0.165 mg/kg per day to 0.04 mg/kg per day over a course of 21 days was used (DeLuca et al. 2008). Alternatives are inhaled and injectable forms (see below).

Injections of dexamethasone have improved clinical signs of airway obstruction when administered at doses of 0.1 mg/kg (Rush et al. 1998). Despite clinical improvement, dexamethasone does not improve indicators of airway inflammation in the airways, such as AP-1, NFκB, or cytology. Dexamethasone by injection was more effective than inhaled corticosteroids in this study, but there is a concern that repeated use of injections of corticosteroids in horses may result in adverse effects, such as adrenal suppression, signs of hyperadrenocorticism, and laminitis. Nevertheless, dexamethasone can be valuable for some cases, and one of the formulations most often used is dexamethasone 21-isonicotinate suspension (Voren), which may be administered at a dose of 0.06 mg/kg IM (not intended for IV use).

INHALED CORTICOSTEROIDS. Glucocorticoids are among the most valuable drugs for managing asthma in people. For people, a metered-dose inhaler is used to deliver the drug topically in order to avoid systemic adverse effects. According to one review, Inhaled corticosteroids are the most effective agents available for the symptomatic control of asthma and improvement in pulmonary function (Busse and Lemanske 2001). Examples of aerosolized corticosteroids are listed in Table 49.7 and include beclomethasone (Beclovent®), flunisolide (Aerobid®), fluticasone (Flovent®), triamcinolone (Azmacort), and budesonide (Pulmicort). Fluticasone is the most potent (18 × dexamethasone) and is usually the one used in veterinary medicine (Table 49.7). When glucocorticoids are delivered topically with these devices, systemic adverse effects are minimized, but not eliminated. Suppression of the hypothalamic-pituitary-adrenal axis can still be observed (see also Chapter 30).

TABLE 49.7 Examples of corticosteroids available as metered-dose inhalers

Drug	Brand Name	Dose Delivered
Beclomethasone dipropionate	Vanceril	40 or 80 µg per puff
Budesonide	Pulmicort	200 µg per puff (dry powder)
Flunisolide	Aerobid	250 µg per puff
Fluticasone propionate (most potent)	Flovent	44, 110, or 220 µg per puff
Triamcinolone acetonide	Azmacort	100 µg per puff

Use in Horses. The metered-dose inhalers designed for people can be used in horses with the aid of an equine-adapted handheld metered-dose delivery device (Derksen et al. 1996; Rush et al. 2000). Delivery devices used in horses include the Equine Aeromask (Trudell Medical International), Equine Haler, (Equine Health Care), NebulalAIR (IVX Animal Health), and the 3M Equine Inhaler (3M and Boehringer Ingelheim).

Aerosolized beclomethasone dipropionate using an equine-adapted metered dose inhalation device has been effective for reducing airway inflammation in horses with recurrent airway obstruction (RAO) (Rush et al. 1998, 2000). Horses responded within 24 hours. Administration of 500 µg every 12 hours to horses was shown to produce less adrenal suppression than larger doses and still provided beneficial effects.

Use in Small Animals. Metered-dose inhalers have been successfully used in small animals, particularly cats. For this use, a chamber with a valve on one end, fitted with a mask (for example the OptiChamber by Respironics and AeroKat by Trudell Medical International) has been used to deliver the drug. Budesonide or fluticasone are most often administered because of their high potency (Table 49.7) and low systemic effects. Fluticasone has been

used most often. In people it has a systemic absorption of only 18–26%, but there are extensive first-pass effects preventing systemic blood concentrations if it is swallowed after delivery. Therefore, the systemic action—and adverse effects—is expected to be small. A typical dose for fluticasone for a cat is 110 µg (one puff from a 110 µg metered dose inhaler) per day. Higher dose inhalers that deliver 220 µg are also available. In a recent study (Cohn et al. 2008) three fluticasone doses (44, 110, and 220 µg per cat) twice daily via metered dose inhaler were equivalent in an experiment model of feline asthma. When asthmatic cats were given inhaled corticosteroids twice a day and allowed 5–7 breaths (10 sec) from the chamber, it reduced the need for oral prednisolone. After 10 days, the patient may be reevaluated and frequency of administration reduced.

In one study, inhaled fluticasone reduced bronchial hyperresponsiveness and bronchoconstriction in cats with bronchitis with a dose of 250 µg per cat daily (Kirschuink et al. 2006). This dose also decreased inflammatory cells and prostaglandins in bronchoalveolar lavage fluid. In cats, flunisolide was studied for its systemic effects after administration by inhalation (Reinero et al. 2006). Although there was some suppression of the hypothalamic-pituitary-adrenal axis (indicating some systemic absorption), no systemic effects on immune cells were observed.

NONSTEROIDAL ANTIINFLAMMATORY DRUGS (NSAIDs)

NSAIDs have been administered for some types of pulmonary disease. The drug most often investigated has been flunixin meglumine. It is registered for cattle to treat inflammatory respiratory problems and as an adjunct treatment of Bovine Respiratory Disease (BRD).

Diseases in which NSAIDs may have a benefit include pulmonary thromboembolism, (for which antiplatelet doses of aspirin are used), pulmonary effects from endotoxin in horses and dogs (for which flunixin meglumine has been used) and in cattle with bovine respiratory disease, and pulmonary disease from PI-3 and 3-methyl indole in cattle.

LEUKOTRIENE INHIBITORS

Leukotrienes, such as LTD_4 contribute to airway inflammation by increasing migration of eosinophils, producing bronchoconstriction, and increasing airway wall edema. Inhibitors or blockers of leukotrienes have been used to treat these airway diseases. These were discussed in more detail by Drazen et al. (1999) and reviewed by Werz and Steinhilber (2006) and Peters-Golden and Henderson (2007). The leukotrienes have not been demonstrated to be important mediators in feline asthma (Norris et al. 2003). Therefore, these inhibitors may not have a role in feline respiratory disease. However, there is evidence that LTB_4—rather than the other leukotrienes—may contribute to airway inflammation in horses with recurrent airway obstruction (RAO) (Lindberg et al. 2004). An experimental 5-lipoxygenase inhibitor (fenleuton)—which decreases LTB_4—produced improvement in horses with RAO (Marr et al. 1998), but an LTD_4 receptor antagonist did not (Lavoie et al. 2002).

LIPOOXYGENASE INHIBITOR: ZILEUTON (ZYFLO®). Zileuton is an oral drug for treating asthma in people. It inhibits the enzyme 5-lipoxygenase and thereby inhibits synthesis of inflammatory leukotrienes. This drug has broader actions than the leukotriene receptor blockers because it inhibits effects of both LTB_4 and the cysteinyl leukotrienes (LTC_4, LTD_4, LTE_4). However, it has been less effective than leukotriene receptor blockers (see below) because, at the doses administered, it does not achieve complete suppression of the 5-lipoxygenase enzyme. In people, the safety profile has not been as good as the receptor blockers (see below). The effectiveness of zileuton for respiratory diseases in animals has not been reported. For people the dose is 600 mg, q6h and these doses have been extrapolated to animals for some studies. Treatment of other diseases in animals (e.g., allergic skin disease) have been investigated, but it has not been effective. In people it has been associated with hepatitis in some individuals.

LEUKOTRIENE RECEPTOR BLOCKERS. Zafirlukast (Accolate®), pranlukast, and montelukast (Singulair®) are leukotriene receptor blockers that have been used as oral drugs for treating asthma. They block the cysteinyl leukotriene receptor, therefore blocking the effects of LTC_4, LTD_4, and LTE_4—primarily at the $CysLT_1$ receptor site—but these drugs do not block receptors for the leukotriene LTB_4 (Drazen et al. 1999). The $CysLT_1$ receptor mediates sustained bronchoconstriction, mucus secretion, and edema in the airways (Peters-Golden and Henderson 2007). These drugs have been generally well tolerated in people, but there are some drug interactions with zafirlukast (inhibition of CYP-450 enzymes). Montelukast has

fewer adverse effects in people and less risk of drug interaction than zafirlukast. The use of these drugs has not been reported to be effective for treating respiratory diseases in animals. Doses in animals are not established, but the dose in people for zafirlukast is 20 mg/person twice daily and for montelukast it is 5 mg for children and 10 mg for adults.

DUAL BLOCKERS. The only dual blocker of prostaglandins and leukotrienes (COX and LOX) is the NSAID tepoxalin (Zubrin). It is currently registered as an oral treatment for arthritis in dogs. It is not known whether the antileukotriene effect will be beneficial in patients with respiratory disease.

EXPECTORANTS AND MUCOLYTIC DRUGS

The expectorants and mucolytics comprise a diverse group of compounds, with many proposed benefits but few clinical studies that have documented efficacy. These drugs have been used to increase the output of bronchial secretions, enhance clearance of bronchial exudate, and promote a more productive cough. Some of these drugs have a traditional use in veterinary medicine and their efficacy has not been established.

SALINE EXPECTORANTS. These drugs are promoted to stimulate bronchial mucus secretions via a vagal-mediated reflex action on the gastric mucosa. Even though there are no well-designed studies that support an expectorant effect from these products, particularly the ammonium compounds, stimulating the stomach appears to trigger a reflex that stimulates bronchial secretions. However, for some of these drugs, such as potassium iodide, the dose used clinically is too low to be effective. Examples of expectorants include ammonium chloride, ammonium carbonate, potassium iodide, calcium iodide, and ethylenediamine dihydroiodide (EDDI). EDDI is the best known of these compounds by veterinarians because it is also added to the feed of cattle for the purpose of decreasing foot rot infections, lumpy jaw (*Actinomyces bovis*), woody tongue (*Actinobacillus lignieresi*), and bronchitis. There is a lack of published scientific evidence for a beneficial effect.

DIRECT STIMULANTS. Volatile oils such as eucalyptus oil (found in cough drops such as Halls Mentho-Lyptus) and oil of lemon are believed to directly increase respiratory tract secretions. Their clinical efficacy in veterinary medicine is unknown.

GUAIFENESIN (GLYCERYL GUAIACOLATE) AND GUAIACOL. Guaifenesin compounds are typically classified as muscle relaxants in anesthesia and as anesthetic adjuncts, but they also may have an expectorant effect. The anesthetic effects were discussed in Chapters 11 and 13. Their mechanism of action is uncertain, but it is possible that these compounds stimulate bronchial secretions via vagal pathways. Although guaifenesin is contained in many over-the-counter cough remedies, such as Robitussin, the efficacy is highly questionable because most preparations do not contain a dose large enough. Studies that have measured the expectorant effect of guaifenesin have noted that it does not change the volume or viscosity of bronchial secretions, but it may accelerate particle clearance from the airways.

Formulations used in people (but not evaluated in animals) employ higher doses than older over-the-counter drugs. The higher dose formulations for people include Mucinex (600 and 1200 mg tablet), Mucinex-D (with pseudoephedrine), and Mucinex-DM (with dextromethorphan). Most typical OTC older formulations contain doses of 100 mg.

ACETYLCYSTEINE (MUCOMYST®). Acetylcysteine is available as a 10% solution that can be nebulized to patients. It is used in human patients with obstructive airway disease and children with cystic fibrosis (CF) to help clear mucus. Its mucolytic effect is caused by an interaction of the exposed sulfhydral groups on the compound with disulfide bonds on mucoprotein (Ziment 1988). Acetylcysteine helps break down respiratory mucus, reduce the viscosity of mucus, and enhance the clearance. Acetylcysteine may also increase the levels of glutathione, which is a scavenger of oxygen-derived free radicals. In Europe this drug is also available as an oral formulation.

Acetylcysteine also is used to treat certain types of toxicoses. The most common condition is acetaminophen (Tylenol®) toxicosis in cats.

DEMULCENTS. Many over-the-counter preparations are formulated in an oily or syrup base to provide a demulcent action (soothing effect). They are usually used to soothe the pharynx and thus may have an antitussive effect. Home remedies such as honey mixed with herbal tea or distilled spirits probably have this effect.

DECONGESTANTS

Decongestants are used to "dry up" mucus membranes when rhinorrhea occurs (in people, caused by the common cold and allergic rhinitis). Decongestants are sympathomimetic drugs that stimulate the α-adrenergic receptors in mucus membranes and cause local vasoconstriction. The pharmacology of adrenergic agonists was discussed in more detail in Chapter 6.

TOPICAL DECONGESTANTS. Short-acting topical agents include phenylephrine and phenylpropanolamine, which are common ingredients in over-the-counter nasal sprays (e.g., NeoSynephrine®). These products also have been applied topically to decrease bleeding associated with some surgical procedures (for example, nasal turbinate surgery in horses and dogs). Some topical decongestants are particularly long-acting, such as oxymetazoline (Afrin®) and xylometazoline (Dristan®). Caution should be exercised when using the topical products chronically. Rebound inflammation and hyperemia may occur when the action of the drug diminishes, resulting in a worsening of the problem. The clinical use of these agents for nasal problems is rare in animals because they are difficult and inconvenient to administer.

SYSTEMIC DECONGESTANTS. The systemic use of adrenergic agonists as decongestants has been a common practice in medicine for decades. In human medicine, over-the-counter (nonprescription) formulations for colds and allergies have contained ephedrine, the isomer pseudoephedrine (Sudafed®), or a similar drug, phenylpropanolamine (PPA). Side effects from the orally administered drugs include vasoconstriction and increased blood pressure in susceptible individuals, and excitement. A change in heart rate is possible from direct stimulation (increased heart rate), or vasoconstriction (decreased heart rate). There are some problems with the abuse of these agents in humans, which has limited the veterinary availability of

The Controversy about Phenylpropanolamine (PPA) and Pseudoephedrine

Phenylpropanolamine was first approved in 1959 and has been widely available over-the-counter (OTC) as a nonprescription drug for many years for humans. Popular brand names were Dexatrim and Acutrim (appetite suppressants), and Propagest and Rhindecon (decongestants). A study in 2000 suggested that phenylpropanolamine in appetite suppressants, and possibly decongestants, is a risk factor for hemorrhagic stroke in women (Kernan et al. 2000). *Because of the risk of hemorrhagic stroke in women, the Food and Drug Administration (FDA), announced on November 6, 2001, that it was taking steps to remove phenylpropanolamine from all drug products and has requested that all drug companies discontinue marketing products containing phenylpropanolamine.* After this action, it created a void for veterinary prescribing because PPA has been used frequently in dogs to control incontinence. However, after the FDA action, there were soon replacement drugs on the veterinary market containing PPA. There are now several formulations that are marketed for use in dogs, even though there is not formal FDA approval.

The other major concern with over-the-counter decongestants is the diversion to manufacturing methamphetamine. Phenylpropanolamine, ephedrine, and pseudoephedrine have been used as raw ingredients to illegally manufacture methamphetamine for "street use" in the so-called "Meth Labs." Pseudoephedrine closely resembles methamphetamine in structure. Because of this diversion, the quantity of pseudoephedrine (the only one currently available OTC) that one can purchase is limited by most pharmacies. In some states, pseudoephedrine may be obtained without prescription, but it must be dispensed by the pharmacists (behind the counter). Pseudoephedrine has been eliminated from all over-the-counter medications and replaced by less effective drugs.

Sympathetic amines, such as ephedrine and ephedra alkaloids (found in herbal products), are also used and abused as CNS stimulants. Nonprescription use of so-called "herbal" products has been popular. These products contain ephedra alkaloids (also known as *ma huang*), which produces a similar effect as the drug ephedrine. Side effects are possible and fatal cardiac events and seizures have occurred in young adults consuming high doses. Adverse cardiovascular and central nervous system effects have been reported (Haller and Benowitz 2000).

these compounds (see sidebar, "The Controversy about Phenylpropanolamine (PPA) and Pseudoephedrine").

USE OF DECONGESTANTS FOR TREATMENT OF INCONTINENCE. Although these drugs are rarely used as sinus decongestants in veterinary medicine they are popular drugs for treating incontinence in dogs. The effect of phenylpropanolamine (PPA) and other sympathetic agonists, such as pseudoephedrine, for treating urinary incontinence arises from their stimulation of the alpha-receptor—to increase the tone of the urinary sphincter, and its beta-receptor effects—to relax the detrussor muscle of the bladder wall and allow more urine filling.

The most common drug used for this purpose has been phenypropanolamine (PPA) (Moreau and Lappin 1989). There is a registered formulation of phenylpropanolamine available in Europe for treatment of urinary incontinence in dogs, (Propalin syrup) which has now been marketed in the U.S. The dose is approximately 1–2 mg/kg q8 to 12 h. The PROIN phenylpropanolamine is available as 75, 50, and 25 mg liver-flavored tablets and 25 mg flavored syrup. Propalin syrup is available as a 50 mg/ml syrup.

RESPIRATORY STIMULANTS

Respiratory stimulation is due to direct effect on the chemoreceptors of carotid artery and aorta. These receptors are sensitive to changes in CO_2, which in turn stimulate the respiratory center. Doxapram (Dopram®) is used primarily in an emergency during anesthesia, or to decrease the respiratory depressant effects of certain drugs (e.g., opiates, barbiturates). In horses, doxapram will cause cardiac stimulation as well as respiratory stimulation. There have been reports that administration to neonates may increase their suckling activity shortly after birth and subsequently decrease the incidence of failure of passive transfer of immunoglobulins. Scientific studies documenting this effect are lacking. An additional use of doxapram in foals is for treatment of hypercapnia associated with hypoxic-ischemic encephalopathy (Giguere et al. 2008). This treatment with doxapram at a constant rate infusion of 0.02 to 0.05 mg/kg/hr for 8 hours, improved by restoring respiratory control and corrected hypercapnia. In this study, caffeine was not as effective.

Pharmacogenetics and Hypersensitivity Reactions	**1319**
Pharmacogenetics in Clinical Practice	**1319**
Future Directions	**1319**

A patient's response to a drug includes both beneficial (therapeutic) effects as well as any adverse effects, including lack of therapeutic efficacy. While the goal of drug therapy is to produce a specific pharmacological effect without producing adverse effects, it is often difficult to predict how effective or how safe a medication may be for a particular patient. If 10 patients with a particular disease were administered the same drug, each might respond differently with respect to both drug efficacy and the likelihood of an adverse reaction. A number of factors may influence a patient's response to drug therapy, including the patient's age, species, concurrent medications, diet, health or disease status, and others. However, consideration of all of these factors is often not sufficient to explain the degree of interpatient variation observed. The observed interpatient variability in drug response may result primarily from genetically determined differences in drug metabolism, drug distribution, and/or receptors or drug target proteins. The branch of pharmacology that involves identifying genetic variations leading to interindividual differences in drug response is called *pharmacogenetics*. Pharmacogenetics is likely the ultimate way to establish the right drug and dose for each patient, thereby optimizing efficacy and minimizing toxicity. Despite the fact that this branch of pharmacology is still in its infancy as a science, a number of important discoveries have already contributed to improved pharmacotherapy in human and veterinary patients.

The term *pharmacogenetics* is often used interchangeably with the term *pharmacogenomics*. Strictly speaking, pharmacogenetics refers to monogenetic (single gene) variants that affect a patient's response to a particular drug. An example of a pharmacogenetic study might be one that examines the influence of mutations in the thiopurine methyl transferase gene on the response to azathioprine. Pharmacogenomics, on the other hand, refers to the entire spectrum of genes that are involved in determining a patient's response to a particular drug. An example of a pharmacogenomic study would be one that examines the interaction between cytochrome P450 genes, beta-1, beta-2, alpha-1, and alpha-2 adrenergic receptor genes, and drug transporter (i.e., MDR1) genes on the response to carvedilol. The relatively few reports of gene-drug responses in veterinary medicine are pharmacogenetic in nature.

While dramatic alterations in drug response have been identified in pharmacogenetic studies, the overall response to most drugs will likely require a pharmacogenomics approach to characterize the individual contribution of multiple genes to drug response. For the purposes of this chapter, the terms *pharmacogenetics* and *pharmacogenomics* will be used interchangeably.

The concept that inheritance might explain individual variation in susceptibility to adverse drug reactions and/or variation in drug efficacy was proposed in 1957. The term *pharmacogenetics* was coined shortly afterward, in 1959. Relatively little pharmacogenetic research occurred for the next 3 decades. A resurgence in pharmacogenetic research occurred coincidentally with the advent of the Human Genome Project in 1990. Since then, research in pharmacogenetics has expanded at a remarkable rate. There are now at least two journals exclusively devoted to pharmacogenetic/pharmacogenomic research, and many other medical and pharmacological journals encouraging submissions reporting results of pharmacogenetic research. Following completion of the Human Genome Project (announced in 2003), the National Human Genome Research Institute challenged investigators to develop genome-based approaches to predict drug response, setting the stage for continued growth in the field of pharmacogenetics.

BASIC GENETIC CONCEPTS

The human genome contains approximately 3 billion nucleotide bases, representing roughly 30,000 genes. When a gene is expressed, DNA is transcribed into RNA, which is then translated to make proteins. Three consecutive nucleotide bases form a specific codon, specifying a particular amino acid or signaling amino acid chain termination (stop codons). The genetic code is said to have redundancy, which simply means that there may be two or more different codons for the same amino acid. In humans, for example, both GGA and GGC code for the amino acid glycine. Redundancy exists in the canine genome as well, with TAA, TGA, and TAG representing stop codons. A gene is simply the DNA sequence containing a series of codons that specify a particular protein. The variation that occurs between individuals in a population is a result of differences, often the result of mutations, in specific genes.

A mutation alters the base sequence of DNA, which in turn alters the transcribed RNA creating a different codon. Some mutations, because of the redundancy described above, are silent, meaning that if the mutation results in a base change that creates a codon for the same amino acid (i.e., GGA to GGC) as specified by the original DNA sequence, there is no change in protein structure or function. However, if the mutation results in a different amino acid, or the creation of a stop codon, the change in protein structure and function can be deleterious. At each gene locus, an individual carries two alleles, one from each parent. An allele is defined as the DNA sequence at a given gene's location on the chromosome. If an individual has two identical alleles, that individual is said to have a homozygous genotype. If an individual has two different alleles, that individual is said to have a heterozygous genotype. The phenotype of each individual with regard to a specific gene is the outward, physical manifestation of a given genotype. That outward physical manifestation might be something immediately obvious in a given individual such as eye color, or it may not be apparent until a particular drug is administered to that individual.

Variations in a given gene may be present rarely in a population, or in relatively large numbers in a population. Polymorphisms are defined as genetic variations occurring at a frequency of 1% or greater in the population (species of interest). In humans, many of the genes encoding cytochrome P450 enzymes are polymorphic (specific mutations are present in greater than 1% of the population), whereas some inherited human diseases such as cystic fibrosis are caused by rare mutations occurring in less than 1% of the population. Identification of the specific mutation may be used to provide specific treatment regimens and, in the case of veterinary patients, guide breeding decisions as well. However, many common human diseases such as diabetes mellitus or hypertension are polygenic (more than one gene contributes to the disease). For diseases that are polygenic in nature, the pathophysiology of the disease is complex, and specific treatments based on particular mutations will be difficult to sort out. It is likely that many important diseases in veterinary medicine (i.e, hip dysplasia, epilepsy, most types of cancer) are polygenic also; therefore, genes linked to disease susceptibility will not be discussed in this chapter. Rather, this chapter will focus on genetic variations associated with variation in response to pharmacological agents.

APPROACHES USED TO IDENTIFY GENETIC VARIATION. In attempting to identify a molecular defect, several approaches can be used. Using the "candidate gene" approach, the researcher makes an educated

guess as to which gene(s) might be involved in a particular phenotype (disease process or drug response). Candidate genes may be genes that are associated with a similar phenotype in a different species. In many instances, a molecular defect may have been identified in humans or mice, providing a reasonable candidate gene for veterinary researchers to investigate. Alternatively, a candidate gene may be selected because it encodes a protein that is structurally or functionally intimately associated with the disease process or drug response of interest. For example, cytochrome P450 enzymes are known to be involved in the metabolism of many (if not most) drugs. The genes encoding these enzymes would be logical candidate genes to investigate if attempting to identify the molecular defect associated with drug toxicities. Once a candidate gene(s) has been identified, it is then evaluated in affected and unaffected animals by one or more techniques including sequencing, Northern or Southern blot analysis, or expression arrays.

Another method, linkage analysis, can be used if the candidate gene approach was unsuccessful or in cases where a rational candidate gene is not apparent. Linkage analysis involves identifying families segregating the phenotype of interest. Linkage analysis requires well-characterized multigeneration families segregating the disease, with the likelihood of identifying true linkage increasing with larger family size, and greater numbers of families included. Once an appropriate family or families have been characterized, a set of highly polymorphic DNA markers are analyzed for each of the family members characterized (affected and unaffected). A statistical program is then used to determine the likelihood that linkage exists between the genetic markers and the phenotype of interest (disease or drug response locus).

PHARMACOGENETICS

Genetic variation can affect both the pharmacokinetics (i.e., drug absorption, distribution, metabolism, and excretion) and pharmacodynamics (i.e., interaction with drug transporters and receptors) of pharmaceutical agents. The concept of pharmacogenetics originated in the 1950s when it was discovered that the antimalarial drug primaquine caused hemolysis in a subpopulation of individuals.[1] Ultimately it was shown that the enzyme glucose 6-phosphate dehydrogenase had reduced function in affected individuals as compared to the majority of the population.[1] At the time, techniques to study molecular biology were not available, so the field of pharmacogenetics was initially based purely on phenotypic observations (measurement of enzyme function). Discovery of the specific mutation in the glucose 6-phosphate dehydrogenase gene would not occur until a few decades later.

With the rapid advancement of molecular techniques, modern pharmacogenetic research differs significantly from those initial phenotypic observations. It currently involves identifying both the phenotype and the genetic variation responsible for it. Researchers perform systematic searches to identify functionally significant variations in DNA sequences in genes that affect drug disposition. In many instances, the genetic variation in a gene is identified before the phenotypic consequence is known. Sequencing of the human, and now the canine, genome will speed the progress of pharmacogenetic discoveries, facilitating the ultimate goal of pharmacogenetics, which is individualization of drug therapy.

It is important to note that individualization of drug therapy encompasses two distinct, yet equally important, clinical implications. First is the ability to predict those patients at high risk for developing drug toxicity. These patients may have a mutation in a drug-metabolizing enzyme that results in low clearance rates for the drug. For such patients a lower drug dose or alternate drug should be administered. Second is the ability to predict those patients that are most likely to benefit from a particular drug because of appropriate receptor interactions. Patients with mutations in drug receptors may be poor responders to certain pharmaceutical agents. Rather than using a trial-and-error approach to drug therapy, a veterinarian could select the drug most likely to produce the desired pharmacological response in a particular patient, decreasing the amount of time in which the patient's disease state is poorly controlled.

Described in this chapter are several recent discoveries in veterinary pharmacogenetics and examples of pharmacogenetically based differences in drug absorption, distribution, metabolism, excretion, and drug-receptor interactions. The impact of these discoveries in clinical veterinary medicine will also be presented. To date, most of the clinically relevant pharmacogenetic discoveries involve dogs. When applicable, information about other species will also be included.

PHARMACOGENETICS OF ORAL DRUG ABSORPTION.

Until recently, systemic bioavailability of orally administered drugs has been considered to be a function of physicochemical characteristics of the drug and subse-

quent hepatic metabolism. A number of other factors have recently been shown to impact the ability of a drug to be absorbed into the systemic circulation after oral administration. Intestinal Phase I drug metabolism and active drug extrusion by efflux transporters are now considered to be among the most important determinants of oral drug bioavailability. Consequently, genetic variation in intestinal drug metabolizing enzymes and drug transporters should dramatically affect oral drug absorption.

In people, CYP 3A is expressed at higher levels in mature villus tip enterocytes than in hepatocytes.[2] Because intestinal villi comprise such a large surface area, there is a high likelihood that absorbed drug will interact with intestinal CYP 3A enzyme, facilitating substantial first-pass metabolism. Interpatient variability in intestinal CYP3A levels has been studied in a small sample of human patients. Elevenfold variations in CYP3A protein content, and sixfold variation in enzymatic activity were identified, suggesting that CYP 3A polymorphisms exist in the human population.[3] While intestinal drug metabolism is thought to be important in veterinary patients also, relatively little is known with regard to interpatient variability in enzyme activity.

Drug transporters are also known to play an important role in drug absorption. Many drug transporters have been identified in people, but the most well-characterized drug transporter is P-glycoprotein (P-gp), the product of the MDR1 (also known as the *ABCB1*) gene. The potential impact of transporter pharmacogenetics on drug pharmacokinetics is dramatically illustrated by P-gp. P-gp is a transmembrane protein that was first described in highly resistant tumor cell lines.[4] Tumor cells expressing P-gp were cross-resistant to various anticancer agents (anthracyclines, vinca alkaloids, taxanes, and others). P-gp has since been shown to act as an ATP-dependent pump that exports drugs from nonneoplastic cells as well. In normal mammalian tissues, P-gp appears to function in a protective capacity. P-gp is expressed on bile canaliculi, renal tubular epithelial cells, the placenta, brain capillary endothelial cells, and at the luminal border of intestinal epithelial cells.[5] At these locations, P-gp pumps selected drugs either out of the body (into the bile, urine, or intestinal lumen) or away from protected sites (brain tissue, fetus).

The significant role intestinal P-gp can play in determining oral drug bioavailability has been demonstrated in rodent studies. In mdr1 (-/-) knockout mice, oral bioavailability of many P-gp substrate drugs (vinblastine, taxol, digoxin, loperamide, ivermectin, cyclosporine A, others) is substantially greater than in wildtype mice.[6,7] Similarly, MDR1 polymorphisms in people have been shown to result in altered oral bioavailability of P-gp substrate drugs. Studies have shown that oral bioavailability of digoxin, a P-gp substrate, is greater in subjects with the 3435TT MDR1 genotype compared with those with the MDR1 3435CC genotype.[8] Similarly, the P-gp substrate phenytoin has been shown to have lower oral bioavailability in subjects with the MDR1 3435 CC genotype.[9]

P-gp has been fairly well characterized in dogs. The tissue distribution of P-gp in dogs is similar to that in people,[10] and it has been shown to contribute to chemotherapeutic drug resistance in vitro and in vivo.[11–13] Although its role in determining oral drug bioavailability is not well characterized, there is some evidence that P-gp is important. Bioavailability of the anticancer agent (and P-gp substrate) docetaxel was increased seventeenfold when coadministered with a P-gp inhibitor. A polymorphism of the MDR1 gene has also been described in dogs, but results of studies investigating the effect of this polymorphism on oral drug bioavailability are not yet available.

The MDR1 polymorphism in dogs consists of a 4 base-pair deletion mutation. This deletion results in a shift of the reading frame that generates several premature stop codons.[14] Because protein synthesis is terminated before even 10% of the protein product is synthesized, dogs with two mutant alleles exhibit a P-gp null phenotype, similar to mdr1 (-/-) knockout mice. Affected dogs include many herding breeds. For example, roughly 75% of collies in the United States, France, and Australia have at least one mutant allele.[15] Other affected herding breeds, albeit at a lower frequency, include Old English Sheepdogs, Australian Shepherds, Shelties, English Shepherds, Border Collies, German Shepherds, Silken Windhounds, McNabs, and Long-haired Whippets.[16] Studies investigating the effect of the MDR1 deletion mutation on oral drug bioavailability in herding breeds are ongoing in the author's laboratory.

PHARMACOGENETICS OF DRUG DISTRIBUTION. Drug distribution, the delivery of drugs from the systemic circulation to tissues, can be dramatically affected by pharmacogenetics. The drug transporter P-gp serves as an important barrier to the distribution of substrate drugs to selected tissues. For example, P-gp is a component of the blood-brain barrier, the blood-testes barrier, and the placenta. Therefore, distribution of P-gp substrate drugs to

these tissues is greatly enhanced in dogs with the MDR1 deletion mutation. Dogs homozygous for the deletion [MDR1 (mutant/mutant)] experience adverse neurological effects after a single dose of ivermectin (120 µg/kg). Heterozygous (MDR1 wildtype/mutant) or homozygous wildtype dogs are not sensitive to ivermectin neurotoxicity at the 120 µg/kg dose, but heterozygote animals may experience neurotoxicity at ivermectin doses greater than 300 µg/kg, particularly if daily doses are administered (i.e., protocols for treatment of demodectic mange). Dogs homozygous for the normal MDR1 allele (normal/normal), can receive 2000 µg/kg in a single dose without signs of toxicity, and can receive 600 µg/kg/day for months without signs of toxicity. Affected Collies also appear to have increased susceptibility to neurologic adverse effects of other avermectins including milbemycin, selamectin (Revolution® package insert), and moxidectin.[17] Interestingly, a retrospective study conducted by a national veterinary poison center reported that Collies were overrepresented in canine cases of loperamide-induced neurotoxicity.[18] Many Collies displayed signs of neurologic toxicity after administration of routinely recommended doses of the antidiarrheal agent loperamide (Imodium®). Loperamide is an opioid that is generally devoid of CNS activity because it is excluded from the brain by P-gp.[19,20] Loperamide neurotoxicity was recently reported in a Collie that had received a routine dose (0.14 mg/kg orally).[21] The dog in this report had the MDR1 (mutant/mutant) genotype. Homozygous wildtype (normal/normal) dogs do not exhibit neurologic signs after receiving even higher doses of loperamide, indicating that P-gp plays a key role in modulating distribution of substrates such as loperamide to canine brain tissue. Less information is available regarding P-gp and the blood brain barrier in cats. The author has received anecdotal reports of ivermectin toxicity in cats after standard doses, but whether the underlying cause is a result of altered P-gp expression or function is not currently known.

Distribution of some drugs to the testes and fetus may also be limited by P-gp. In human patients, this creates a problem for treating certain diseases. For example, the testes and brain are considered to be a sanctuary site for the human immunodeficiency virus (HIV).[22] Because HIV-1 protease inhibitors are substrates for P-gp, the virus can remain viable in these sanctuary sites, hampering effective therapy. Similarly, therapeutic concentrations of certain chemotherapeutic agents may not be achievable for testicular cancers because of active efflux by P-gp.[23] The effect of placental P-gp on distribution of drugs to the fetus is an area of active research in human medicine.[24] Understanding the role of pregnancy-related hormones in regulating P-gp expression and function is one possible key in developing strategies to deliver drugs to the mother with minimal fetal risk.

PHARMACOGENETICS OF DRUG METABOLISM. Presently the greatest body of knowledge with regard to pharmacogenetics involves genetic variation in drug metabolism. Pharmacogenetic variation can affect both Phase I and Phase II metabolic enzyme activity. A mutation in the pseudocholinesterase enzyme serves as an example of how pharmacogenetic variation can result in dramatic differences in drug response between patients. Patients with a normal pseudocholinesterase genotype metabolize succinylcholine and recover from neuromuscular blockade rapidly; those with the mutant genotype undergo sustained neuromuscular blockade that can result in prolonged apnea and the necessity for mechanical ventilation.[25] A number of polymorphisms have been described in human cytochrome P450 enzymes, many of these resulting in profound variations in clinical response. For example CYP2D6 is a highly variable P450 pathway in humans with individuals ranging from undetectable activity (found in 6–10% of Caucasians) to "ultrarapid" activity (found in 3–10% of Europeans and 30% of one black population).[26] The ultrarapid phenotype is due to a highly unusual gene duplication. Drugs that are substrates for CY2D6 in people include beta receptor antagonists (propranolol, timolol, metoprolol), antiarrhythmics (quinidine, flecainide), antidepressants (amitriptyline, clomoipramine, fluoxetine, imipramine), neuroleptics, and certain opioid derivatives. Depending on the patient's CYP2D6 genotype, the "typical" dose of a substrate drug may need to be decreased (poor metabolizers require 1/10 of the standard dose of nortriptyline to avoid toxicity) or increased (ultrarapid metabolizers require 5 times the standard dose to achieve therapeutic concentrations).

Relatively few polymorphisms in drug metabolizing enzymes have been described in veterinary patients, although this is likely to change as research in this area is currently in progress. However, variation in metabolism of some drugs has been documented in dogs. CYP2B11 has been shown to have at least a fourteenfold variation in activity in mixed-breed dogs.[27] Greyhounds have been shown to have particularly low CYP2B11 activity, which

results in sustained plasma concentrations of propofol and delayed recovery compared to mixed-breed dogs.[28] The specific genetic alteration responsible for reduced CYP2B11 in greyhounds as compared to other canine breeds has not been determined. There is some evidence to suggest that CYP 2D15 may also be polymorphic in dogs. The NSAID celecoxib is metabolized to a large degree by CYP2D15. Clearance of celecoxib in beagles is polymorphic, with about half the population being extensive metabolizers and the remainder being poor metabolizers.[29] Celecoxib has a 1.5–2-hour half-life in extensive metabolizers and a 5-hour half-life in poor metabolizers. One pharmacogenetic variant that has been identified in the canine CYP2D15 gene, a deletion of exon 3, results in undetectable celecoxib metabolism. The frequency and breed distribution of this polymorphism has not yet been determined. However, it is likely to have clinical significance for other drugs that are CYP2D15 substrates including dextromethorphan, imipramine, and others.

A number of other mutations in drug metabolizing enzymes have been described in animals, but the clinical relevance of these mutations, if any, has yet to be determined. For example, 10% of beagles in one study were deficient in CYP1A2 because of a mutation that resulted in premature termination of protein synthesis.[30] CYP1A2 does not appear to be responsible for metabolizing clinically used drugs in veterinary medicine, but CYP1A2 is studied frequently in people with regard to susceptibility to certain types of cancers. A feline hepatic CYP 2E polymorphism has been identified, but the clinical relevance of this polymorphism has not been described.[31] Similarly, polymorphisms have been described in several drug metabolizing enzymes in cattle,[32] but these single nucleotide polymorphisms are used as molecular markers available in cattle for linkage analysis, testing of parentage, and distinction of breeds, rather than for predicting response to drug therapy.

With respect to Phase II metabolic enzymes, a panspecies defect in UDP-glucuronyl transferase exists in cats. While this is not a true example of pharmacogenetics, it serves as an example of genetic variation between species, rather than within a species, that significantly affects drug disposition. Cats have a pseudogene, rather than a functional glucuronyltransferase gene; therefore, acetaminophen and other drugs are not conjugated with glucuronide as they are in other species. Another panspecies Phase II metabolic defect occurs in dogs. N-acetyltransferase is the enzyme responsible for metabolizing sulfonamides, procainamide, hydralazine, and other drugs. Both N-acetyltransferase genes are absent in dogs, increasing the risk for hypersensitivity reactions and adverse effects from these drugs relative to other species.[33]

A true pharmacogenetic variation exists for the thiopurine methyltransferase (TPMT) enzyme. TPMT is a Phase II enzyme that is responsible for metabolizing azathioprine and its active metabolites to their inactive forms. A ninefold range in TMPT activity exists in dogs, and enzyme activity level appears to be related to breed. Giant Schnauzers had lower TPMT activity while Alaskan Malamutes had high TMT activity.[34] Decreased TPMT activity has been documented to be associated with increased susceptibility to azathioprine-induced bone marrow suppression.

PHARMACOGENETICS OF DRUG EXCRETION. Drugs are eliminated from the body either unchanged or as metabolites. Renal and biliary excretion are the most important pathways of drug elimination, but excretion may occur by other routes as well. As noted previously, P-gp is expressed on renal tubular cells and biliary canalicular cells, suggesting that it may play a role in drug excretion. Concurrent administration of a P-gp inhibitor decreases the biliary and renal clearance of doxorubicin in rats.[35] In a separate study, biliary and renal excretion of digoxin and vincristine were increased in rats after treatment with a P-gp inhibitor.[36] Further research is necessary to fully define the role of P-gp in regulating renal and biliary drug excretion in veterinary patients. However, altered biliary and/or renal excretion may play a role in the apparent increased sensitivity of herding breeds to chemotherapeutic drugs that are P-gp substrates. For example, a Collie with lymphoma developed myelosuppression and GI toxicity after treatments with vincristine or doxorubicin, even at lowered doses, but tolerated cyclophosphamide at the full dose. The patient was subsequently genotyped and was determined to have one mutant MDR1 allele and one normal MDR1 allele.[37] It is possible that deficient P-gp in this patient resulted in delayed renal and/or biliary excretion and subsequent toxicity. Other reports of severe doxorubicin and/or vincristine sensitivity in Collies and other herding breeds have surfaced on internet veterinary discussion groups. The MDR1 mutation may be a reasonable explanation for this apparent breed predilection to chemotherapeutic (vinca alkaloids; anthracyclines) drug sensitivity.

PHARMACOGENETICS OF DRUG RECEPTORS. A relatively new and important area of pharmacogenetics research involves polymorphisms in genes encoding drug receptors and effector proteins. In human patients polymorphisms have been described in angiotensin converting enzyme, beta-2 adrenergic receptors, the dopamine receptor, the estrogen receptor, and others.[38] In vitro functional studies suggest that these polymorphisms have functional significance, but reports regarding clinical effects are not available. A polymorphism in the canine dopamine receptor D4 gene has been described but its clinical implications, if any, are not yet understood.[39]

PHARMACOGENETICS AND HYPERSENSITIVITY REACTIONS. Pharmacogenetic differences in metabolic pathways can not only affect Type A adverse drug reactions (predictable; generally correlating with plasma drug concentration), but can also affect type B adverse drug reactions (idiosyncratic). Idiosyncratic toxicity to sulfonamides is similar in dogs and people and can be characterized by fever, arthropathy, blood dyscrasias (neutropenia, thrombocytopenia, or hemolytic anemia), hepatopathy consisting of cholestasis or necrosis, skin eruptions, uveitis, or keratoconjunctivitis sicca.[40] In people, slow acetylation by NAT2 has been shown to be a risk factor for sulfonamide hypersensitivity reactions. It has been proposed that the alternative metabolic pathway in these individuals produces reactive metabolites.[41] Covalent binding of reactive metabolites of these drugs to cell macromolecules results in cytotoxicity and immune response to neoantigens. Ongoing research in one veterinary pharmacology laboratory (Department of Medical Sciences, School of Veterinary Medicine, University of Wisconsin-Madison, 2015 Linden Drive, Madison, WI 53706; latrepanier@svm.vetmed.wisc.edu) is underway to characterize dogs with possible idiosyncratic sulfonamide reactions, using several methodologies including ELISA for antidrug antibodies, immunoblotting for antibodies directed against liver proteins, flow cytometry for drug-dependent antiplatelet antibodies, and in vitro cytotoxicity assays.

PHARMACOGENETICS IN CLINICAL PRACTICE. Scientific interest in the field of human pharmacogenetics has increased each year in parallel with the knowledge of the human genome. However, interest in this field by physicians has lagged significantly behind, presumably because relatively few significant clinical consequences can be correlated to the vast number of pharmacogenetic mutations described in the literature. There are two main reasons for this discrepancy. Up to this point, polymorphisms described in human patients either have had low allelic frequencies or the clinical relevance of a particular polymorphism was not significant. For example, a highly clinically relevant polymorphism in the human TPMT gene has been described. TMPT metabolic activity in affected patients is essentially absent, so these patients experience severe neutropenia after a "normal" dose of azathioprine. Because this TPMP polymorphism affects approximately 0.3% of the Caucasian population, pharmacogenetic testing is not routinely performed in clinical practice.[42] Conversely, the allelic frequency of a genetic polymorphism of the human MDR1 gene has been shown to be associated with lower levels of P-gp expression in the duodenum and other tissues. While the allelic frequency of this particular MDR1 polymorphism is relatively high (>10%), it does not appear to have an important and predictable clinical impact on drug disposition. The vast majority of pharmacogenetic research in human medicine has not extended to clinical medical practice.

In veterinary medicine, however, a commercial veterinary pharmacogenetics laboratory (Veterinary Clinical Pharmacology Laboratory, Washington State University, Pullman, WA, 99164; www.vetmed.wsu.edu/vcpl) is performing canine MDR1 genotyping for veterinarians, dog breeders, and owners. One important reason that commercial pharmacogenetic testing is readily available for canine patients, and not for human patients, is because the MDR1 mutation in dogs has a very high allelic frequency (55% in Collies; 42% in Longhaired Whippets; and roughly 20% in Australian Shepherds), and because the polymorphism is highly predictive for serious adverse drug events, not just for one drug class but for several drug classes. See Table 50.1 for a partial list of drugs that are substrates for P-gp.

FUTURE DIRECTIONS. The field of pharmacogenetics, particularly in veterinary medicine, is still in its infancy. However, we have an ever-increasing arsenal of molecular tools that can be used to expand our knowledge of pharmacogenetics. Furthermore, with the recent completion of the canine genome project, and the ongoing elucidation of its data, we may soon know the sequences of virtually all genes encoding drug metabolizing enzymes, drug trans-

TABLE 50.1 Selected P-gp substrates[43–47].

porters, receptors, and other drug targets. With this information, the traditional clinical approach to variation in drug response (phenotype-to-genotype) will likely give way to a prospective approach (genotype-to-phenotype). That is, genetic variation identified in a specific gene will be investigated to determine whether it alters pharmacological response. While the ultimate goal of modern pharmacogenomics, individualization of drug therapy, may not be achieved for all drugs, it certainly has the potential to increase both safety and efficacy of many drugs.

THERAPEUTIC DRUG MONITORING

MARK G. PAPICH

Therapeutic Drug Monitoring: Considerations	1323
Timing of Sample	1323
Assay	1324
Type of Sample	1324
Phenobarbital	1325
Timing of Samples	1326
Bromide	1326
Pharmacokinetics	1326
Effect of Diet	1326
Clinical Use	1326
Loading Doses	1326
Clinical Use in Cats	1326
Therapeutic Monitoring of Bromide	1327
Cyclosporine	1327
Assay Specificity	1327
Timing of Sample	1328
Aminoglycosides	1328
Digoxin	1329
Therapeutic Monitoring	1330

Methods for therapeutic drug monitoring have been published in popular textbooks. Some of the guidelines are listed the tables of this chapter. Veterinarians can find local hospitals and diagnostic laboratories that have the capability of performing drug analysis. Because of large interindividual variations in pharmacokinetics for the drugs listed, monitoring is advised for the following conditions: 1) animal refractory to medication, despite an adequate dose; 2) animal showing toxicity, despite an adequate dose; 3) assessing owner compliance; 4) switching medications (e.g., from a brand name to a generic and need to establish a baseline; 5) drug interaction (for example, to see whether or not interactions are occurring with cyclosporine administration); and 6) pharmacokinetic differences in individual patients, such as altered absorption or elimination.

THERAPEUTIC DRUG MONITORING: CONSIDERATIONS

TIMING OF SAMPLE. For short half-life drugs, more than one sample (three is ideal) is the most useful for determining individual pharmacokinetic parameters. Alternatively, a peak (C_{MAX}) and a trough (C_{MIN}) can be collected to determine the bounds of high and low concentrations at steady-state. For long half-life drugs (digoxin, bromide, phenobarbital), a single sample during the dosing interval is sufficient. If one suspects altered clearance rates, however, more samples can be collected to assess half-life. For cyclosporine, a single trough sample has been used for many years, but now recommendations are changing to a single 2-hour sample (C_2).

ASSAY. The assay will vary according to the laboratories. Many automated chemistry machines used for biochemical analysis have drug detection kits that can be added to their menus. Some laboratories use RIA methods, others use other immunoassay methods (e.g., chemiluminescence). One of the popular bench-top assay machines is the fluorescence polarization immunoassay by Abbot, known commonly as the *TDx method*. Rarely is HPLC used because of the expense and slow turnaround time, but it is still considered the gold standard for specificity.

TYPE OF SAMPLE. The type of sample will vary according to the specific assay. Most assays allow serum, some require plasma, and for some assays either is acceptable. Samples should be collected and centrifuged as soon as possible. Avoid serum-separator tubes because these may lower drug concentrations by adsorbing drug into the matrix. Some assays are specific about storage of samples. Plastic cryo-vial type tubes are acceptable for most assays. For cyclosporine, the assay specifically calls for whole blood, not plasma, collected in an EDTA tube.

Examples of drugs that can be measured in most routine clinical or diagnostic laboratories are listed in Table 51.1.

TABLE 51.1 Examples of drugs that can be measured in most clinical or diagnostic laboratories

Test	Specimen	Timing of Sample	Tube	Storage	Effect of Interference	Reference Range
Amikacin	Serum or plasma 0.5 ml	1, 2, and 4 hours after dose, preferably. Other strategies for collecting two or three samples also have been used to assess clearance.	red-top or lavender-top	30 days @ −20°C	Hemolysis: no effect Icterus: no effect Lipemia: no effect Cross-reactivity: <1% interference with other drugs and antibiotics, except tobraymycin, with which there is high cross-reactivity. Limit of detection: 0.8 µg/ml	Peak: 40 µg/ml Trough: <0.8 µg/ml Other methods to assess clearance are possible if more than two samples are collected.
Bromide (potassium or sodium bromide)	Serum 0.5 ml	Anytime during dosing interval.	red-top	60 days @ −20°C	No interference with other drugs. Bromide and phenobarbital can be analyzed in same sample. Hemolysis: no effect Icterus: no effect Lipemia: no effect	100–200 mg/dl (with phenobarbital) 200–300 mg/dl (monotherapy)
Cyclosporine	Whole blood 1.0 ml	Trough (12 hours after last dose). Alternatively, peak concentrations at 2 hours have been used.	lavender-top	30 days @ −20°C	Because of metabolites, the assay overestimates true cyclosporine concentrations by 1.5–2×. For a true level, correct result by ×0.7 in dogs; and ×0.5 in cats.	300–600 ng/ml @ 12 hr (may vary with disease)
Digoxin	Serum 0.5 ml	Anytime during dosing interval. Generally 4–6 hours after dosing.	red-top	7 days @ 2–8°C 2 months @ −20°C	Hemolysis: no effect Bilirubin: No effect Lipemia: No effect Heparin tube: decrease by 5% EDTA tube: decrease by 7% Do not use serum-separator tubes.	0.8–2.5 ng/ml

TABLE 5.1 ***continued***

Test	Specimen	Timing of Sample	Tube	Storage	Effect of Interference	Reference Range
Gentamicin	Serum or plasma 0.5 ml	1, 2, and 4 hours after dose, preferably. Other strategies for collecting two or three samples also have been used to assess clearance.	red-top or lavender-top	30 days @ –20°C	Hemolysis, Icterus, Lipemia produce <5% error in the assay. Cross-reactivity: <1% interference with other drugs and antibiotics. Limit of detection: 0.27 µg/ml	Peak: 20 µg/ml Trough: <0.27 µg/ml Other methods to assess clearance are possible if more than two samples are collected.
Phenobarbital	Serum or plasma 0.5 ml	Anytime during dosing interval.	red-top or lavender-top	2 days @ 2–8°C 1 month @ –20°C	Bilirubin: no effect Hemolysis: no effect EDTA or heparin tube: no significant effect. Do not use serum-separator tubes.	15–40 µg/ml
Theophylline	Serum 0.5 ml	Ideally, a peak and trough should be collected. If that is not possible, collect a trough immediately before the next dose.	red-top	30 days @ –20°C	Hemolysis, Icterus, produce <5% error in the assay. Lipemia produces <10% error. Cross-reactivity: <1% interference with other drugs, and 1.5% cross-reactivity with theobromine. Limit of detection: 0.82 µg/ml	10–20 µg/ml. In some patients, trough concentrations of 5 µ/ml have been effective.
Vancomycin	Serum 0.5 ml		red-top	30 days @ –20°C	Hemolysis, Icterus, Lipemia produce <5% error in the assay. Cross-reactivity: <1% interference with other drugs, and 1.5% cross-reactivity with theobromine. Limit of detection: 2.0 µg/ml	Peak: 30–40 µg/ml Trough: 5–10 µg/ml

PHENOBARBITAL

As an example of clinical therapeutic drug monitoring, specific guidelines for phenobarbital are provided: To adjust dose, monitor compliance, and assess toxicity, it is the usual practice to regularly monitor plasma or serum phenobarbital concentrations during therapy. Assays are available at most diagnostic laboratories. This can be done initially after the first 2 weeks of starting treatment and then every 6–12 months, or as needed to assess treatment.

The recommended plasma/serum therapeutic concentration for dogs is 15–40 µg/ml (65–180 mmol/l). Some textbooks list this range as 20–45 µg/ml and 15–45 µg/ml. If dogs are also receiving bromide, phenobarbital concentrations in the range of 10–36 µg/ml have been reported as therapeutic (Trepanier et al. 1998). For cats, the optimum range has been cited as 23–30 µg/ml (Quesnel et al. 1997). In the cited study, cats were more unstable than dogs, possibly because of more serious CNS disease, and required more frequent monitoring.

TIMING OF SAMPLES. Because phenobarbital has such a long half-life, fluctuations between plasma peaks and troughs are minimized when it is administered on an every 12-hour schedule. Therefore, it makes no difference when a sample is collected during a 12-hour schedule for the assessment of plasma phenobarbital concentrations (Levitski and Trepanier 2000).

BROMIDE

Bromide is the oldest of the anticonvulsants; yet, it is chemically simple. It was used in people as early as the mid-1800s and its use was first described in dogs as early as 1907. Because it is toxic in people, it was replaced by other anticonvulsants after the introduction of phenobarbital in 1918. It is now used commonly in dogs, and sometimes in cats (Podell and Fenner 1993, 1994; Trepanier 1995).

Bromide has been used in combination with phenobarbital to treat refractory seizures, and also has been used as monotherapy (single drug). When bromide is administered as a single drug, the doses may need to be higher compared to administering bromide with phenobarbital. When bromide is administered with phenobarbital, phenobarbital doses can be decreased by as much as one-half. One study reported that, in 19% of dogs receiving phenobarbital and bromide, eventually the phenobarbital was discontinued while still maintaining seizure control (Trepanier et al. 1998).

When potassium bromide (KBr) has been used to treat canine epileptics that have not responded to phenobarbital alone, success rates have been 60%, and higher. One author reported as high as 72% improvement in seizure control (Trepanier et al. 1998).

PHARMACOKINETICS. The half-life of bromide in humans is 12 days. The half-life in dogs appears to be 25 days, but can be variable and as short as 15 days. Elimination rate can vary depending on the patient's diet. Because the half-life is long, chronic daily administration will be necessary for this drug to accumulate to steady-state plasma concentrations. However, during the accumulation phase (loading dose period) the half-life is shorter (16.5 days), which results in faster accumulation. The half-life in cats appears to be a bit less than in dogs; about 14 days, and perhaps as short as 10 days.

EFFECT OF DIET. Diets high in chloride will cause bromide to be excreted more rapidly (as much as 50% decrease in half-life with high-chloride diets); therefore, keep the diet constant throughout therapy, or monitor serum bromide concentrations each time the diet is changed. Some prescription diets have either high or restricted chloride content and patients receiving these diets may need dose adjustments.

CLINICAL USE. Usually the potassium salt of bromide is used, but sodium bromide also can be substituted. Most veterinary compounding pharmacies have recipes for making up an oral solution and it is reasonably inexpensive. The typical dosage for dogs is 20 to 40 mg/kg, orally, once per day. The lower doses are more common when used with phenobarbital, while the higher doses are given when monotherapy is used.

There is high variability among animals with respect to absorption and excretion. Therefore, it is suggested that each patient be monitored for signs of toxicity (ataxia, CNS depression), as well as plasma concentration monitoring, and the dose adjusted if necessary.

LOADING DOSES. Loading doses of 600 mg/kg orally, divided over 3–4 days, have been administered in patients that need therapeutic concentrations quickly in the range of 1.0 to 1.5 mg/ml. In some cases it has been necessary to administer sodium bromide IV as a loading dose. This has been accomplished by mixing sodium bromide (potassium bromide may be too toxic if given IV), in a solution to deliver an initial dose of 600–1,200 mg/kg over approximately 8 hours. If the plasma concentration is still in the low range, an additional IV loading dose can be administered.

CLINICAL USE IN CATS. The most common dose for cats is 30 mg/kg per day. A report and accompanying review evaluated use of bromide in cats (Boothe et al. 2002). In that report, the authors identified a half-life in cats of only 11.2 days. An evaluation of the clinical use showed that there was inadequate seizure control in approximately half of the cats, despite serum concentrations that are considered effective in dogs. More importantly, there were adverse effects in approximately half of the cats. The most common adverse effect was coughing.

THERAPEUTIC MONITORING OF BROMIDE. Plasma concentrations can be measured at most veterinary diagnostic laboratories. Samples are easy to assay using a simple gold-chloride color-based (spectrophotometric) assay. Assays can be completed in less than 30 minutes. Ordinarily, effective concentrations are reported as between 1 and 2 mg/ml (100–200 mg/dl). If concentrations are less than 1.0 mg/ml, one should increase the dose. If bromide is used as the sole anticonvulsant (without phenobarbital) concentrations as high as 2–3 mg/ml (200–300 mg/dl) may be necessary.

CYCLOSPORINE

A common oral dose in people is 5–10 mg/kg/day to achieve targeted whole blood concentrations of 150–400 ng/ml. In people, dosages are adjusted to meet the needs of the individual patient on the basis of clinical response and monitoring trough plasma concentrations. For animals, doses of 10–20 mg/kg/day were frequently cited in older publications, but more recent recommendations, in which newer formulations have been used, cite lower doses. For organ transplantation in cats (Mathews and Gregory 1997) a dose of 3 mg/kg q12h of the Neoral formulation (dose was doubled for Sandimmune formulation) was used to achieve trough blood concentrations of 300–500 ng/ml. At NCSU we routinely administer 25 mg/cat for suppression of immunity for transplantation, and modify as needed with monitoring. For organ transplant in dogs, 10 mg/kg q12h to achieve concentrations of 500–600 ng/ml has been used (Mathews et al. 2000). A report on treating perianal fistulas in dogs (Mathews and Sukhiani 1997) found that an average dose of 6 mg/kg q12h was needed to achieve a targeted blood concentration of 400–600 ng/ml. However, this recommendation was later modified to 2.5 to 6 mg/kg/day (3 mg/kg q12h) to achieve an effective blood concentration of 100–300 ng/ml. When treating perianal fistulas in dogs we have achieved adequate blood concentrations, without producing toxicity, at a dose of 3 mg/kg q12h.

For treating dermatitis in dogs, the effective dose has been 5 mg/kg/day. Some clinicians have been able to lower the dose, or administer the dose every other day, and still maintain clinical remission. The pharmacokinetics of cyclosporine in treated animals has been examined by Steffan and colleagues (2004). They found that routine monitoring of cyclosporine in dogs with atopic dermatitis was not necessary. When animals were administered a dose of 5 mg/kg/day, there did not appear to be a strong correlation between blood concentration achieved and clinical response. Nevertheless, because of wide individual variation in cyclosporine pharmacokinetics, monitoring has been used to determine the optimum dose for each patient. According to one paper, clinical benefits have not been observed when trough concentrations have fallen below 50 ng/ml; therefore, blood testing of patients failing therapy was suggested to reveal inadequate dosing (Robson and Burton 2003).

Cyclosporine is available in human formulation capsules of 25 and 100 mg, 20 mg/ml oral solution, and 50 mg/ml injection. The veterinary brand (Atopica) is available as 10, 25, 50, and 100 mg. There are also generic preparations available, but their absorption and pharmacokinetics have not been reported for animals. Some comparisons have not demonstrated that the generic formulations are significantly less expensive than brand name products.

ASSAY SPECIFICITY. One must be cognizant of the assay used when monitoring cyclosporine. Plasma values will be lower than whole-blood assays because as much as 50–60%, and 10–20% of the dose is concentrated in erythrocytes and leukocytes, respectively. Nonspecific assays will report higher values than a more specific (monoclonal or HPLC) assay. Despite the hypothesized higher specificity when using the monoclonal assay, important discrepancies between these assays and the more specific HPLC assay have been reported (Steimer 1999). For example, in people the difference between HPLC and the commonly used TDx monoclonal immunoassay was 57%. In cats, we found that the TDx assay overestimated the true cyclosporine concentration by approximately twofold. (That is, TDx assay reporting 500 ng/ml corresponded to an actual value of 250 ng/ml.) In dogs, the TDx assay overestimates the true cyclosporine concentrations by a factor of 1.5 to 1.7 (Steffan et al. 2004). When using a specific radioimmunoassay or HPLC, true concentrations are measured. But, when using a TDx fluoroescence polarization assay (monoclonal whole blood) multiply the feline concentrations by 0.5 to get the true concentration, and multiply the canine concentration by 0.6 to get the true concentration.

TIMING OF SAMPLE. Most recommendations have been based on trough blood sample monitoring. Trough samples are collected immediately before the next scheduled dose; therefore, the sample is either 12 or 24 hours after the last dose. These recommendations are being modified in human medicine to a recommendation of a 2-hour sample (C_2). Apparently there is evidence that a C_2 blood sample value correlates better with clinical results than trough samples (Levy et al. 2002; Nashan et al. 2002). In cats, levels are approximately twice as high at 2 hours compared to the levels at 12 hours (Mehl et al. 2003).

AMINOGLYCOSIDES

Rational aminoglycoside dosing regimens should be based on pharmacokinetic and pharmacodynamic information derived from populations of diseased animals, and the relationship of these data to clinical outcome. Once-daily dosing regimens are the standard approach for both small animals and equine patients. In human patients, it has been shown that doses of aminoglycosides that result in peak plasma concentrations (C_{MAX}) approximately 8–10 times MIC confer optimal bactericidal effect. Aminoglycoside dosing regimens for animals also target a C_{MAX}/MIC ratio of 8 to 10. To achieve these ratios in horses, a gentamicin dose of 6.8 mg/kg and an amikacin dose of 10 mg/kg were adequate to achieve the target C_{MAX}/MIC in adult horses. For dogs and cats, the doses for gentamicin are 9–14 mg/kg and 5–8 mg/kg, respectively. For administration of amikacin in dogs and cats, the doses are 15–30 mg/kg and 10–14 mg/kg, respectively.

The aminoglycosides are distributed in the extracellular fluid (ECF) space, and neonatal foals (<4 weeks of age) have larger total body water and ECF volume compared with adult horses (see Table 51.2). Accordingly, to avoid therapeutic failure associated with inadequate peak drug concentrations, larger aminoglycoside doses are recommended for young foals. As the foals mature, the transition to adult pharmacokinetic values occurs rapidly after 6 weeks of age. The table shows recommended once-daily dosing regimens for gentamicin and amikacin in neonatal foals compared to adult horses, together with suggested target peak and trough plasma drug concentrations.

Therapeutic drug monitoring (TDM) in animals receiving aminoglycoside treatment has been used to optimize therapy. If TDM can identify situations in which the dose can be lowered, there are also cost benefits. TDM can be useful because there may be a wide variation in drug disposition among sick patients, especially in critically ill neonates. Therefore, TDM can identify those patients with parameters that do not represent the average. For example, the effective volume of distribution for the aminoglycosides is often higher in septic patients or those with a "third-space" problem (uroperitoneum, pleural effusion), necessitating a higher dose to produce the target peak plasma concentrations. Furthermore, longer clearance times for gentamicin and amikacin have been observed in premature and full-term foals with hypoxia, azotemia, and septicemia, likely the result of renal hypoperfusion and decreased glomerular filtration rate. In these cases, a longer interdose interval may be needed to reduce the risk for nephrotoxicity. Disadvantages of TDM in veterinary patients include the added expense and, particularly in field situations, the lack of access to a laboratory capable of performing the drug assays. Collecting serial blood samples after dosing in a field situation also is not often practical.

When TDM is employed, it is helpful to determine: 1) whether the target C_{MAX} is achieved, and 2) whether there is adequate clearance of the drug. (For aminoglycosides,

TABLE 51.2 Pharmacokinetic information and dosing regimens for gentamicin and amikacin in horses

	T1/2 (hr)	CL (ml/min/kg)	VD (L/kg)	C_{MAX} (μg/ml)	Dose
AMIKACIN					
Foal (<30 days old)	3.9	1.84	0.52	40	20–25 mg/kg, q24h
Adult	1.9	1.3	0.22	40	10 mg/kg, q24h
GENTAMICIN					
Foal (<30 days old)	1.6	2.7	0.356	20	10–14 mg/kg, q24h
Adult	1.70	1.5	0.18	20	4–6.8 mg/kg, q24h

T1/2: elimination half-life; CL: systemic clearance; VD: apparent volume of distribution (area method); C_{MAX}: Desired peak plasma concentration; Dose listed can be administered either IV or IM (IM absorption is nearly complete).

Pharmacokinetic values presented here are an approximation derived from several sources listed in the reference section. Values listed represent averages from more than one study.

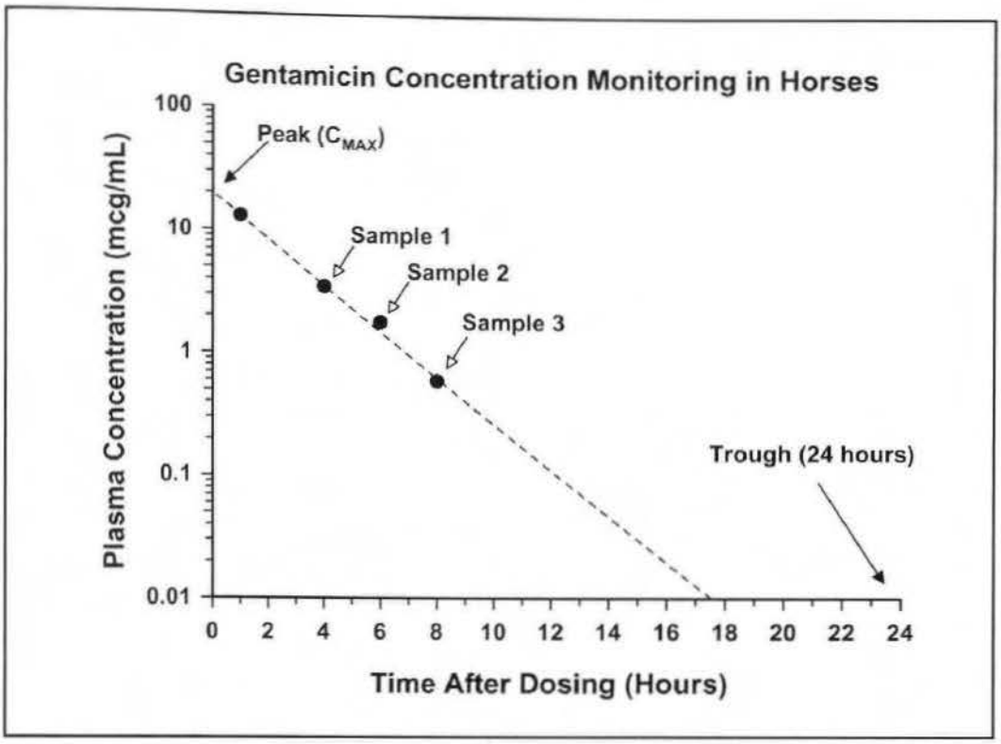

FIG. 51.1 Example of gentamicin plasma concentration monitoring. In this figure is an example in which plasma samples were collected from an adult horse given 4 mg/kg, IV, to determine gentamicin concentrations. Three strategies for plasma concentration monitoring are illustrated: (1) A single concentration, collected 1 hour after drug administration represents an approximate peak (C_{MAX}). The C_{MAX} in this case at 1 hour was 13 µg/ml, which would be adequate (i.e., 8–10 × the MIC) for organisms with an MIC of approximately 1.3 µg/ml, or less. (2) A sample collected immediately prior to the next dose (24 hours) represents the trough. The trough in this example is below the limit of detection, indicating that the risk of renal toxicity is low. If elevated trough concentrations were identified, it would increase the risk of nephrotoxicosis. (3) To estimate the half-life (T1/2) and clearance, a series of three samples can be collected approximately 1–2 hours apart, represented here by Sample 1, 2, and 3, at 4, 6, and 8 hours, respectively. In this example, the three samples were used to estimate the half-life, which was 1.6 hours—normal for an adult horse. It also can be seen that the advantage of collecting a series of three samples is that peak and trough concentrations can be extrapolated by extending the straight line to the intercepts (dashed line) to determine the true peak and trough concentrations. The true C_{MAX} in this example (y-axis intercept) was approximately 20 µg/ml. The apparent volume of distribution, calculated from VD = Dose/C_{MAX}, was approximately 0.2 l/kg—normal for an adult horse. The systemic clearance (CL) in this case, calculated from the formula: CL = (0.693 × VD)/T1/2, was 1.44 ml/kg/min—normal for an adult horse.

the systemic clearance value is a close approximation of the glomerular filtration rate (GFR) measured by creatinine clearance methods.)

To perform TDM, either a single sample can be collected 30 min to 1 hour postdosing for an estimate of the peak drug concentrations (C_{MAX}), or two or three samples can be collected at 1- or 2-hour intervals to identify the slope of the elimination curve. Analysis of a series of points requires the use of linear regression and calculation of the slope of the curve plotted on a logarithmic axis (see Fig. 51.1). From the elimination curve, an estimate of clearance, volume of distribution, and half-life (T1/2) is possible. These approaches are illustrated in Figure 51.1. Alternatively, a single trough sample can be collected immediately prior to the next scheduled dose. But as illustrated in the figure, this sample is frequently below the limit of detection of the assay, unless there is impaired clearance and drug accumulation. In situations in which TDM is not available, repeated evaluation of renal function is recommended during aminoglycoside therapy.

DIGOXIN

Digoxin is available in injectable forms (0.1 and 0.25 mg/ml Lanoxin®) and can be given IV. It is also available in

TABLE 51.3 Digoxin pharmacokinetic information

Species	Half-Life (hr)	Volume of Distribution	Recommended Dose (mg/kg)
dog	15–32	9.5–15.6 l/kg	0.01, q12h or 0.22 mg/m^2 q12h
cat	33–58	15–26 l/kg	0.01, q48h
horse	13–30	4.7–7 l/kg	0.002 IV, q12h or 0.015 oral, q12h 0.009 IV
cattle	7.8–15.2	6.4 l/kg	
man	39	3.12 l/kg	

tablet (Lanoxin®) at 0.125, 0.25, 0.5 mg, and elixir form (Cardoxin® 50 or 150 µg/ml) for oral administration.

Digoxin is eliminated approximately 15% by hepatic, and 85% by renal mechanisms. Animals with renal disease may have trouble excreting digoxin. Although digoxin has a high apparent volume of distribution, it does not distribute to fat. Therefore, when calculating doses, it often is done according to lean body weight (Table 51.3). Oral absorption is 60% and 85% for digoxin tablets and elixir, respectively (adjustments for oral absorption should be made when switching from one dosage form to another).

THERAPEUTIC MONITORING. The therapeutic serum level for most animals is believed to be 0.9 to 2.5 ng/ml (1.12–3.5 nmol/l). However, it is observed that some animals benefit from lower concentrations. In humans, it has been shown that the neurohumoral effects occur at plasma concentrations of 0.5 to 1.0 ng/ml and some of the dosing protocols are being revised to reflect this change. In veterinary medicine, there is not yet evidence relating the neuroendocrine effects with blood concentrations. Concentrations above 3.0 to 3.5 ng/ml usually will produce toxic effects.

THE USE OF VETERINARY PHARMACEUTICALS IN MINOR FOOD-PRODUCING ANIMALS: SPECIAL CONSIDERATIONS AND CHALLENGES

Antibiotics, antiparasitics, nonsteroidal antiinflammatory drugs, and exogenous hormones are among the essential components in the armamentarium of a food animal veterinarian to combat disease, alleviate animal pain, and minimize economic losses. In the United States, many of these veterinary products are labeled for use in a large number of major food-producing animals but not for the minor food-producing animals. According to the United States of America (USA) Food and Drug Administration (FDA), the major food-producing animals are cattle (meat and milk), swine, chickens (meat and eggs), and turkeys. The minor food-producing animals are those that do not fall into the major food-producing animal category with the most popular being goats, sheep, ranched cervids, commercially raised game birds, and nonornamental fish and shellfish. This category also includes less obvious food-producing species such as rabbits, ratites, and honey-producing bees. In the U.S., horses are a major animal species; however, they are considered companion animals and are not customarily used for human food as in some other countries. In Europe, the European Agency for the Evaluation of Medicinal Products has defined the major food-producing animals to be cattle (meat and milk), sheep (meat); pigs; chickens (meat and eggs), and salmonidae. Minor food-producing animals include minor ruminants (meat and milk), deer (including reindeer), other avian species (meat and eggs), other fish species, and other

mammalian species (horse and rabbit). In other countries, the minor food-producing animals category has the potential to be considerably larger because a greater variety of species are consumed such as small rodents, canids, invertebrates, and various avian species.

In recent years there has been an increased interest in eating more meat and other products from minor food-producing animals, especially aquaculture species. As this interest grows, so will the expectations to provide safe food items for human consumption. Maintaining the overall health of minor food-producing animals is similar to managing the health of major food-producing animals, and typically requires some use of veterinary pharmaceuticals. In contrast to the major food-producing animals, few drugs have been approved for use in the minor food-producing animals.

One of the major challenges for getting veterinary products approved for use in minor food-producing animals is the minimal economic return due to small market size. Additionally, some of the minor food-producing animals are less tractable (e.g., cervids and buffalo), and there is wide variation in breeds/species with respect to size and pharmacokinetics. For aquatic species, such as finfish, mollusks, and crustaceans, there is a large number of species and incredible diversity within this category. Not only are there species differences, but environmental considerations (salinity, pH, temperature), physiologic differences (heterothermy), and management practices also impact metabolism and excretion of drugs.

This chapter addresses the availability of veterinary pharmaceuticals for use in minor food-producing animals, outlines the unique issues when considering regulatory requirements for getting a drug approved for use in a minor food-producing animal, and highlights legislation that has helped address the veterinarians' need for medications to treat these animals. In addition, government programs and scientific approaches used to meet the therapeutic needs for treating minor food-producing animals are discussed.

THE APPROVAL PROCESS FOR VETERINARY PHARMACEUTICALS FOR USE IN MINOR FOOD-PRODUCING ANIMALS

There are many veterinary pharmaceuticals marketed today that may be administered to minor food-producing animals. The ideal scenario for a veterinarian wanting to treat a minor food-producing animal is having an FDA-approved drug labeled for the intended use in question. For example, an anthelmintic approved for treating specific gastrointestinal parasites in sheep. This product will have been demonstrated to FDA's satisfaction to be safe for sheep, safe for the person administering the drug to the sheep, safe for anyone who later consumes meat from the treated sheep, and safe for the environment, both during the drug's use and its disposal. It will also have been shown to be effective for the labeled use and that it is consistently manufactured to standards of strength and purity. Such a product is labeled with intended uses, doses, and withdrawal times that are appropriate to use in sheep.

In contrast to the major food-producing animals, there are not many FDA-approved drugs labeled for use in minor food-producing animals. This is mainly because the development of new drugs for use in animals is a very expensive and time-consuming process, especially for drugs to be used in animals intended for human consumption, and the minor food-producing animal markets are too small to readily recover the pharmaceutical sponsor's investment. FDA-approved drugs for minor food-producing animals (as of September 2006) are summarized in Tables 52.1–52.5.

For a drug to be approved for use in a minor food-producing animal, the sponsor must demonstrate to the satisfaction of the scientific reviewers at FDA's Center for Veterinary Medicine (CVM) that it is safe and effective for its intended use. CVM is the part of FDA responsible for the regulation of veterinary drugs including the evaluation of such drugs prior to approval.

The information that a sponsor needs to present to support a New Animal Drug Application (NADA) includes the following as outlined in regulations published in the Code of Federal Regulations (21 CFR 514): 1) Effectiveness for the proposed use, 2) Safety to the target animal species (the animal species for which the drug is to be used) 3) Human food safety (safety to consumers of meat, milk, or eggs derived from treated animals), 4) Environmental safety, 5) Manufacturing Methods and Controls, 6) All Other Information, 7) Freedom of Information (FOI) Summary, and 8) Product labeling. These components are discussed in detail in Chapter 55 of this book. The FDA also provides a variety of guidance documents to assist sponsors in understanding the various requirements. Of particular note for sponsors seeking drug approval for a minor species use is Guidance #61 "FDA Approval of New Animal Drugs for Minor Uses and for Minor Species." These are all available on the CVM website.

Compared to the drug approval process for major food-producing animals, the drug approval process is

TABLE 52.1 Veterinary pharmaceuticals approved by the Federal Drug Administration for use in small ruminants that are considered minor food-producing animals in the United States of America as of December, 2008

Drug	Formulation	Species	Indication*
Albendazole	Liquid suspension	Sheep Goats	Internal parasites Liver Flukes
Ceftiofur sodium	Injection	Goats Sheep	Respiratory infection
Chlortetracycline	Premix (for feed)	Sheep	Vibrionic abortion Weight gain/feed efficiency
Decoquinate	Premix (for feed)	Goats Sheep	Coccidiosis
Fenbendazole	Liquid suspension	Goats	Internal parasites
Fenbendazole	Premix (for feed)	Zoo/wild Goats Bighorn Sheep	Internal parasites
Flurogestone acetate	Vaginal sponge	Sheep	Estrus synchronization
Follicle stimulating hormone	Injectable—IV, IM, SQ	Sheep	FSH deficiency
Ivermectin	Drench	Sheep	Internal parasites
Lasalocid	Premix (for feed)	Sheep	Coccidiosis
Levamisole hydrochloride	Drench Bolus Powder	Sheep	Internal parasites
Monensin sodium	Premix (for feed)	Goats	Coccidiosis
Morantel tartrate	Premix (for feed)	Goats	Internal parasites
Methoxyflurane	Inhalation	Sheep	Anesthetic
Moxidectin	Drench	Sheep	Internal parasites
Neomycin sulfate	Powder Liquid	Goats Sheep	Colibacillosis
Neomycin sulfate	Premix (for feed)	Sheep	Colibacillosis
Neostigmine methylsulfate	Injectable—SQ	Sheep	Rumen atony Curare antagonist
Oxytetracycline	Premix (for feed) Powder	Sheep	Respiratory infection Colibacillosis Weight gain/feed efficiency
Oxytetracycline hydrochloride—Polymyxin B Sulfate	Ointment	Sheep	Superficial ocular infections
Oxytocin	Injection—IM, IV, SQ	Sheep	Uterine contractions Milk letdown
Penicillin G procaine	Injectable—IM	Sheep	Respiratory infection
Pituitary luteinizing hormone	Injectable—IV, SQ	Sheep	Pituitary hypofunction
Proparacaine hydrochloride	Liquid	Sheep	Ophthalmic anesthetic
Sodium chloride gelatin	Oral liquid	Sheep	Shock/hypovolemia
Sodium selenite/ Vitamin E	Injectable—IM, SQ	Sheep	Selenium deficiency
Tetracycline	Injectable—IM	Sheep	Bacterial infection
Thiabendazole	Drench Premix (for feed) Pellet Liquid	Goats Sheep	Internal parasites
Thialbarbitone sodium	Powder—Injectable IV	Sheep	General anesthetic
Tilmicosin phosphate	Injection	Sheep	Respiratory infection
Zeranol	Implant—SQ	Sheep	Weight gain/feed efficiency

*Listed indications are broad. For specific indications, the drug label or Code of Federal Regulations should be consulted.

TABLE 52.2 Veterinary pharmaceuticals approved by the Federal Drug Administration for use in cervids/other ruminants that are considered minor food-producing animals in the United States of America as of December, 2008

Drug	Formulation	Species	Indication*
Carfentanil citrate	Injectable—IM	Deer Elk Moose	Immobilization
Ivermectin	Injection	Bison (American) Reindeer	Hypodermosis Warbles
Ivermectin	Liquid	Sheep	Internal parasites
Naltrexone hydrochloride	Injectable—IV, SQ	Elk Moose	Carfentanil antagonist
Xylazine hydrochloride	Injectable—IM, IV	Deer Elk	Sedation
Yohimbine hydrochloride	Injectable—IV	Deer Elk	Xylazine antagonist

*Listed indications are broad. For specific indications, the drug label or Code of Federal Regulations should be consulted.

TABLE 52.3 Veterinary pharmaceuticals approved by the Federal Drug Administration for use in avian species that are considered minor food-producing animals in the United States of America as of December, 2008

Drug	Formulation	Species	Indication*
Amprolium	Premix (for feed)	Pheasants	Coccidiosis
Bacitracin methylene disalicylate	Premix (for feed)	Pheasants Quail	Weight gain/feed efficiency
Bacitracin methylene disalicylate	Water-soluble powder	Quail	Ulcerative enteritis
Bacitracin zinc	Premix (for feed)	Pheasants Quail	Weight gain/feed efficiency
Bacitracin zinc	Water-soluble powder	Quail	Ulcerative enteritis
Carnidazole	Tablets	Pigeons	Trichomoniasis
Iodinated casein	Premix (for feed)	Ducks	Weight gain/feathering
Lasalocid	Premix (for feed)	Partridge (Chukar)	Coccidiosis
Monensin sodium	Premix (for feed)	Quail (Bobwhite)	Coccidiosis
Novobiocin	Premix (for feed)	Ducks	Bacterial infection
Penicillin G procaine	Premix (for feed)	Pheasants Quail	Weight gain/feed efficiency
Salinomycin sodium	Premix (for feed) Powder	Quail	Coccidiosis
Sulfadimethoxine ormetoprim	Premix (for feed)	Ducks Partridge (Chukar)	Bacterial infection Coccidiosis
Thiabendazole	Premix (for feed)	Pheasants	Gapeworm

*Listed indications are broad. For specific indications, the drug label or Code of Federal Regulations should be consulted.

not significantly easier for products intended for use in a minor food-producing species. However, there are a few advantages afforded to products intended for use in a minor food-producing animal. These include the possibility of a waiver from user fees, the ability to apply conclusions reached from the radiolabeled residue study in the major food-producing animal to the human food safety evaluation for the minor food-producing animal, the possibility of a categorical exclusion from the need to provide an environmental assessment, and the possibility that fewer sites will be needed for effectiveness clinical trials.

TABLE 52.4 Veterinary pharmaceuticals approved by the Federal Drug Administration for use in aquaculture species in the United States of America as of December, 2008

Drug	Formulation	Species	Indication*
Florfenicol	Premix (for feed)	Catfish	Enteric septicemia of catfish
Florfenicol	Premix (for feed)	Freshwater-reared Salmonids	Coldwater disease Furunculosis
Florfenicol (conditional Approval)	Premix (for feed)	Catfish	Columnaris disease
Formalin	Water treatment	Finfish eggs Shrimp (Penaeid)	Antiprotozoal Antifungal
Human chorionic gonadotropin	Injection	Finfish (male & female broodstock)	Spawning aid
35% Hydrogen peroxide	Water treatment	Freshwater-reared Salmonids	Bacterial gill disease
35% Hydrogen peroxide	Water treatment	Freshwater-reared finfish eggs	Saprolegniasis
35% Hydrogen peroxide	Water treatment	Freshwater-reared cool water finfish and channel catfish	External columnaris disease
Oxytetracycline dihydrate	Premix (for feed)	Lobsters	Gaffkemia
Oxytetracycline dihydrate	Premix (for feed)	Salmonids	Ulcer diseases
Oxytetracycline dihydrate	Premix (for feed)	Salmonids and catfish	Bacterial hemorrhagic septicemia and Pseudomonas disease
Oxytetracycline hydrochloride	Water treatment	Finfish	Skeletal marking
Sulfadimethoxine ormetoprim	Premix (for feed)	Catfish Salmonids	Enteric septicemia of catfish Furuncluosis
Sulfamerazine	Premix (for feed)	Trout	Furunculosis
Tricaine methanesulfonate	Water treatment	Fish	Temporary immobilization

*Listed indications are broad. For specific indications, the drug label or Code of Federal Regulations should be consulted.

TABLE 52.5 Veterinary pharmaceuticals approved by the Federal Drug Administration for use in miscellaneous minor food-producing animals as of December, 2008

Drug	Formulation	Species	Indication*
Bicyclohexyl ammonium (Fumagillin)	Powder	Bees	Nosema
Lasalocid	Premix (for feed)	Rabbits	Coccidiosis
Oxytetracycline	Premix (for feed) Water soluble powder	Bees	American foulbrood
Sulfaquinoxaline	Premix (for feed)	Rabbits	Coccidiosis
Tricaine methanesulfonate	Water Tx	Amphibians	Temporary immobilization
Tylosin tartrate	Water soluble powder	Bees	American foulbrood

*Listed indications are broad. For specific indications, the drug label or Code of Federal Regulations should be consulted.

LEGISLATION AND POLICIES SUPPORTING THE USE OF VETERINARY PHARMACEUTICALS IN MINOR FOOD-PRODUCING ANIMALS

ANIMAL MEDICINAL DRUG USE CLARIFICATION ACT (AMDUCA). The U.S. Congress recognized the drug availability problem for both major and minor animal species when it passed the Animal Medicinal Drug Use Clarification Act (AMDUCA) in 1994 (Public Law No. 103–396; Monti 2000). This law addressed the fact that FDA generally approves veterinary drugs for narrow intended uses. For example, a broad-spectrum antibiotic that would be safe and effective for the treatment of a wide variety of bacterial infections may only be *approved* for use

in cattle for the treatment of respiratory disease caused by specific bacteria. From a practical standpoint, the pharmaceutical sponsor cannot demonstrate safety and effectiveness for every possible intended use of the product. This means that veterinarians frequently administer the drug for indications that are not on the label. In other words, they use the drug for different diseases, at different doses, by different routes of administration, and in different animal species than what is indicated on the label. AMDUCA legalized this practice for veterinarians within a set of limitations described in the Code of Federal Regulations (21 CFR 530). In general, veterinarians, within the context of a valid veterinarian-client-patient relationship, may use approved dosage form products (but not medicated feeds) outside their labeling. This is allowed only when there is no approved drug for the intended use; other approved drugs are not effective for such use, when the dose is not effective for that use, or in cases where an approved formulation is not appropriate. When using a drug outside of its labeling for a food-producing animal, the veterinarian is responsible for using the drug in a manner that will not result in a violative residue in any food product derived from that animal. The veterinarian must establish a withdrawal period based on some scientific information although resources for establishing such times are few. The withdrawal period may be based on data in published literature, extrapolated from the pharmacokinetic profile of the drug, or determined through consultation with organizations such as the Food Animal Residue Avoidance Databank (FARAD).

COMPLIANCE POLICY GUIDE 615.115. Because the extralabel use of medicated feeds is prohibited by law, an undue hardship was placed on minor food-producing animals that could not be practically medicated in any other way. An example would be commercially raised game birds, such as pheasants, that are raised in very large outdoor pens. If these birds become ill, they cannot be dosed individually and they will drink water from puddles rather than medicated water. Therefore, they are most often treated via the feed. Aquaculture species are another group of animals best treated with medicated feed. Given that there are few drugs approved for these species (and some of these not marketed) a means of relief was provided through a compliance policy guide (CPG). This CPG is FDA's direction to field investigators to exercise enforcement discretion in these cases. This does not make extralabel use of medicated feed legal and a CPG can be rescinded at any time. It simply means that if veterinarians and producers follow the parameters laid out in the guide, no action will be taken against them. In effect, this guide allows veterinarians to recommend approved medicated feeds to be fed to minor food-producing animals in an extralabel manner. For example, pheasants can be fed medicated feed that is labeled for chickens. However, the formulation of the feed cannot be altered to accommodate the dietary requirements of the pheasants. The CPG is not the answer to the issue of drug availability, but is a temporary solution that should someday be made unnecessary by drug approvals.

MINOR USE AND MINOR SPECIES ANIMAL HEALTH ACT. In 2004, the Minor Use and Minor Species (MUMS) Animal Health Act was passed giving the United States Food and Drug Administration the opportunity to encourage the approval of drugs for minor animal species and for minor uses in major animal species (Haley 2006). The MUMS legislation modified the Federal Food, Drug and Cosmetic Act in three significant ways; by providing the options of conditional approval, indexing, and designation for veterinary drugs used in minor animal species (Public Law 108–282).

Conditional Approval. The MUMS Act provides an opportunity for drugs that will be used for minor uses in major species and for minor species, including minor food-producing animals to be conditionally approved. Conditional approval allows drug sponsors to market the product on a yearly renewal basis for up to 5 years while gathering effectiveness data. All other requirements for a conditional approval (e.g., human food safety) are the same as for a full approval. The standard for conditional approval is "a reasonable expectation of effectiveness" rather than "substantial evidence." Within the 5 years allowed for conditional approval, the sponsor must provide effectiveness data to the full approval standard. Conditionally approved new animal drugs must be so labeled and are not eligible for extralabel use.

Indexing. Indexing will not apply to minor food-producing animals as indexing is reserved for drugs to treat diseases or conditions in animals where human food safety is not a concern. It is also limited to minor species exclusively. The intent of the Legally Marketed Unapproved New Animal Drug Index is to provide a means for sponsors to make products available for markets that cannot meet requirements of the new animal drug application (NADA) due to small populations, intrinsic value of the animals, wide variety of species, etc. The index is intended to serve laboratory animals, zoological animals, companion rodents, ornamental fish, etc.

Designation. The designation portion of the MUMS legislation created a program for veterinary medicine that somewhat mirrors what has been done with the orphan drug program in human medicine. Designation is intended to create incentives to encourage pharmaceutical companies to support drug development for minor species and minor uses. Designated drugs are granted 7 years of marketing exclusivity beginning on the date of approval or conditional approval. The MUMS Act also authorizes future availability of grants to support safety and effectiveness testing of designated new animal drugs.

PROGRAMS SUPPORTING THE USE OF VETERINARY PHARMACEUTICALS IN MINOR FOOD-PRODUCING ANIMALS

NATIONAL RESEARCH SUPPORT PROJECT #7 (NRSP-7). As already noted, the small market size for therapeutic veterinary products for minor food-producing animals makes the time and expense of drug approval unattractive to pharmaceutical companies. To assist and increase drug availability for minor food-producing animals, the United States Department of Agriculture (USDA) sponsors a program to generate data to support such drug approvals.

The National Research Support Project #7 (NRSP-7) is a USDA-supported program for minor use of drugs in major food-producing animals and primary use of drugs in minor food-producing animals of agricultural importance. This encompasses animals used to produce food or fiber. This program is intended to help fill the need for effective and safe drugs for use in minor food-producing animals, such as sheep, goats, rabbits, game birds, bison, deer, bees, and aquaculture species. A review of this program has been published by Ringer et al. (1999). The program accepts requests for needed drugs from a wide range of stakeholders, including veterinarians, producers, and pharmaceutical companies. In most cases the program funds studies to complete data requirements for effectiveness, target animal safety, human food safety, and environmental safety. Once these requirements have been reviewed and accepted by CVM, the data are gathered into a Public Master File, and a notice of availability of the data is published in the Federal Register. Because public money was used to conduct these studies, the data are all publicly available. A pharmaceutical sponsor can use these data in conjunction with its own manufacturing and labeling information to file an NADA for the product. In this way, costs to the pharmaceutical company are drastically reduced.

Because the NRSP-7 program has a limited budget, it generally, but not always, selects projects for minor food-producing animals that will be supplemental to existing products that are already labeled for use in major food-producing animals. The toxicology part of the human food safety technical section of an NADA is much too expensive for the program to fund for each minor food-producing animal. If this was already done by the pharmaceutical sponsor to support a cattle or swine approval, for example, it does not need to be repeated for the minor food-producing animal. Residue depletion and antimicrobial resistance issues still need to be addressed. Effectiveness and target animal safety need to be demonstrated in the minor food-producing animals and the environmental component must be addressed. Again, if an approval for a major food-producing animal already exists, a categorical exclusion from the requirement to provide an environmental assessment is a likely option, unless the new approval is for an aquaculture use.

At any given time, the NRSP-7 program is sponsoring 15 to 20 active projects. Working in cooperation with universities, producers, veterinarians, and government agencies, the program leverages a small budget into many studies. Since its inception in the early 1980s, the program has been successful in supporting over 25 drug approvals for a wide range of species. Information about the program and its projects can be found at http://www.nrsp7.org.

THE FOOD ANIMAL RESIDUE AVOIDANCE DATABANK (FARAD). The Food Animal Residue Avoidance Databank (FARAD) assists veterinarians in the establishment of scientifically based withdrawal intervals (not withdrawal times) that will prevent the occurrence of illegal residues in edible products derived from food-producing animals treated in an extralabel manner (Payne et al. 1999). (A *withdrawal time* is a legal requirement established by the FDA/CVM as part of the drug approval process. A *withdrawal interval* is a recommended preslaughter or milk discard time provided by FARAD to veterinarians in support of the AMDUCA requirement for an extended withdrawal interval for extralabel drug use in food animals.)

FARAD utilizes a decision tree approach to the problem and uses all available published data (and unpublished confidential data from pharmaceutical firms whenever possible) to guide the establishment of a withdrawal interval. When tissue or milk data are not available, the establishment of withdrawal intervals sometimes relies on blood (and serum or plasma) pharmacokinetic data to help define the final phase elimination of a drug. In such cases where serum or

plasma data are used for estimating tissue residue depletion, it is assumed that the final edible tissue elimination phase will be at least as long as that seen in plasma. All possible data are used to help in this estimation, and whenever a recommendation is made, withdrawal estimations are increased to provide a wider margin of safety. In this way, "safety factors" are built in when assumptions must be made to help ensure that the estimated withdrawal interval will be sufficient. In many cases, data do not exist that can be used to make a withdrawal interval estimation, and the practitioner is advised to consider a different drug for treatment.

Recently, a patented algorithm called the Extended Withdrawal Estimator (EWE) has been established to help automate this process. The EWE utilizes data in the FARAD pharmacokinetic database, residue tolerances from the FARAD tolerance database, and a sophisticated mathematical procedure to calculate the best estimate for a withdrawal interval following a specific dose, via a specific route to a species (Martin-Jimenez et al. 2002). Allometric comparisons between species are built into the EWE as a subroutine that can be used if there are data-gaps for a particular species. Newly published data on the pharmacokinetics of drugs in food-producing animals are constantly being added to the FARAD pharmacokinetic files, and as the knowledge base increases, so will the predictive capability of the EWE. Additionally, new algorithms will be established and linked to the EWE based on in vitro and in vivo data from minor food-producing animals.

METHODS FOR ESTIMATING WITHDRAWAL INTERVALS FOR VETERINARY PHARMACEUTICALS ADMINISTERED TO MINOR FOOD-PRODUCING ANIMALS IN AN EXTRALABEL MANNER

When drugs are used in an extralabel manner in food animals, veterinarians need to determine withdrawal intervals to prevent the occurrence of illegal drug residues. FARAD uses several methods to establish withdrawal intervals for drugs administered to minor food-producing animals in an extralabel fashion. All of the methods are dependent in some way on pharmacokinetic and tissue residue data to estimate withdrawal intervals after extralabel use. When pharmacokinetic data are lacking in a minor species, these data may be estimated using allometric scaling techniques, species grouping, and in vitro and molecular techniques.

PHARMACOKINETIC STUDIES. Drug absorption, distribution, metabolism, and excretion (pharmacokinetics of a drug) in minor food-producing animals are the key factors for determining withdrawal intervals for drugs used in an extralabel manner. A traditional pharmacokinetic study carried out in small groups of individual animals is the "standard" method. Additionally, tissue residue studies are carried out in a similar manner, with a small number of animals serially slaughtered at various times after drug treatment allowing the establishment of the kinetics of residue depletion.

Pharmacokinetic Studies Using Individual Animal Subjects. Pharmacokinetic studies using individual animals have been the cornerstone in the study of comparative pharmacology to elucidate interspecies differences in drug response. Thousands of manuscripts have been published on the pharmacokinetics of drugs in food-producing animals. Some of the studies focus on just one species whereas others are more helpful in that they compare the pharmacokinetics of drugs between major and minor food-producing animals (Modric et al. 1998; Craigmill et al. 2000; Lanusse 2003). When using pharmacokinetic data from a major food-producing animal to predict drug pharmacokinetics in a minor food-producing animal, it is important to consider factors that will impact absorption, distribution, metabolism, and excretion of a drug before determining whether extrapolation is feasible. The potential for one species of animal (e.g., a major food-producing animal) to help predict the pharmacokinetics of a drug in a minor food-producing animal depends on a number of factors. These include similarities and differences in absorption (e.g., intrinsic absorption of a given drug across the gastrointestinal wall mucosa, gastric pH, first-pass metabolism, etc.), elimination (e.g., glomerular filtration, hepatic blood flow if the drug is excreted primarily through the liver, etc.), and biochemical factors (e.g., protein binding, drug metabolism, etc.) (Lin 1995).

For major and minor food animals, there do not appear to be species differences in the types of metabolites formed; however, there may be differences in the ratios of these metabolites formed. Juskevich published a review of comparative food animal drug metabolism that provides an excellent overview covering important factors that must be considered when comparing drug metabolism between species (Juskevich 1987). Short (1994) published a review comparing factors that impact drug metabolism and disposition in sheep and other domestic ruminants to

demonstrate whether pharmacokinetic profiles could be predicted for antimicrobials used in these animal species.

FARAD has been collecting pharmacokinetic data from the published literature since 1982 and currently has 8,280 citations that contain pharmacokinetic data on chemical or drug residues for a variety of animal species. The data from numerous food-producing animals have been compiled and published as a reference textbook (Craigmill et al. 2006). Data are available for minor food-producing animals for comparison to those from major food-producing animals. In comparison to the major food-producing animals, the minor food-producing animals have considerably fewer published pharmacokinetic studies for the various categories of antibiotics, anthelmintics, nonsteroidal antiinflammatories and exogenous hormones. Using ruminants as an example, Table 52.6 demonstrates the preponderance of pharmacokinetic-based publications in the FARAD database for cattle versus some of the minor food-producing animals. While the focus of the FARAD data collection has been residue avoidance, considerable data are also available on serum/plasma pharmacokinetics of drugs that can be useful for therapeutic purposes as well.

Population Pharmacokinetics and Meta-Analysis. One of the limitations of most comparative pharmacokinetic studies that have been done to date is the small number of animals of each species used. In most studies, all of the animals representing a species have been obtained from one supplier and are of one breed or strain. Therefore, the variability in parameters within a species (intraspecific variability) cannot be assessed. Such unknown variability within a species makes it even more difficult to evaluate variability between species (interspecies). The use of population-based pharmacokinetic modeling procedures will help to define this, but these methods require substantial amounts of data to give the best results. Martin-Jiminez and Riviere defined population pharmacokinetics as "a study of the basic features of drug disposition in a population, accounting for the influence of diverse pathophysiological factors on pharmacokinetics, and explicitly estimating the magnitude of the interindividual and intraindividual variability" (Martin-Jimenez and Riviere 1998). The advantage to this technique is that it allows for assessment of how clinical factors (age, gender, renal and hepatic function, etc.) impact the pharmacokinetic parameter estimate. Another proposed benefit is that population pharmacokinetic studies could be conducted using a multicompartment experimental protocol to predict food animal residue avoidance. The application of such a methodology would greatly benefit minor food-producing animals because collective sampling might ultimately establish significant baseline data reflecting the pharmacokinetic parameters of a drug in a field or production setting.

Another approach is meta-analysis, in which data from multiple studies are carefully combined to increase the number of subjects. This approach was applied to procaine penicillin G and oxytetracycline using data from FARAD to look at the intramuscular pharmacokinetics in nonlactating cattle (Craigmill et al. 2004) and to ampicillin trihydrate in cattle (Gehring et al. 2005). Meta-analysis requires careful selection of data according to predetermined standards to ensure data quality, including such factors as analytical methodology and study design. Under optimal conditions, the meta-analysis is conducted using population pharmacokinetic modeling procedures when individual animal pharmacokinetic data from multiple studies and individual animal covariate data (sex, weight, age, health, etc.) are available.

TABLE 52.6 Comparison of numbers of Food Animal Residue Avoidance Databank publications with drug concentration versus time dependent data for ruminants as of December, 2008

Drug Category	Cattle	Buffalo	Cervids	Sheep	Goats
Aminoglycosides	164	11	2	48	48
Cephalosporins	144	5	1	32	17
Fluoroquinilones	82	6	0	17	32
Macrolides	87	2	1	20	8
Penicillins	448	13	0	59	40
Sulfonimides	284	47	0	79	111
Tetracyclines	212	8	2	52	37
Anthelmintics	270	33	6	312	75
Hormones	161	0	0	37	4
Nonsteroidal Antiinflammatories	115	3	0	33	29

Physiologically Based Pharmacokinetic (PBPK) Modeling. Physiologically based pharmacokinetic (PBPK) modeling might prove a very effective method for making interspecies comparisons for drugs. Physiologically based pharmacokinetics (PBPK) offers another way to study interspecies relationships, and has been used extensively for predicting human tissue concentrations of

toxicants using animal data. PBPK also offers researchers the opportunity to utilize in vitro metabolism data (K_m and V_{max}) to help predict clearance rates of chemicals in multiple species. PBPK modeling uses physiological and biochemical parameters, therefore this method can be mechanistic as well as predictive. Physiological parameters used in PBPK models may be measured directly or derived from allometric equations. PBPK models have been developed for fish (Law 1999), turkeys (Pollet et al. 1985), cattle (Achenbach et al. 1998), horses (Trachsel et al. 2004; Knobloch et al. 2006), swine (Buur et al. 2006), rabbits (Tsuji et al. 1985), and sheep (Craigmill 2003). PBPK modeling has been used to evaluate oxytetracycline residues in cattle, sheep, and fish and may prove useful for predicting the depletion of drug residues in the tissues of other minor food-producing animals in the future (Achenbach et al. 1998; Law 1999; Craigmill 2003).

ALLOMETRIC SCALING. For decades, veterinary medicine has used allometric scaling to ascertain effective doses and dosage regimens for a variety of animals. For a detailed presentation of the use of allometry for interspecies pharmacokinetic parameter scaling, readers are referred to recent published review manuscripts (Mahmood et al. 2006; Martinez et al. 2006). Riviere and colleagues (1997) gathered pharmacokinetic parameter data for 44 drugs using the Food Animal Residue Avoidance Databank and found that 11 of the 44 drugs showed significant allometric relationships of their pharmacokinetic parameters for extrapolation between veterinary species. Nine of these eleven drugs were antibiotics. Some of the drugs that did not demonstrate allometric relationships with respect to their pharmacokinetic parameters were low hepatic excretion drugs. For the other drugs, the results were equivocal.

These pharmacokinetic allometric studies can also be used to estimate withdrawal intervals using kinetic parameter data for drugs in blood, serum or plasma. For unmetabolized drugs (e.g., ones that are not highly protein bound in plasma and are not specifically bound by tissue components), one could expect that tissue residue parameters would mirror blood kinetic parameters. Tissue residue elimination would then be dependent on blood flow and the tissue/plasma partition coefficient, and drugs that are highly fat soluble would be removed from fat depots slowly. This slow removal would subsequently be seen as a prolonged elimination phase.

SPECIES GROUPING. Researchers within and external to the NRSP-7 program have been working collaboratively to develop approaches to group minor food-producing animals by doing studies in an "indicator" species for that group. Animal categories that have been considered for such grouping include avian species, cervids, and fish. The primary focus has been on aquaculture species due to the large number of aquatic species that are in need of drugs to treat diseases and parasites that are often caused by the same organism in multiple species. Several possible ways to achieve this goal include grouping of species based on physiology, drug delivery mechanism, target pathogen, culture system, economic importance, and human food safety concerns (Greenlees and Bell 1998). Sources of variability in the pharmacokinetics of drugs in aquaculture species include interspecific variability, intraspecific variability, habitat variability, temperature, size/age, and sexual maturity (Gingerich et al. 1998). Poikilothermic animals present a greater challenge than homeothermic animals because the environmental temperature has such a great effect on their physiology. Therefore, studies focusing on poikilothermic animals should consider environmental temperature as a mixed "physiological" and environmental variable.

For grouping of the minor aquatic and avian species, two approaches are being used by the NRSP-7 program. The first is to explore species grouping of finfish for drugs that are not significantly metabolized and thus are excreted unchanged. The primary method being used for this aspect is the development of pharmacokinetic data for serum and tissues in several fish species at different temperatures. A second approach is focusing on establishing in vitro drug metabolism parameters in avian species and linking them with pharmacokinetic serum and tissue data using physiologically based pharmacokinetic modeling.

FUTURE DIRECTIONS: IN VITRO AND MOLECULAR STUDIES. **In vitro** and molecular based research might help establish some differences in drug metabolism before going to whole animal models. **In vitro** methods for exploring comparative metabolism include P450 assays, microsomes, tissue slices, isolated cells, and cell culture. P450 assays have been used to evaluate species differences for major and minor food-producing animals (Dalvi et al. 1987; Nebbia et al. 2001; Machala et al. 2003; Dacasto et al. 2005). Microsomes from food-producing animals

have been used to evaluate gender and breed differences (Dacasto et al. 2005). Another study evaluated the biotransformation of cultured hepatocytes from goats, sheep, and cattle using five different test substrates and determined that cultured hepatocytes appeared to be a good in vitro model to study comparative metabolism of veterinary drugs in these animal species (van 't Klooster et al. 1994).

Genomic and proteomic methods to evaluate interspecies differences in drug metabolizing enzymes might also be useful for minor food-producing animals. Examination of DNA using Southern blot analysis can be used to determine if genes exist that code for specific drug metabolizing enzymes. Northern blots may be used to find mRNA transcripts of genes that code for drug metabolism enzymes. For minor food-producing animals, this investigation could start by using cDNA probes for a subfamily of P450 enzymes that are extensively involved in drug metabolism, such as the CYP3 family. Hepatic mRNA from a minor food-producing animal of interest could also be evaluated using commercially available P450 cDNA probes. Using this approach, one could establish only that probe hybridization patterns were similar between the minor food-producing animals being considered. If similar hybridization patterns existed, one could hypothesize that those species evaluated might be similar in drug metabolic capability, at least on a qualitative basis. This hypothesis could then be tested using in vitro (including expression vectors and drug substrate assays) or in vivo methods.

Immunoblotting would be another approach to assess similarities or differences between minor food-producing animals. For this approach, antibodies for the specific protein of interest would need to be developed for minor food-producing animals because most of the commercial probes/antibodies are usually from non–food-producing animals (e.g., mouse, rat, monkey, human). Therefore, the use of the commercial antibodies in such assays would be limited for interspecies analysis because the metabolic enzymes from different species cannot be assumed identical. In addition, structural homology does not guarantee functional homology. Nevertheless, because there is considerable sequence conservation across species in the cytochrome P450 enzyme superfamily and metabolic enzymes in general, such studies may be quite useful to characterize potential metabolic enzyme capacities of minor food-producing animals.

As the field of proteomics expands and protein sequence methods become quicker, the identification and characterization of drug-metabolizing enzymes for minor food-producing animals will be easier and more economical. Progress in this area is dependent on increased funding for such research, which may result from growing concern over therapeutic drug residues in food-producing animals.

SUMMARY

Improving drug availability for food-producing minor species is proceeding on several fronts. It will still take time for the various incentive programs and research programs to have a noticeable effect. With the great variety of diseases and species that this group represents, every possible incentive must be exploited and every research option explored. Veterinarians, researchers, pharmaceutical companies, governmental agencies, producers, and consumers all have a stake in the success of this work.

ZOOLOGICAL PHARMACOLOGY

ROBERT P. HUNTER

Introduction	**1343**
Species Groups	**1343**
Invertebrates	**1344**
Vertebrates	**1344**
Allometry in Zoo Medicine	**1349**

INTRODUCTION

Species differences in drug absorption, distribution, metabolism, and excretion (ADME) for numerous pharmaceutical agents have been well documented for domestic species; however, there is limited information concerning the ADME of drugs in nondomestic species. Lack of approved pharmaceutical agents and/or pharmacokinetic data in the literature for exotic, wildlife, and zoo species is a major issue for veterinarians attempting to treat these animals. Under the Animal Medicinal Drug Use Clarification Act (AMDUCA), practitioners take approved agents (veterinary or human) and extrapolate their use to nonapproved species, often with little scientific basis to support this decision. To further complicate treatment, zoo veterinarians often have to formulate the medication(s) into a meal or treat, hoping that the animal will ingest it. Due to lack of patient compliance, the clinician may have to resort to other means of drug administration. Additionally, due to the value of these animals or their status as threatened or endangered species, the traditional method of trial and error for treatment selection is inappropriate. This results in a mentality where no zoo veterinarian wants to be the first to administer an agent/formulation in an untested species.

The range of animals a zoo veterinarian cares for varies from very small invertebrates (honeybees) to megavertebrates such as elephants and whales. There is currently only one United States approval for the class amphibians, four agents approved for use in invertebrates, and eight to ten compounds for mammalian zoo and wildlife species compared to almost 300 for domestic cattle. Various methods have been used to extrapolate/predict safe and effective dosage regimens. No attempt will be made to turn this chapter into a formulary. Excellent formularies already exist to provide for that need (Antinoff et al. 1999; Carpenter 2005; Hawk and Leary 1999; Kreeger et al. 2002; Nielsen 1999). This chapter provides information and guidance on comparative physiology, formulation considerations, and dosage scaling across wide and varied species.

SPECIES GROUPS

Working with exotic animals, even during routine daily care, can be very dangerous. This is magnified when working around sick or injured animals where the patient is subject to increased stress, pain, and deviations from the usual routine—for example, those associated with treatment and drug administration. If given the opportunity,

most animals can inflict injury to humans using almost any body part. They can crush with the body or head; kick with exceptional force; or grasp with their hands, body, tail, or trunk. During medication attempts, the individuals administering the treatment are at great risk because they are close to the animal and often working near the head, teeth, fangs, or hands. Safety precautions must be considered prior to treating any animal.

INVERTEBRATES. The numbers of invertebrate zoos and species within those facilities are increasing rapidly. The main concern when treating these species is that they typically lack the membrane barriers that are foundations for therapeutic choices in domestic mammalian species. This likely makes them more susceptible to serious adverse events from agents that are considered safe in mammals, especially anthelmentics or neuro-acting agents.

There are only four agents approved for use in invertebrates (shellfish, shrimp, lobsters, or honeybees): bicyclohexylammonium, formalin, oxytetracycline, and tylosin. All of these species are treated as food animals and residues are of concern. These agents have specific approvals in one or more of these species.

Another consideration is the use of invertebrates as drug delivery devices. This is typically done for insectivores or marine mammals (squid to sperm whales). The book *Eat this Bug*, by Davis (1996) may be useful for assisting veterinarians in selecting appropriate "treat" species to use as drug vehicles. This concept is similar to the use of rodents as dosage forms ("fuzzy" dosage forms) for raptors or reptiles. This concept of using insects as dosage forms is commonly used clinically to increase calcium in the diet of insect-eating reptiles (Donoghue and Langenberg 1996).

VERTEBRATES

Reptile and Amphibian. With over 4,000 amphibian species, 3,750 species of lizards, 2,500 species of snakes, 270 species of turtles, and 22 species of crocodilians there is currently only one approval in the U.S. for this group. Tricaine methanesulfonate (MS-222) is a Na^+-channel–blocking local anesthetic. It is used for temporary immobilization to aid in handling during weighing, measuring, marking, surgical operations, transport, photography, and research.

Route of administration is especially challenging in these species. For amphibians, oral, topical, and injectable routes are common. Topical baths can be very beneficial since the skin of amphibians has similar properties to mammalian mucosal surfaces. The pH and temperature of the bath must be appropriate for the treated species (Mader et al. 1985; Walker and Whitaker 2000). This can also allow for group treatment of animals that are on display or for treatment off-exhibit in special treatment tanks. As with all treatments, the animals must be monitored so that they are not harmed or injured in the bath (Walker and Whitaker 2000).

Routes of drug delivery are similar between reptiles and amphibians. Several studies have been done investigating the pharmacokinetics of various agents in all four groups of reptiles: snakes, turtles, lizards, and crocodilians.

Drug metabolism may be affected by prandial state in the snake and other sporadic feeding reptiles. This mechanism allows for minor metabolic investment of digestion to occur after a period of fasting and energy reserve depletion; thus nutrient metabolism peaks about 1 week after feeding. With variable physiological states, drug metabolism and elimination could be affected by feeding intervals. Thus, the effect of feeding could greatly affect the way orally administered pharmacologic agents are absorbed by snakes. When a snake consumes a meal, the small intestinal mucosa will increase in thickness at least three times while total length of the small intestine does not change. Correspondingly, villi length is two times prefeeding length, resulting in an increase in small intestine surface area as a result of feeding. Azithromycin absorption in ball pythons was prolonged, compared to all mammalian species reported, based on relatively large mean absorption time (MAT) and T_{max} values.

Four of the fifteen circulating azithromycin metabolites: 3′-desamine-3-ene-azithromycin, descladinose dehydroxy-2-ene-azithromycin, 3′-desamine-3-ene descladinose-azithromycin, and 3′-*N*-nitroso,9a-*N*-desmethylazithromycin are unique to the ball python. As azithromycin metabolism in mammals is mediated by several cytochrome P450 isoforms, it is possible that these systemic metabolites are a result of novel cytochrome P450 isoforms, the unique gastrointestinal physiology of the ball python, or some combination of both. The unique gastrointestinal physiology of the snake does appear to lend itself to increased metabolism of xenobiotics. Due to the long GI transit times of boid snakes of >1 week, this presents the opportunity for a xenobiotic, such as azithromycin, to undergo repeated enterohepatic recirculation during the course of a single drug administration. This provides an

effect similar to that produced by sustained-release oral formulations in mammals. The percentage of each plasma metabolite differed for only a few metabolites when comparing i.v. with p.o. administration results from this study (Hunter et al. 2003b). This phenomenon would be expected to correspondingly prolong tissue concentrations of the parent compound and its metabolites. These factors are also likely to have an impact on bioavailability relative to time of feeding in snakes. This would likely make prediction of oral drug absorption dependent, to some extent, on time after feeding.

Reptiles have a renal portal system. This means that a first-pass effect of renally cleared drugs can take place if the animal is injected in the posterior half of the body. This system is not fully understood, and it may not be as restrictive as once believed. However, until definitive data are available, reptiles should be injected in the anterior portion of the body when agents dependent upon renal clearance are administered.

The rehabilitation of wild reptiles, such as sea turtles, requires the use of a variety of different medications; most have never undergone any pharmacokinetic studies in the target species to establish a basis for a safe and efficacious dose. Many of the commonly used treatments have had few studies (pharmacokinetic or efficacy) in any reptile species. This makes use of these drugs guesswork at best and dangerous at worst. For instance, when antimicrobials are underdosed this may not only lead to ineffective treatment of bacterial infections but may also lead to the development of resistant strains of bacteria. Likewise, overdosing may lead to adverse effects. The low basal metabolic rate of reptiles, in general, may correlate to the overall metabolism and distribution of drugs; this, along with the variation in metabolic rates among reptile species, makes dosage determination from dramatically different reptile species far less than desirable—let alone when extrapolation from mammalians species is done. The extent of plasma protein binding varies between species and is temperature-dependent. This is a key point to remember when treating poikilothermic species.

Avian. Avian medicine is a field of rapid growth in veterinary medicine. Greater than 95% of all pharmaceuticals used in clinical practice to treat various avian species are based upon empirical doses and the personal experiences of the attending clinician. This raises issues concerning the health of the animals being treated. Therefore, the pharmacokinetics of pharmaceutical agents used to treat avian species is an area of research that is needed to ensure the safe and proper dosing of these animals. However, there is limited information on the pharmacokinetics of agents used to treat psittacines, anseriforms, galiforms, passerines, softbills, and raptors. As a result of the lack of pharmacokinetic data, dosage regimens are designed using linear extrapolation from doses approved in domestic species, such as poultry (Baert and De Backer 2003). It is possible that use of linear extrapolation could lead to the development of toxicity or lack of efficacy in the treated animal(s) as a result of inaccurate dosing.

Extrapolation of doses is difficult between mammalian and avian species, both qualitatively and quantitatively. The avian renal cortex is more similar to the reptile cortex than the mammalian cortex. Glomerular filtration is not constant in birds, as it is in mammals, and likely has an impact on the pharmacokinetics of pharmaceuticals in avian species (Frazier et al. 1995). Avian species appear to be more susceptible to the renal ischemia and tissue damage of nonsteroidal antiinflammatory drugs (NSAIDs) than the gastrointestinal side effects (Paul-Murphy and Ludders 2001). While avian cytochrome P450 activities have been reported, their expression and role in avian drug metabolism is not well documented (Walker 1998).

All of the approvals in this group are for species used as food animals (poultry and galliforms). While it would seem logical to extrapolate a dose from a chicken to an ostrich, this could be equated to extrapolating a dose in horses to elephants.

The concept of "fuzzy" (use of rodents) dosage forms for raptors has been mentioned previously. While rodents can be viewed in many ways (pets, pests, or research test subjects), to the avian (and reptile) veterinarian they are a drug delivery device. In red-tailed hawks, the extent of oral bioavailability of enrofloxacin between intramuscular and "fuzzy" oral dosing was not different, even though the oral T_{max} was five times the intramuscular route (Harrenstien et al. 2000). The difference in T_{max} appears logical when considering dissolution and gastrointestinal transit in these animals.

Mammalian. Oral absorption has been shown to vary within a species. Within domestic dog breeds (Beagle and mongrel), different gastrointestinal transit times and mouth-to-small-intestine transit times have been reported (Sagara et al. 1995). When one considers the anatomical differences between true monogastrics (canine or feline species), hindgut fermentors (rodents, rabbits, horses, or

elephants), foregut fermentors (Colobus monkeys, camelids, and kangaroos), and ruminants (cattle, goats, sheep, or antelope), the potential differences are staggering and support the concept that bioavailability is not scalable across mammalian species (Mahmood 2000, 2002). The large body sizes of some mammalian species produces problems for treatment and places significant limitations on drug delivery. Aside from the weight of the animal, the size, thickness, and density of various anatomical structures can physically hinder drug administration.

Small/Pocket Pets/Rodents. There is a wealth of data in the literature concerning the pharmacokinetics and safety of almost every human drug in rodents, such as mice and rats and often for rabbits as well. While ferrets are a laboratory species, research is narrower in scope, but could still be useful in treating these small mammal species. While the doses may be above that needed for efficacy, safety is well understood. The issue is typically formulating the agent into a dosage form that can be used clinically. With the Internet and various medical literature search tools, such as Medline, PubMed, and Highwire, the busy clinician can find information for treating just about any disease in small mammals.

However, there is no published, peer-reviewed information concerning the pharmacokinetics of drugs used in more exotic small mammals, such as hedgehogs, sugar gliders, and honey bears. Historically, mite infestations (*Chorioptic* sp.) in hedgehogs have been treated with either ivermectin or amitraz (Lightfoot 2000). This treatment has been shown to be effective, but requires weeks or months of therapy. Fleas and lungworms also infest these animals, and with a broad-spectrum, topical endectocide, such as selamectin, treatment could be carried out easily and rapidly, allowing for treatment of both the mite and flea infestations with a single compound (Fig. 53.1).

Farmed/Domestic Species. There are ≤50 compounds approved in the United States for sheep, ≤12 for goats, and none for New World camelids (Sundlof et al. 1992). As producers and veterinarians have taken approved agents for cattle, sheep, or goats and extrapolated their use to exotic domestic species, such as New World camelids, safety and efficacy have been the main issues. There are many different species-related factors, such as absorption, elimination, and metabolism, that could lead to variation in the pharmacokinetic parameters between species and possibly decrease the efficacy or increase the toxicity of a compound (Hunter and Isaza 2002; Short 1994; Xia et al. 2006). These differences make extrapolation very difficult from one species to another.

FIG. 53.1 Topical dose administration to an African hedgehog.

An example of species differences in pharmacokinetics is the data for topical doramectin. The mean C_{max} and AUC values for llamas and alpaca was approximately 33% less than that reported for cattle using the same dose and formulation. The mean T_{max} values for both species were 1 day longer than reported in cattle. It appears that the extent of absorption, as evaluated by C_{max} and AUC, is much less than that reported for cattle (Hunter et al. 2004a). This was also the case for moxidectin in these two species (Hunter et al. 2004b).

Zoo/Marine Mammals. All of the routes and issues discussed previously apply to this group of patients. If a well-trained animal can be difficult to treat (which they are), an uncooperative animal can easily prevent almost any unwanted medication from being administered. This is especially true of large carnivores, primates, and megavertabrates (elephants). The animal's combined size, strength, and/or intelligence effectively precludes forcing it to ingest medication or allowing someone to get close enough to manually administer medication.

The capture and chemical immobilization of a variety of zoo and wildlife species has been enhanced with the use of potent synthetic opiates, such as carfentanil (Haigh 1990). These opiates generally provide rapid induction and relatively long-lasting immobilization. They are usually administered parenterally, the small volumes required making them ideally suited for use in remote delivery

systems such as darts (Fowler 1995). Furthermore, immobilization by these drugs can be completely reversed by the administration of specific opioid antagonists. This is particularly important for immobilization of free-living wildlife, which cannot be closely monitored after the immobilization period. These opioid anesthetic agents have provided zoo veterinarians and wildlife researchers not only a method to restrain animals for a variety of medical and research procedures, but have become an indispensable tool to the practice of zoological veterinary medicine.

Carfentanil has become the drug of choice for a wide variety of non–domestic animal immobilizations, particularly for hoofstock, and has been used either alone or in combination with sedatives for rapid immobilization of captive and free-ranging wildlife. The potency and formulation of this drug allow for a small volume to be administered, which is ideal for remote delivery systems (darts). Naltrexone is the antagonist used routinely in carfentanil immobilization procedures, because it has a longer half-life than other antagonists such as naloxone or nalorphine in domestic species. One adverse effect with the use of carfentanil is that of renarcotization. This is the reoccurrence of the effects of the opioid agonists up to 72 hours after apparent full recovery from the drug. The effect varies in severity from mild sedation to full immobilization and has also been associated with a high incidence of mortality. The choice of antagonist and dose used are important factors in the incidence of renarcotization. Also, certain species appear to have a higher tendency to develop renarcotization than others. Possible mechanisms for renarcotization are listed by Haigh (1990): enterohepatic recycling, metabolism of antagonist to form a metabolite with agonist properties, release of the agonist from body depots after the antagonist has been eliminated, antagonist underdosing, and metabolism of a short-acting antagonist and reestablishment of a longer-acting agonist. Studies are needed to assist with determining the actual cause(s) but there are currently no published PK/PD studies of any opioid agonist or antagonists in exotic ungulates.

Anesthesia of nonhuman primates is risky and stressful. Squeeze cages and darts have been used for administration of parenteral anesthetic agents, and various anesthetics have been administered orally using treat or food items. Although these formulations work well for these primate species, care should be taken to avoid conditioning the animal to associate the treat or personnel with the procedure (Hunter and Isaza 2002). Transmucosal fentanyl is approved for use in the United States as a preanesthetic agent in humans in a lollipop formulation. When this preparation of fentanyl is chewed and swallowed, it still results in a sedative effect with a corresponding longer T_{max} when compared to true transmucosal absorption. When this formulation was used in a study on great apes (Figs. 53.2, 53.3), nine chimpanzees were evaluated with only one being successfully offered a dose after having refused

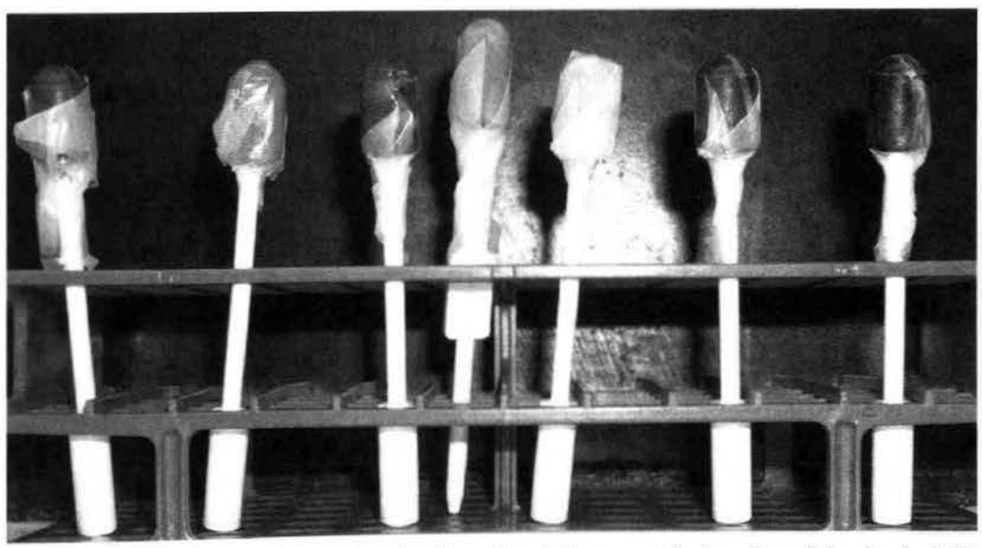

FIG. 53.2 The white fentanyl (Actiq®) lollipops were painted with candy coloring to match the colors of the placebo lollipops.

FIG. 53.3 Use of fentanyl lollipops to sedate an orangutan.

the lollipop on an earlier attempt; two other animals also refused to ingest their lollipops. All orangutans accepted at least one dose with several accepting two or more. The gorillas accepted multiple lollipops. The orangutans and gorillas demonstrated less stress when darted and showed signs of sedation after fentanyl administration. The main metabolite in humans, norfentanyl, was identified in only one of the test subjects, an orangutan. An effective dosage of fentanyl for orangutans and gorillas was dependent on an effective training program; cooperation of the keeper staff and zoo administration; and facilities that allow for individual, overnight housing of animals. In contrast, chimpanzees were suboptimally sedated with transmucosal fentanyl (Hunter et al. 2004c).

Foot problems affect over 50% of the captive elephant population. These problems may progress to arthritis, a debilitating condition often resulting in euthanasia of the animal. Arthritic elephants are typically treated with a wide variety of antiinflammatory and analgesic drugs, which offer only palliative treatment. Due to the side effects of these agents in domestic species, accurate therapeutic regimens are critical to properly treating diseased elephants. Simply guessing at a dosage can have disastrous consequences, as was illustrated in a case report where lysergic acid diethylamide (LSD) was tested in an elephant and the animal died violently within minutes (West et al. 1962).

The lack of pharmacokinetic data is reflected in the sparse number of published studies in elephants. Almost all of these studies have focused on antimicrobials, with little data being reported for analgesic and/or antiinflammatory agents. As a result of the lack of pharmacokinetic data, dosage regimens are designed using the assumption that pharmaceuticals administered to the elephant are absorbed, distributed, metabolized, and excreted in approximately the same manner as horses (Page et al. 1991). However, at least one example exists in the published literature to contradict this statement. For the chiral NSAID ketoprofen, the *S*-enantiomer is cleared from elephant plasma much more rapidly than the *R*-form. This is different than the domestic horse where the *R*-form is cleared more rapidly. This was explained as either selective clearance from plasma in the Asian elephants or as chiral inversion. Also in this study a possible novel metabolite, a Phase II glycine conjugate, was reported (Hunter et al. 2003a).

ALLOMETRY IN ZOO MEDICINE

Allometric scaling of pharmaceuticals to predict pharmacokinetics in zoo/exotic animals has considerable benefit for zoological veterinarians. This tool, when used appropriately, can provide an *estimate* for designing dosage regimens. The example of differences in ketoprofen inversion across species emphasizes the need to understand and be aware of the assumptions when designing treatment regimens based on allometric scaling data.

Just as mammals can range from a few grams to thousands of kilograms, reptiles and birds can also vary in body weight across a wide range. It has been suggested that it is impossible to derive a single equation correlating body mass to metabolic rate for all 6,000 species of reptiles (Funk 2000). Without knowledge as to the extent and route of elimination of an administered pharmaceutical agent, extrapolation of dosage regimens from one class to another is difficult, if not impossible, with any certainty. It is apparent that more research is needed on the drug metabolism and excretion capabilities in snakes, let alone reptiles in general. This type of research would increase the ability of clinicians to determine more effective and safe dosage regimens for their patients. Another consideration when using allometry is the nonlinearity of pharmacokinetics in some species (Manire et al. 2003; Rush et al. 2005).

There are two major components of hepatic clearance of xenobiotics: hepatic blood flow and enzymatic metabolism. Renal clearance is the other major route by which drugs are excreted. Renal clearance is composed of three parts: glomerular filtration, active tubular secretion, and tubular reabsorption. Glomerular filtration rate is allometrically scalable in mammalian species, as is *p*-aminohippuric acid clearance (Edwards 1975; Holt and Rhode 1976). However, allometric scaling of active tubular secretion and tubular reabsorption have not been reported in the published literature.

The concept of metabolic or allometric scaling has been used as the basis for comparison across species since the 1930s. Benedict's *Vital Energetics* appears to be the first comprehensive discussion on the topic of metabolic scaling. Benedict's work laid the foundation for scaling of metabolic rates across a wide range of species. Metabolic rate for mammals was described by Kleiber (1932, 1961). Various physiologic processes such as heart rate, blood volume, and glomerular filtration rates can be predicted reasonably accurately for a wide variety of species based solely on the weight of the animal.

Linear extrapolation is the use of a single mg/kg dose across all species, so that the total amount of drug increases in a linear fashion as body weight increases. When dosages are extrapolated to other species of different weights, this method assumes that dosage versus weight is directly (linearly) proportional. This method assumes that differences in weight and in species pharmacokinetics are not clinically relevant. Although this is the simplest and most common method of extrapolation, it may overdose large animals and underdose small animals.

Metabolic scaling uses the ratio of a known physiologic process (i.e., metabolic rate) of two species to estimate a dosage in a species where there are no measured pharmacokinetic data. This method uses the dosage in a specific species and links the dosage to a physiological function instead of the animal's body weight (Dorrestein 2000; Mortenson 2001; Sedgwick 1993; Sedgwick and Borkowski 1996). In this method the chosen function forces an allometric (log-log) relationship, usually with an exponent of 0.6–0.8. The key assumption is that since most physiological functions follow allometric equations relative to body weight, pharmacological parameters must also follow similar allometric relationships, and to this end, basal metabolic rate is used as the universal scaling factor. This method of dose extrapolation provides a relatively smaller dose for large animals and a higher dose for small animals. A specific method for interspecies extrapolation of drug dosages used in the zoological medicine field is metabolic scaling as described by Sedgwick and others (Dorrestein 2000; Mortenson 2001; Sedgwick 1993; Sedgwick and Borkowski 1996). All species are placed in one of five groups, termed *Hainsworth's energy groups:* passerine birds, nonpasserine birds, placental mammals, marsupial mammals, or reptiles. Using a predetermined K value, a specific minimum energy cost (SMEC) value is calculated and the ratio of the target species SMEC to the SMEC of a safe effective dose in a known species is calculated to achieve that appropriate dosage regimen (Dorrestein 2000; Mortenson 2001; Sedgwick 1993; Sedgwick and Borkowski 1996). This method is simple in that the metabolic rate can be estimated for most species and applied to any pharmaceutical agent. A known drug dosage is multiplied by the ratio of metabolic rate of a known, similar species and the new species. Unfortunately, this method has not been well validated and several pharmacologic papers have illustrated specific failures in this method of extrapolation.

The allometric approach is to measure a pharmacokinetic parameter in multiple species and to plot the data

against weight to derive a new allometric equation that can be used to estimate the pharmacokinetic parameter in an unknown species. Similar to its use for selecting the first time dose in humans (Boxenbaum and DiLea 1995), interspecies extrapolation serves an important function within the framework of veterinary medicine. In this regard, among its uses, it is especially important for estimating an appropriate dose in large animal species for which there does not exist pharmacokinetic or clinical information to support dose estimation. The caveat is that where first dose in humans is a prediction of a safe dose, in zoological medicine, the extrapolated dose in nonapproved species must be *both* safe and efficacious. Despite the potential for extrapolation error, the reality is that allometric scaling is needed across many veterinary practice situations and therefore will be used. For this reason, it is important to consider mechanisms for reducing the risk of extrapolation errors that can seriously affect target animal safety, therapeutic response, or the accuracy of withdrawal time predictions. Based upon this analysis, it appears that inclusion of at least one large animal in the scaling (with or without human data) can improve predictions (Mahmood et al. personal communication). In large animals, correction factors could not be applied because there was no trend seen between the exponents of the simple allometry and the appropriate correction factor for improving our predictions (Mahmood et al. personal communication). In addition, the vast majority of large animals for which pharmacokinetic data are available are herbivores. Conversely, the smaller animal species are either omnivores (mouse, rat, monkey, and human) or carnivores (dogs and cats). This difference in feeding behavior itself can influence drug metabolism and renal elimination. While large carnivore data (lion, tiger, polar bear, etc.) would be helpful, the obvious dangers hinder this area of research. Some marine mammal species may be worthy of consideration, but due to body fat composition of species, such as killer whales (*Orcinus orca*), the results would be of limited use. There is little way to predict, a priori, which animal species will be best suited for inclusion in the interspecies predictions. Another point of consideration is the interspecies differences in the contribution of various organ systems and differences in body composition as it pertains to the body weight estimates.

All extrapolation methods assume that the route of elimination is similar across all species used in the extrapolation and this is simply not true. The reality is that most drugs, 75% in Riviere's published data (Riviere et al. 1997) are not scalable across multiple species and that allometric scaling of pharmacokinetic parameters, while useful, has limitations. It is necessary, for the best therapeutic outcome, to have pharmacokinetic and efficacy data in each species that is treated in zoological medicine. The use of the available literature to understand the route of elimination and the extent of metabolism of therapeutic agents will greatly assist in determining allometric relationships of pharmacokinetic parameters. This should lead to more realistic and rational design of dosage regimens in zoological medicine.

"No presently available chemical restraint agent is equally effective and safe for use with all 45,000+ vertebrate species" (Fowler 1995). This statement relates not just to chemical restraint, but to therapeutic use in general within zoological medicine. Changes in minor species drug approval could make it easier for the needed information to get into the hands of veterinarians. The Minor Use and Minor Species Animal Health Act of 2004 (MUMS) has been enacted to address the lack of drug availability for minor species. This includes food animals, companion pets, wildlife, and zoo species. An increase in basic pharmacokinetic parameters in zoological species will increase the therapeutic options for veterinarians. Any pharmacokinetic or pharmacodynamic studies in these species would be welcomed.

Some of the specific needs for zoological medicine are formulations that would allow for administration of therapeutic agents via the drinking water or milled into the feed. Other routes of administration that have not been used to their full extent in zoological medicine are rectal, sustained or controlled release, and topical. Increased information and formulations that would allow for administration of appropriate therapeutic agents would be of great benefit. This chapter brings to light some of the issues that face veterinarians on a daily basis when they deal with nontraditional species. Clearly it is not economically feasible to develop every drug for every species. However, targeted approvals or research could greatly increase the efficacy and safety of current and future therapeutics. Also, this type of approach would increase the quality of care provided to zoological species.

Regulatory Considerations

CHAPTER

54

LEGAL CONTROL OF VETERINARY DRUGS

STEPHEN F. SUNDLOF

Legislative Milestones in the Development of Laws Pertaining to the Regulation of Animal Drugs 1355

Drug Compendia 1363

LEGISLATIVE MILESTONES IN THE DEVELOPMENT OF LAWS PERTAINING TO THE REGULATION OF ANIMAL DRUGS

There are indications that the regulation of drugs in America began with the earliest colonies. For example, records of the Massachusetts Bay Colony tell of Nicholas Knopf, who in 1630 was sentenced to pay a fine or be whipped for selling "a water of no worth nor value" as a cure for scurvy. However, federal controls over drugs did not begin until 1848, when the Import Drug Act was passed to stop the adulteration of quinine used to treat American troops who had contracted malaria in Mexico. The Import Drug Act was the first federal statute to guarantee the quality of medicines, and US Customs laboratories were established to administer the law. The mission of the new Customs laboratories was to enforce the purity and potency standards of the *US Pharmacopeia,* which had been compiled in 1820 by trade and professional leaders. Subsequently support dwindled and the program gradually faded away. There was no organizational connection with the agency now known as the Food and Drug Administration.

The first state pure food and drug law was passed by California in 1850. During subsequent years many other states enacted similar legislation, but the need for regulation on an interstate basis was becoming more and more evident.

In 1880, Peter Collier, chief of the Division of Chemistry, US Department of Agriculture (USDA), began advocating enactment of a national food and drug law. In 1883 Dr. Harvey W. Wiley succeeded Collier as chief chemist and continued and broadened his efforts advocating a national food and drug law. Initially there was little interest in this kind of reform. Advocates were generally regarded as cranks and radicals. Over 100 bills were to be introduced in the US Congress before the first Federal Food and Drugs Act (and the Meat Inspection Act) of 1906 was enacted.

Conditions in the drug industry can scarcely be imagined today. The great advances in bacteriology were just beginning to have an impact on infectious diseases. Milk was still unpasteurized and cows were not tested for tuberculosis. Thousands of so-called patent medicines such as Kickapoo Sagwa Renovator for Stomach, Liver, and Kidney; Dr. Shreve's Anti-Gallstone Remedy; and Hamlin's Wizard Oil—Cures All Pain in Man or Beast flooded the

marketplace. "Medicine-men" competed with circuses, minstrel shows, and "Wild West" shows to entertain the public and sell their products. Medicines containing opium, morphine, heroin, and cocaine were sold without restriction and without even any indication of the presence of the drugs in the product. Preparations that were otherwise harmless, other perhaps than being alcohol based, were labeled for the cure of every disease or symptom of man and beast. Labels did not list ingredients, and warnings against misuse were virtually nonexistent. Of course, such practices were by no means universal, and many firms were producing reliable and wholesome products. However, there was no lack of material for investigation and disclosure by Dr. Wiley's chemists. In order to generate support for his cause, Dr. Wiley took their findings to the public, speaking frequently at women's clubs and civic and business organizations. Crusading reporters (muckrakers), organized women's clubs, and farsighted businessmen became his strong supporters. In 1903, Dr. Wiley captured the attention of the public by establishing his now famous volunteer "poison squad" of young men who agreed to eat only foods treated with measured amounts of chemical preservatives, in order to evaluate the safety of such products. Thanks to the publicity engendered by Dr. Wiley's work, public concern began to build. It reached a climax with the publication of Upton Sinclair's book *The Jungle*, a brutally graphic novel, which focused national attention on the unsanitary conditions in U.S. meat packing plants. As a result the first federal food and drug law, the Food and Drugs Act of 1906, was passed by Congress and signed into law by President Theodore Roosevelt on June 30, 1906.

Basically the law banned from interstate commerce any traffic in adulterated or misbranded food or drugs. The act defined "drug" to include all medicines and preparations recognized in the *US Pharmacopeia* or *National Formulary* for internal or external use and any substance or mixture of substances intended to be used for the cure, mitigation, or prevention of disease in either humans or other animals.

Drugs were to be deemed "adulterated" if they were sold under or by a name recognized in the official compendia (the *US Pharmacopeia* and the *National Formulary*) but failed to meet the standards set forth therein, except that a recognized drug not meeting the official standard would not be deemed adulterated if it met its own standard of strength, quality, and purity as stated on the container. A drug was deemed "misbranded" if the label bore any statement, design, or device regarding the contents which was false or misleading, or if the drug was falsely branded as to the state, territory, or country in which it was manufactured. Drugs would also be misbranded if they were an imitation of, or offered for sale under the name of, another article or if the original contents had been removed in whole or in part and/or other contents added. Drugs would also be misbranded if their labels failed to disclose any quantities of alcohol, narcotics, and other specified substances present in the product.

Although the 1906 law represented a great step forward, there were obvious weaknesses. In 1911, the Supreme Court ruled that the labeling provisions of the act prohibited *only* false statements about the identity of the drug product but not false therapeutic claims. The Congress responded by passing the Shirley Amendment of 1912, which outlawed false *and fraudulent* curative or therapeutic claims. Under the Shirley Amendment, the government was required to prove that a false claim was also fraudulent, that is, that the promoter *intended* to deceive the purchaser. A defendant had only to show that he personally believed in his patent medicine to escape prosecution. This remained a major weakness in the law for 26 years.

The USDA's Bureau of Chemistry enforced the law until 1927, when the bureau was reorganized in order to separate law enforcement functions from agricultural research and development. The Food, Drug, and Insecticide Administration was formed. It was renamed the Food and Drug Administration (FDA) in 1931, and in 1940 the FDA was transferred from the USDA to the Federal Security Agency, in order to eliminate recurring conflicts between consumer interests and producer interests. In 1953, the Federal Security Agency became the Department of Health, Education. and Welfare—now the Department of Health and Human Services (DHHS).

An interesting side note: FDA's budget (appropriations), because of its origins in the USDA, comes through the House and Senate Agricultural Appropriations committees. Amendments to the Federal Food, Drug, and Cosmetic Act, however, come under the jurisdiction of the Senate Committee on Labor and Human Resources and the House Committee on Energy and Commerce.

By the early 1930s it was evident that there were serious shortcomings in the 1906 act. False advertising in print and on the radio was blatant, and manufacturers had found many ways to circumvent the law. Technological

advancements were revolutionizing the production and marketing of foods, drugs, and related products, making the 1906 law obsolete.

In 1933 Walter Campbell, then chief of the FDA, seized an opportunity to work with Rexford Tugwell a member of newly elected president Franklin D. Roosevelt's "brain trust" who had been appointed assistant secretary of agriculture, in developing a complete revision of the Food and Drugs Act. When the resulting "Tugwell bill" was introduced in Congress, it was a legislative disaster. Opposition to this New Deal legislation by industry and advertising interests was total. This was due in part to Rexford Tugwell's reputation in the business community and to some extent in Congress. The Columbia University economics professor, who believed in and advocated a planned economy, was greatly feared in business circles. The Senate sponsor of the bill, Royal S. Copeland, M.D., of New York, aided by FDA officials, consumer-minded congressmen, attorneys, and staffers, began the laborious process that was to become a bitter 5-year battle for new legislation.

As before, public opinion was to play a major role in pushing Congress to act, and again organized clubwomen were very important in generating and molding public support. Public opinion was aroused by a shocking and tragic drug disaster that resulted in more than 100 deaths. The drug involved was "Elixir of Sulfanilamide," sulfanilamide dissolved in diethylene glycol. Sulfanilamide had only recently become available, and salesmen reported that there was a demand for a liquid form. Since sulfanilamide is poorly soluble in water. The manufacturer dissolved the drug in diethylene glycol and added coloring and flavoring. The solution was tested for flavor, appearance, and fragrance, but since existing laws did not require manufacturers to demonstrate that their products were safe, no safety or toxicity testing was done. Before the product could be identified and recalled it had claimed 107 lives in 15 states from Virginia to California.

Shortly after the sulfanilamide disaster, Congress adopted portions of the Copeland bill and it was passed as the Federal Food, Drug, and Cosmetic Act (FFD&C Act) of 1938, also referred to as the Copeland Act. Under the 1938 act, interstate commerce in a new drug (for humans or animals) was prohibited unless it had been adequately tested to show that it was safe for use under the conditions of use prescribed on its label. Thus, it was illegal to ship a drug across state lines unless it had been shown to be safe. An exemption to this requirement was provided for a drug intended solely for investigational use by qualified scientific experts.

The 1938 act also required labels to bear adequate directions for use and to include warnings against unsafe use, where drugs (or devices) might be injurious to health. It required official drugs to be packaged and labeled as prescribed by the official compendia; required the labels of nonofficial drugs to list active ingredients; and required precautionary labeling of drugs subject to deterioration. Note that the 1938 act still did not require demonstrated proof of effectiveness of drugs.

The new law, and World War II, greatly expanded the FDA's workload. This period was characterized by the development of many new "wonder drugs," especially antibiotics, which were made subject to FDA testing beginning with penicillin in 1945. Fortunately the law required premarket approval of new drugs, but there were no premarket clearance requirements for a host of new chemicals of unknown safety. The law prohibited poisonous substances but provided no requirement that food ingredients be shown to be safe. The law did provide for exemptions and establishment of safe tolerances for unavoidable or necessary poisons such as pesticides, but when the FDA attempted to set a pesticide tolerance, the courts ruled that the lengthy procedure required by law was unworkable. The FDA was able to stop the use of known poisons where they posed a hazard (and did so in many cases) but the vast research effort needed to ensure that all food chemicals were safe was clearly beyond available resources. During the 1940s there was a substantial increase in the use of commercial pesticides in the growing of agricultural products and in the use of chemicals for flavoring, coloring, preserving, and packaging of processed foods. In 1950, the House of Representatives adopted a resolution creating a Select Committee to Investigate the Use of Chemicals in Foods. Representative James T. Delaney of New York served as its chairman. The committee began extensive hearings that were to go on for 2 years. As a result of the committee's work and the work of the FDA and others, three very significant amendments to the FFD&C Act were enacted: the Pesticide Amendment (1954), the Food Additives Amendment (1958), and the Color Additives Amendment (1960).

The Food Additives Amendment of 1958 was particularly significant in terms of its impact on the regulation of animal drugs since animal drugs approved for use in food animals were considered to be food additives and thus had to meet not only the drug standards of the act but also the

food additive standards. Further, since the 1958 amendment required the pre-market clearance of food additives, this meant that for the first time, sponsors of drugs indicated for use in food animals were required to demonstrate, as a condition of approval, the safety to humans of any residues present in food products derived from treated animals. A direct result of this provision has been the development, within veterinary pharmacology and toxicology, of a whole new subdiscipline, that of residue sciences.

This was also significant because it brought animal drugs for use in food animals under the provisions of the "Delaney anticancer clause," which provided that no additive will be deemed to be safe if it is found to induce cancer in humans or animals. The Delaney anticancer clause as it applied to animal drugs was amended in 1962 to include a provision that permits administration of a compound known to induce cancer in humans or animals to food-producing animals when it has been shown that "no residue" will occur in food products. Specifically, this exception, known as the DES Proviso required that no residue will be found by methods of examination prescribed or approved by the secretary of the DHHS. Initially, the "no residue" provision was met simply by applying the most sensitive analytical methods available. However, it was recognized in doing so that "no residue" did not mean "zero residue" but rather was defined by the sensitivity of the analytical method employed. This was unacceptable. As a result, FDA developed a regulation commonly referred to as the Sensitivity-of-Method procedure, or SOM, now known as the animal drug safety policy, which defined "no residue" in terms of the level of residue that presents an insignificant risk of cancer to the consuming public. The safe level is then described with a finite number in parts per million (ppm) or parts per billion (ppb).

The regulation defines an insignificant risk of cancer as a 1 in 1 million increase in risk over the normal lifetime risk of cancer. Further, the regulation spells out how the level of residue that represents an insignificant risk of cancer is determined. The method to be used in monitoring for residues of the compound then must be sensitive enough to detect the level of residue determined to represent an insignificant risk.

During this period two other amendments to the FFD&C Act were to have a significant impact on veterinary medicine. The first was the Durham-Humphrey Amendment of 1951, which for the first time defined the kinds of drugs for human use that may be dispensed by a pharmacist only upon the prescription of a "practitioner licensed by law to administer such drugs." This was very significant because it created and defined the category of prescription drugs. Under previous law, a drug manufacturer decided whether a given drug would be available by prescription or over the counter. The language of the Durham-Humphrey Amendment specifically restricted the term "prescription" to drugs and medical devices for human use by replacing a section of the 1938 FFD&C Act that contained explicit reference to a "prescription signed by a physician, dentist, or veterinarian." Language in both the Senate and House reports that accompanied the amendment, however, recognized the need for a similar category of "prescription" animal drugs, which the FDA had established by regulation. The FDA's authority to restrict a drug to use "by or on the order of a licensed veterinarian" has been upheld by the courts on several occasions, but statutory recognition of the prescription provision pertaining to animal drugs was not codified in the law until the enactment of the Generic Animal Drug Patent Term Restoration Act of 1988.

The Kefauver-Hams Drug Amendments of 1962 were also to have a significant impact on veterinary medicine. The Drug Amendments of 1962, like the 1938 act, were enacted into law following a disaster involving drugs: the "thalidomide disaster." Thalidomide, a sedative that was prescribed to pregnant women, is a potent teratogen causing severe deformities called phocomelia. Although the FDA never approved thalidomide for commercial marketing in the United States, it was distributed to selected doctors for experimental purposes, and it was approved and widely used in Europe.

The 1962 amendments extended, expanded, and strengthened the FDA's regulatory authority with respect to drugs. For the first time manufacturers were required to provide "substantial evidence" of the effectiveness of new drugs, as well as of their safety, as a condition of approval. Labeling now had a material bearing on the matter of new drug approval in that it must not be false or misleading in any particular. With respect to drugs already on the market, the manufacturer was required to report promptly to the FDA any information concerning adverse effects and other clinical experience or data relating in any way to safety and effectiveness.

Relative to effectiveness, the amendments also included a provision that enabled the FDA to require an effectiveness review of every new drug introduced between 1938

and 1962. The program, which began in the late 1960s, was called the Drug Efficacy Study Implementation (DESI) program. As a result of the DESI program, many older products, particularly those with multiple ingredients, were removed from the market. Those products remaining had labeling claims that could be substantiated through adequate studies and thus met the FDA standard for effectiveness. In 1968, legislation was passed to consolidate provisions of the FFD&C Act with respect to the regulation of animal drugs. Prior to 1968 the act generally did not distinguish between human drugs and animal drugs. Both the House and the Senate reports on the amendment pointed out that, in many cases, the requirements for clearance of new animal drugs were more complicated than the clearance procedures for drugs for humans. This was because animal drugs indicated for use in food animals were required to meet not only the drug standards of the act but also the food additives standards. In fact, ensuring that food products from animals treated with a particular animal drug pose no risk to public health is often the most expensive and time-consuming part of the developmental process for a new animal drug intended for use in food animals.

It is important to note two additional aspects of food and drug legislation. First, the Food Additive Amendments of 1958 included language prohibiting the use of an animal drug other than in accord with its approved uses. This reflected congressional concern for human food safety, but it also made extralabel drug use in animals illegal under the act. At the same time Congress was operating on the principle that animal drugs should be routinely available to farmers to treat their animals, i.e., to protect their property. The act requires that for an animal drug to be legally marketed in the United States, it must bear adequate directions for use by a layperson. Animal drugs that do not or cannot bear such directions for use are considered to be misbranded. The FDA, as noted above had recognized the need for an exception to this requirement and had, by regulation, provided for the marketing of "prescription" animal drugs which could be used safely by or on the order of a licensed veterinarian, but for which adequate directions for lay use cannot be written.

The congressional bias in favor of the availability of animal drugs direct to farmers was to have a profound effect on the drug development and approval process and ultimately on veterinary pharmacology in the United States. It is reflected in the history of the FDA approvals of drugs for food animals. Even after establishing a category of prescription animal drugs in 1988, most drugs approved for food animals, with the exception of therapeutic antimicrobial agents, are classified as over-the-counter (OTC), whereas most drugs approved for companion animals are classified as prescription.

This focus on OTC drugs (and the attendant need to be able to provide labeling that can be reasonably followed by laypersons) has led to the approval of OTC drugs that are labeled for very specific and limited indications and that have directions for use which provide little or no flexibility in how the product can be used. As a result, there are many animal species for which there are no drugs approved, and for others the number of approved drugs is very limited and may not include drugs such as anesthetics, antiinflammatory agents, or other drugs with low market potential.

Faced with an insufficient armamentarium of drugs approved for all of the various animal species-disease combinations encountered in veterinary practice, veterinarians historically have exercised considerable judgment in utilizing therapeutic agents, often going beyond the limits of approved labeling. Prior to 1994, veterinarians who engaged in extralabel drug use technically were in violation of federal law, unlike their physician counterparts, who were not prohibited by the act from using or prescribing drugs for use in humans as they deemed appropriate. In spite of the fact that the act clearly specifies that an animal drug must be used in strict accordance with the indications and directions for use contained in its labeling, FDA policy was very permissive in this regard.

During the late 1970s and early 1980s the FDA recognized the need for a more structured policy regarding such use, one that would define the conditions under which such use would not ordinarily result in regulatory action while at the same time drawing attention to the responsibilities incurred by the veterinary practitioner electing to use a drug in an extralabel fashion, especially in a food-producing animal. The policy took the form of a Compliance Policy Guide (CPG). CPGs are used to provide guidance regarding regulatory initiatives and enforcement priorities to FDA field and headquarters personnel. CPG 7125.06, titled "Extra-Label Use of New Animal Drugs in Food-Producing Animals," communicated the FDA's recognition that the extralabel use of a drug in food-producing animals may be considered by a veterinarian when the health of animals is immediately threatened and suffering or death would result from failure to treat the affected

animal(s). In instances of this nature, regulatory action would not ordinarily be considered provided that several criteria were met (see Chapter 61).

The FDA also recognized that in the case of companion animals (nonfood animals) veterinarians had become reliant on a number of drugs approved for use in humans but for which no counterparts were approved for use in animals. Examples of human drugs widely used in companion animals include digitalis derivatives, insulin, and anticancer drugs. CPG 7125.35, "Human Drugs Distributed to Veterinarians for Use in Animals," basically provides that as long as such distribution of a human drug is initiated (ordered) by a licensed veterinarian and is *not* intended for use in food-producing animals, the FDA would *not* ordinarily consider regulatory action. However, it should be noted that the manufacturers are *not* permitted to advertise or otherwise promote the use of human-labeled drugs for use in animals.

Although CPGs generally discourage the use of human drugs in food animals, certain exceptions are recognized. These include certain poison antidotes, insulin for use in the treatment of ketosis, and certain anesthetics and analgesics for use in surgical cases and for relief of pain and suffering.

Despite the efforts of the FDA to establish policies that recognized the needs of animals while protecting the public's health, such policies were based on the agency's authority to exercise discretion in deciding whether to enforce certain provisions of the act. The fact that the FDA elected not to take enforcement actions against veterinarians who administered drugs in an extralabel manner in no way conferred legal status to such practices. Concerned by the notion that veterinarians, unlike the members of any other licensed profession, were forced to repeatedly break the law in order to responsibly carry out their professional duties, the American Veterinary Medical Association actively petitioned Congress to amend the act.

In 1994, Congress, in an effort to decriminalize the everyday practice of veterinary medicine, passed the Animal Medicinal Drug Use Clarification Act of 1994. This law allows licensed veterinarians to use and prescribe, under specified conditions, animal and human drugs for extralabel purposes. In general the law is intended to codify in law and regulations the conditions and restrictions for extralabel use provided in CPG 7125.06 and CPG 7125.35 as outlined above. It also recognized compounding of animal drugs from FDA-approved human or animal drugs as a form of extralabel drug use. Such compounding is permissible by a veterinarian or a pharmacist on the order of a veterinarian provided that 1) there is no approved new animal or new human drug that, when used as labeled and in the available dosage form and concentration, appropriately treats the condition diagnosed; 2) the compounding is performed by a licensed pharmacist or veterinarian within the scope of a professional practice; 3) adequate procedures and processes are followed that ensure the safety and effectiveness of the compounded product; 4) the scale of the compounding operation is commensurate with the established need for compounded products (e.g., similar to that of comparable practices); and 5) all relevant state laws relating to the compounding of drugs for use in animals are followed. Compounding from a human drug for use in food-producing animals is not permitted if an approved animal drug can be used for compounding. Compounding from bulk drugs is not permitted under the act; however, the FDA on occasion has exercised regulatory discretion in allowing compounding from bulk drugs where the need was great and the risk to animals and the public was small. Additional information on compounding of drugs for use in animals is published in CPG 7125.40.

Although the Animal Medicinal Drug Use Clarification Act provided psychological relief to veterinarians by codifying into law practices previously permitted by the FDA under more tenuous compliance policy guides, it did not address the underlying problem that necessitated extralabel use: the insufficiency of drugs available to treat animals. This sentiment was reflected in the Congressional Record immediately following passage of the bill in the Senate. At that time Senator Coates of Indiana stated that the bill "does nothing to expedite the review process of the FDA and CVM. Through future legislative initiatives, we now need to address the animal drug availability deficiencies." Shortly after the passage of the Animal Medicinal Drug Use Clarification Act, the Coalition for Animal Health formed with the purpose of increasing the availability of animal drugs through statutory changes to the FFD&C Act. The Coalition, made up of veterinarians, animal producer organizations, the animal feed industry, and the animal drug industry, drafted proposed legislation, which eventually was signed into law on October 9, 1996. The Animal Drug Availability Act (ADAA) introduced major reforms in the way that the FDA evaluates and approves new animal drugs. These reforms are intended to facilitate the approval of new animal drugs and medicated feeds by building greater flexibility into the existing animal

drug review processes. Such flexibility does not compromise the FDA's authority to ensure that animal drugs are safe for the animal patient and for the public consuming animal-derived foods.

Most of the reform measures brought about by the ADAA addressed the standard for determining whether a new animal drug is effective for its specified conditions of use. The FFD&C Act provides that the FDA may refuse to approve a new animal drug if it finds that there is a lack of *substantial evidence* that the drug will have the effect it claims under the conditions of use prescribed recommended. or suggested in the proposed labeling. Prior to ADAA the FDA had interpreted the phrase *substantial evidence* in fairly rigid terms, requiring a fixed minimum number of field studies (generally three) conducted at geographically distinct locations. (Field studies are clinical studies conducted under conditions that closely approximate the condition under which the new animal drug, if approved, is intended to be applied or administered.) With the changes effected by the ADAA it is now possible that even a single *adequate and well-controlled* study may provide substantial evidence of effectiveness. Furthermore in certain cases a field investigation may not be necessary to allow the FDA to conclude that the drug is effective.

The ADAA further allowed the FDA to redefine the phrase "adequate and well-controlled" as it applies to field investigations. Because field studies are conducted under field conditions (e.g., on farms or commercial livestock production facilities) it is recognized that the level of control over some study conditions need not or should not be the same as the level of control in laboratory studies. Under the ADAA, the FDA will balance the need to control study conditions with the need to observe the true effect of the drug under closely approximated actual-use conditions in determining whether a field study is adequate and well controlled.

Prior to the ADAA, products containing two or more drugs (combination drugs) were required to meet the same rigorous standard for effectiveness as products containing a single drug, even when the individual drugs in the combination product had been previously proven to be effective. The ADAA streamlined the process for approving a combination new animal drug if each of the drugs used in the combination has been previously approved separately for the uses for which it is intended in the combination. In such cases, additional studies for effectiveness and animal safety are often not required.

The FFD&C Act required that the FDA approve new animal drugs based on the concept of a single optimal dose (i.e., a single dosage that does not exceed the amount reasonably required to accomplish the drug's intended effect). This "optimal dose" concept left little flexibility for veterinarians to exercise professional judgment in the treatment of their patients. Furthermore, for certain drugs such as antimicrobial and antiparasitic agents, the approved "optimal dose" may become ineffective over time. Determining the optimal dose is a time-consuming and costly practice requiring pharmaceutical companies to conduct dose titration studies. The ADAA amended the FFD&C Act to allow the FDA to approve any effective dosage regimen as long as it is safe for the patient and does not result in a residue that exceeds the tolerance (see Chapter 61 on Chemical Residues in Tissues of Food Animals). Labeling animal drug products with dosage ranges rather than a single fixed dose allows veterinarians to select a dosing regimen tailored to the specific needs of each patient.

The ADAA defined an entirely new class of drugs differentiating them from over-the-counter and prescription classifications. Veterinary Feed Directive (VFD) drugs are intended for use in or on animal feed and are limited by approved application to use under the professional supervision of a licensed veterinarian. Previously, all feed additive drugs were available through over-the-counter channels. VFD drugs and animal feeds containing them must be labeled with a cautionary statement, and an animal feed containing a VFD drug can be used only by a licensed veterinarian or upon the lawful VFD issued by a licensed veterinarian. Because veterinary supervision is required the VFD classification allows the FDA to approve potent new therapeutic drugs for administration to animals via feed.

The Animal Drug User Fee Act of 2003 (ADUFA) authorized FDA to collect fees from pharmaceutical firms in support of the review of new animal drugs. The law authorizes the collection of fees to enable FDA to hire and train additional scientific reviewers and implement enhanced processes to accelerate and improve the review process. This law is intended to help FDA expedite and improve its review of applications for new animal drugs so that safe and effective new products will be available more quickly. Specifically, the law requires the FDA to continuously reduce the time it takes to review drug applications.

FDA anticipates that ADUFA will bring substantial savings to the animal drug industry in regulatory review

and developmental expenses. A faster, more predictable review process is expected to spur more research and development by the animal drug industry.

The law also requires the agency to adopt administrative processes to ensure that review times for generic animal drugs (which are not assessed user fees) do not increase due to activities under ADUFA.

The Minor Use and Minor Species Animal Health Act of 2004 (MUMS) provides innovative, flexible ways to make drugs available to treat minor animal species as well as uncommon diseases in the major animal species. It is designed to help pharmaceutical companies overcome the financial burdens they face in providing limited-demand animal drugs. By making more drugs available for minor species, the law is expected to benefit certain agricultural groups, zoo and wildlife veterinarians, and owners of pets other than cats and dogs. The new law modifies provisions of the Federal Food, Drug, and Cosmetic Act in three key ways, providing for the following:

1. *Conditional Approval:* The sponsor of a minor use or minor species veterinary drug can ask FDA for "conditional approval," which allows the sponsor to market the drug after that proving the drug is safe and establishing a reasonable expectation of effectiveness, but before collecting all the effectiveness data needed to support a full approval. The drug sponsor can keep the product on the market for up to 5 years, through annual renewals, while gathering the required effectiveness data for full approval.
2. *Indexing:* The law gives FDA authority to add a minor species drug to an index of unapproved new animal drugs that may be legally marketed when the potential market for the drug is too small to support the costs of the drug approval process, even under a conditional approval. This provision will be especially helpful to veterinarians treating zoo or endangered animals, and to owners of minor pet species such as ornamental fish or caged reptiles, birds, or mammals.
3. *Designation:* This aspect of the law provides incentives for minor use or minor species drug approvals, such as grants to support safety and effectiveness testing. Sponsors must apply for designation prior to filing a new animal drug application for FDA approval. At the time that a designated drug gains approval or conditional approval, it is awarded 7 years of exclusive marketing rights, which means that FDA will not approve another application for the same drug in the same dosage form for the same intended use until after the 7 years have elapsed. This is 2–4 years longer than the protection provided from generic copying of nondesignated drugs.

Another area of drug regulation directly affecting the veterinarian is the Comprehensive Drug Abuse Prevention and Control Act of 1970 commonly called the Controlled Substances Act (CSA). At the turn of the century in the United States, opium, morphine, cocaine, and other such drugs were freely available to the public. In fact, as noted previously, many of the nostrums and patent medicines available at that time contained such drugs even though labels gave no hint of their presence. Although the Food and Drugs Act of 1906 required that the presence of such substances be specified on labels, it was clear that the ready availability of such substances had to be restricted. Thus, in 1914, the Congress enacted the Harrison Narcotic Act, which restricted narcotic drugs such as the opiates, cocaine, and ecgonine and any substances containing such compounds to legitimate medical uses. These drugs could be dispensed by pharmacists only on the basis of a prescription written by a veterinarian, physician, or dentist who was registered with the US Treasury Department. It later became apparent that there were dangers inherent in the distribution and use of many nonnarcotic drugs. Accordingly, in 1965, drug abuse amendments to control traffic in barbiturates, amphetamines, and other abused drugs were added to the FFD&C Act. In 1968, the FDA's Bureau of Drug Abuse Control was transferred to the Department of Justice, where it was consolidated, along with the Treasury Department's Bureau of Narcotics, into the current Drug Enforcement Administration (DEA).

Under the 1970 act, controlled substances include opiates, barbiturates, hallucinogens. methadone, stimulants such as amphetamines, and other addictive or habituating drugs. This act regulates the manufacturing, distribution, and dispensing of controlled substances by providing for a closed system of registered people (manufacturers and distributors, pharmacists, licensed practitioners, and others) authorized to handle such compounds. A veterinarian licensed to practice by a state and wishing to use or prescribe controlled substances must register annually with the DEA. Controlled drugs and drug products are categorized in five schedules, and an applicant requests certification for those schedules or categories of drugs that he or she expects to purchase, store, dispense, and use. The registered person or hospital is given a DEA

certificate for display, a registration number, and official forms that must be used in ordering and purchasing controlled substances. The registration number must be used on all prescriptions and order forms. Registrants (and those authorized under a registration) must keep accurate records of orders, receipts, and uses of controlled substances. Current inventory must be reconcilable with amounts received and used or dispensed. All records and activities are subject to inspection by DEA personnel at any time. Both the veterinarian and the pharmacist are legally responsible for the proper prescribing and dispensing of drugs covered by the CSA. Further, controlled substances must be stored in a locked cabinet or preferably in a safe secured to a concrete floor.

The manufacturers and distributors are required to identify a controlled substance on the label of original containers by a symbol corresponding to the schedules specified by DEA for each controlled substance. The symbol is a capital C (for controlled substance), followed by the Roman numeral (I–V) corresponding to the schedule to which the substance is assigned.

Schedule I drugs have a high abuse potential and are not currently accepted in the United States for use in any practice situation, although they may be obtained for research or instructional use. Examples are heroin, LSD, mescaline, marijuana, methaqualone, and peyote.

Schedule II drugs have a high abuse potential, their use can produce severe psychic or physical dependence in humans, and they apparently have similar effects in animals. These are the former Class A narcotic drugs plus certain stimulant drugs. Examples are opium, morphine, hydromorphone (Dilaudid), cocaine, methadone, meperidine (Demerol), fentanyl, and cocaine; and the barbiturates amobarbital (Amytal), pentobarbital (Nembutal), and secobarbital (Seconal) and their salts. The amphetamines are no longer available under Schedule II for veterinary use.

Schedule III drugs have less abuse potential than those in Schedules I and II. Abusive use of Schedule III drugs leads to moderate or low physical dependence but often high psychological dependence in humans. Examples of Schedule III drugs include anabolic steroids such as stanozolol (Winstrol), trenbolone (Finaplix), and testosterone; some opioids such as nalorphine (Nalline) and opium combination products (e.g., Paregoric); some barbiturates that are not classified in Schedule I or II such as thiamylal (Surital) and thiopental (Pentothal); and some nonnarcotic drugs such as tiletamine and zolazepam combination products (e.g., Telazol), phencyclidine, ketamine, and benzphetamine.

Schedule IV drugs have a low abuse potential that can lead to limited physical or psychological dependence in humans. Included here are barbital, phenobarbital, methylphenobarbital, chloral hydrate, butorphanol, meprobamate (Miltown, Equanil), chlordiazepoxide (Librium), and diazepam (Valium).

Schedule V drugs have a lesser abuse potential and include some codeine and dihydrocodeine preparations (Robitussin A, Cophene-S), diphenoxylate preparations (Lomotil), and others.

Anabolic steroids were added to the list of controlled substances in 1991 under the Anabolic Steroids Control Act (ASCA). Certain veterinary products fall under the ASCA and have been classified as Schedule III drugs under the CSA. These products include boldenone, mibolerone, stanozolol, testosterone, and trenbolone and their salts, esters, and isomers. Estrogens and progesterones are not subject to the ASCA or the CSA.

Anabolic steroid implants in the final dosage form, if expressly intended for use in cattle or other nonhuman species in accordance with their approvals under the FFD&C Act, are exempted from the scheduling requirements. However, any person or firm engaged or proposing to engage in the production of such implants must comply with the Schedule III requirements of the CSA and must register with the DEA.

DRUG COMPENDIA

It is critically important to the veterinarian, pharmacist, and physician and their patients and clients that the drugs they employ are of uniform potency, purity, and quality. Without such standardization, rational pharmacotherapy would be impossible. Such assurance is a basic objective of the laws and regulations described above and is the purpose of the *US Pharmacopoeia* (USP)-*National Formulary* (NF). The USP-NF is the legally recognized drug compendium for the United States. The USP was originally compiled and first published in 1820 and has been regularly and continuously revised by the US Pharmacopeial Convention, which is composed of elected delegates representing human medicine, pharmacy, veterinary medicine, dentistry, and nursing. The National Formulary was a separate official compendium published by the American Pharmaceutical Association to serve the need of pharmacists for standardization of certain pure drugs that were

not used widely enough to be included in the USP. During the 1975–80 USP revision period these two official compendia were "unified" into a single USP-NF compendium. At that time the scope of the two components was changed in that the USP covered all drug substances and drug products, while the NF was devoted exclusively to pharmaceutic ingredients.

In addition to USP and NF designations, a drug may be given an International Nonproprietary Name (INN).

The USP and NF derive their official status from the FFD&C Act. Standards promulgated by the Committee of Revision of the USP Convention are enforceable by the FDA.

INTRODUCTION

The availability of new animal drugs for use in livestock, poultry, pets, and other animals is vital to protecting the health of animals, increasing the efficiency of food production, and protecting the health of humans who consume the products of food-producing animals. Appropriate use of animal drugs also enhances human health through prevention of zoonotic disease transmission, protection of the food supply, and preservation of the human-animal bond. Practical application of the principles of pharmacology is important for development of safe and effective animal drugs and for making the best use of these products during clinical practice. An understanding of considerations and regulatory constraints that guide the evaluation of veterinary pharmaceutical products by the US Food and Drug Administration (FDA) is vital for optimizing the animal drug development process and for using label information to customize treatments to match patient needs.

Section 512 of the Federal Food Drug and Cosmetic Act (FFDCA) provides the statutory provisions governing the regulation of veterinary products. Through this act, a new animal drug is considered to be unsafe unless there is in effect an approval of a New Animal Drug Application (NADA) and unless the use of a drug and its labeling conform to the approved application. The term *adulterated* can also apply to new animal drug products that are not the subject of an approved NADA or an Abbreviated NADA (ANADA). Virtually all animal drugs are *new animal drugs* within the meaning of the FFDCA, and are therefore subject to Section 512 (http://www.fda.gov/opacom/laws/fdcact/fdcact5a1.htm).

The url for the FDA home page is http://www.fda.gov and access to the Center for Veterinary Medicine (CVM) home page is obtained by selecting the **Animal & Veterinary** header located in the left column of the FDA website. Alternatively, you can go directly to the CVM home page using http://www.fda.gov/cvm. The regulations and policies governing FDA activities are published in the Federal Register. All FDA regulations are codified in Title 21 of the Code of Federal Regulations (CFR), which can be accessed from the FDA website at http://www.accessdata.fda.gov/scripts/cdrh/cfdocs/cfcfr/cfrsearch.cfm. The booklet *FDA and the Veterinarian,* published by CVM, provides additional details on some of the legal aspects of FDA activities (http://www.fda.gov/cvm/3047.htm). Essential laws, regulations, and guidance applicable to the animal drug approval process are provided as active links [note: forthcoming changes to the FDA website are anticipated in 2009]. Concise summaries are displayed with each link. The CVM home page also provides links to the Freedom of Information (FOI) summaries for NADAs, Supplemental NADAs, and ANADAs. These summaries provide valuable information on the data submitted to support the approval of the application.

This chapter describes the regulatory framework that guides animal drug approval within the United States. This process provides exciting career opportunities for veterinarians, pharmacologists, and others in both industry and the federal government. The efficiency and success of drug development directly impacts the availability and approved uses of drugs for veterinary practitioners. Through the use of published literature and simulated examples, this chapter covers the use and application of the pharmacokinetic principles described in Chapters 2 and 3 of this book.

HISTORY OF THE FDA AND ITS RELATIONSHIP TO VETERINARY MEDICINE

Although veterinarians have been a part of the FDA since it was formed in 1927, regulation of veterinary pharmaceuticals was not initiated until the 1950s. When the FDA was divided into five bureaus in 1954, a branch dedicated to the evaluation of veterinary medicine was created within the Bureau of Medicine. This branch became a bureau of its own in 1965, and in 1984, the Bureau of Veterinary Medicine became the current Center for Veterinary Medicine (CVM). A brief chronology of FDA history is provided in Table 55.1. Additional information on the history and current responsibilities of the FDA and CVM is available on the web (www.fda.gov and www.fda.gov/cvm).

TABLE 55.1 Historical overview of the US FDA

http://www.fda.gov/cvm/aboutcvm/aboutbeg.htm

1848: Import Drugs Act was enacted (first federal statute for guaranteeing quality of medicines).

1862: President Lincoln created the Department of Agriculture (USDA).

1880: After a year's investigation into food and drug adulteration, USDA began advocating enactment of a national food and drug law.

1906: First Federal Food and Drug Act was signed into law and was administered by USDA's Bureau of Chemistry after studying food and drug adulteration.

1927: The Food, Drug, and Insecticide Administration was formed.

1938: Due to deaths from a sulfanilamide elixir containing an antifreeze analogue, the Federal Food, Drug, and Cosmetic Act (FFDCA) was enacted, requiring manufacturers to provide evidence of product safety.

1951: The Durham-Humphrey Amendment initiated prescription requirements for certain human drugs. The veterinary Rx legend was effected through rulemaking.

1953: The FDA was transferred to the Department of Health, Education and Welfare.

1954: The FDA was organized into five bureaus, including a Bureau of Medicine, within which was a Veterinary Medical Branch.

1959: The Veterinary Medical Branch became a Division due to extensive use of animal drugs and medicated feeds.

1962: The Kefauver-Harris Drug Amendments resulted from the thalidomide disaster, requiring that drugs show both safety and effectiveness, and establishing GMPs.

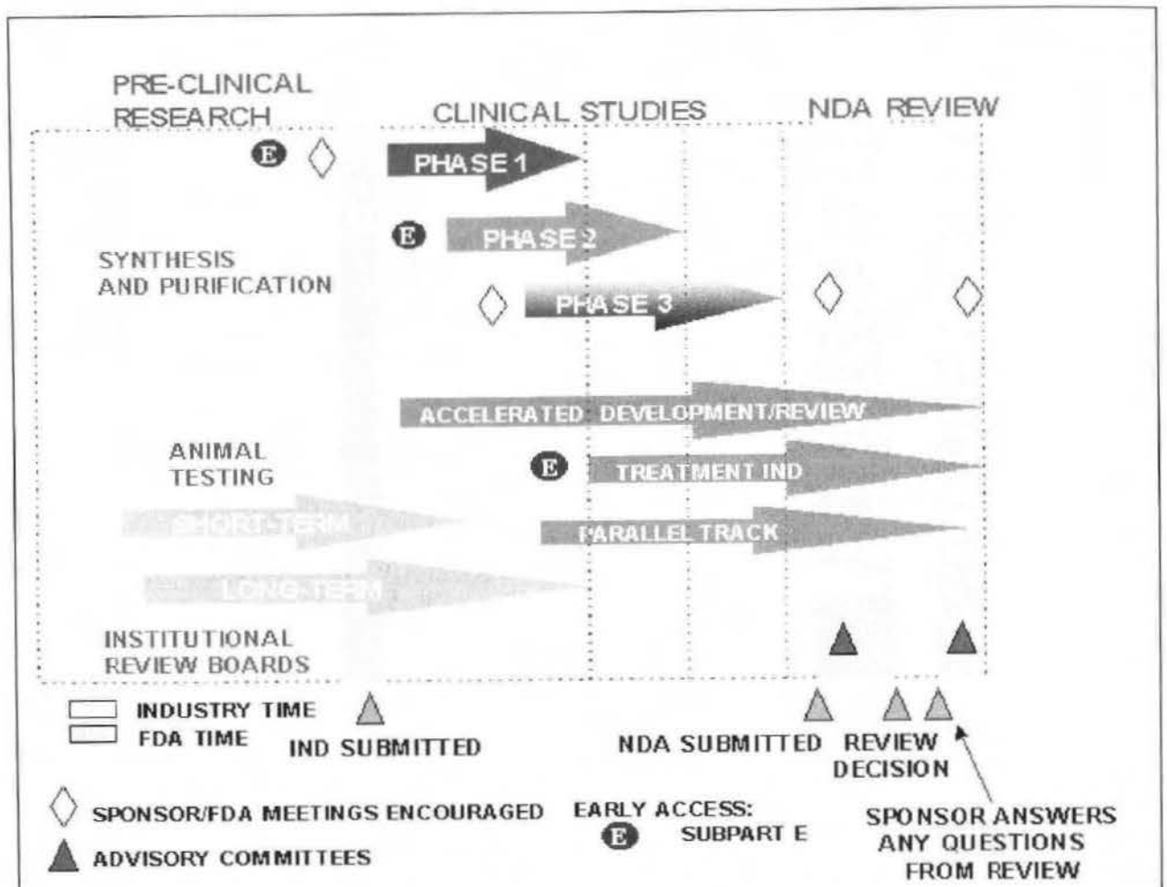
1965: The Bureau of Veterinary Medicine (BVM) was established.

1984: The BVM became the Center for Veterinary Medicine (CVM).

Today, veterinary products are regulated by the FDA, USDA, and Environmental Protection Agency (EPA). FDA/CVM regulates the manufacture and distribution of drugs, food additives, and medical devices used in veterinary species. This includes both product approval and postapproval monitoring to ensure continued product safety and effectiveness. According to the Act, a *device* is an instrument, apparatus, implement, machine, contrivance, implant, *in vitro* reagent, or other similar or related article, including any component, part, or accessory, which is intended for use in the diagnosis of disease or other conditions, or in the cure, mitigation, treatment, or prevention of disease, in man or other animals, or intended to affect the structure or any function of the body of man or other animals, and which does not achieve any of its principal intended purposes through chemical action

within or on the body of man or other animals and which is not dependent upon being metabolized for the achievement of any of its principal intended purposes. Currently, there are no FDA premarketing approval requirements for medical devices intended for animal use. However, veterinary medical devices are subject to the general provisions of the Act that relate to misbranding and adulteration (Sections 501 and 502 of the FFDCA).

Veterinary biologics (such as vaccines, antitoxins, and diagnostics that are used to prevent, treat, or diagnose animal diseases) are regulated by the USDA Animal and Plant Health Inspection Service, Center for Veterinary Biologics under the Virus Serum Toxin Act of 1913 (http://www.aphis.usda.gov/animal_health/vet_biologics/). Pesticides (e.g., including preparations for use on inanimate objects, rodenticides, and most insecticides) are subject to the Federal Insecticide, Fungicide, and Rodenticide Act, administered by the Pesticide Regulation Division of the EPA (http://www.epa.gov/pesticides/). Animal grooming aids are currently not regulated by these agencies, unless the products are intended for any therapeutic purpose or are intended to affect the structure or function of the animal (FDA) or contain pesticides (EPA).



CHALLENGES IN VETERINARY DRUG EVALUATION

The process leading to the approval and marketing of a new animal drug product is similar to that associated with human pharmaceuticals (Fig. 55.1). In fact, many animal drugs were initially developed for potential use in humans. However, veterinary pharmaceutical development encounters numerous complexities that are not faced by our human health counterparts. In addition to the challenges associated with between-individual variability (which is seen both in human and veterinary medicine), the development of new animal drugs also contends with such issues as the following:

- The enormous diversity in size, behavior, metabolic needs, and lifespan between animal species
- Species and breed differences in both pharmacokinetic and toxicity profiles
- A wide spectrum of disease agents that produce different disease manifestations under different conditions
- A range of husbandry practices, which include the array of settings in which animals are kept—ranging from animal companions in the home to large livestock operations
- Inability to communicate directly with the animal patient
- Public health concerns, including environmental safety, human food safety, and the potential influence of veterinary antimicrobial use on development of resistance in bacteria of concern to both veterinary and human medicine

There are also differences in the use of drug products in food-producing animal species versus companion animal species. The focus of diagnostics, drug therapy, and monitoring of treatment response is on the individual companion animal. The goals of therapy are to prevent, treat, or manage a disease or to improve the quality of life for the individual animal. Some therapies may be continued throughout the life of the companion animal. For food-producing animals, the focus is generally on the health of an entire group (herd or flock) of animals instead of an individual animal. Although food-producing animals may be individually dosed using injectable or topical products to treat or control certain diseases, group dosing via medicated drinking water or feed is often used in order to minimize handling stress and to allow for a more efficient means of dosing a large number of animals during a disease outbreak. The goal in food animal medicine is to manage the health of the herd.

A further challenge to animal drug development is the low cost and narrow profit margin of veterinary pharmaceuticals. During the development of animal drug products, the process of product development to marketing approval by the FDA takes, on the average, 10 years and costs about $40 million (http://www.ahi.org/content.asp?contentid=692). In contrast, a 2004 survey estimated that for human pharmaceuticals, it takes on the average of 12 to 15 years to bring a new prescription product to market at an average cost of $800 million dollars (http://www.phrma.org/files/Cost_of_Prescription_Drugs.pdf). Public spending on products used to treat and prevent disease in both companion animals and farm animals in the United States in 2004 reached nearly $5 billion (http://www.ahi.org/content.asp?contentid=692). By comparison, in 2004, U.S. retail prescription sales totaled $168 billion in 2004 (Kaiser Family Foundation: http://www.kff.org/insurance/7031/ti2004-1-19.cfm). Animal Health Institute (AHI) member companies spent $618 million in 2006 to research and develop potential new products and

Short-term testing in animals ranges in duration from 2 weeks to 3 months. Long-term testing in animals ranges in duration from a few weeks to several years. Some animal testing continues after human tests begin to learn whether long-term use of a drug may cause cancer or birth defects.

Phase 1 includes the initial introduction of an investigational new drug into humans. During Phase 1, sufficient information about the drug's pharmacokinetics and pharmacological effects should be obtained to permit the design of well-controlled, scientifically valid, Phase 2 studies.

Phase 2 includes the early controlled clinical studies conducted to obtain some preliminary data on the effectiveness of the drug for a particular indication or indications in patients with the disease or condition. This phase of testing also helps determine the common short-term side effects and risks associated with the drug. Phase 2 studies are typically well-controlled, closely monitored, and conducted in a relatively small number of patients, usually involving several hundred people.

Phase 3 studies are intended to gather the additional information about effectiveness and safety that is needed to evaluate the overall benefit-risk relationship of the drug. Phase 3 studies also provide an adequate basis for extrapolating the results to the general population and transmitting that information in the physician labeling. Phase 3 studies usually include several hundred to several thousand people.

FIG. 55.1 A flow diagram of the informational paradigm supporting human drug approvals is accessible online at the website of the Center for Drug Evaluation and Research (CDER) (http://www.fda.gov/cder/handbook).

to ensure the safety and effectiveness of existing products, according to AHI's latest Research and Development Survey (http://www.ahi.org/content.asp?contentid=692). In comparison, with respect to human pharmaceutical product research and development, the Pharmaceutical Research and Manufacturers of America (PhRMA), which represents the country's leading pharmaceutical research and biotechnology companies, have invested an estimated $44.5 billion in 2007 in discovering and developing new medicines. Industrywide research and investment reached a record $58.8 billion in 2007 (http://www.phrma.org/about_phrma/).

The limited opportunity for cost recovery forms a barrier to increasing the availability of new animal products. As a practical matter, the amount of data contained in a New Animal Drug Application (NADA) is substantially less than that submitted to support a New Drug Application (NDA) for human use. For example, the number of patients enrolled in clinical trials of new animal drugs is substantially smaller than the thousands of patients generally enrolled in trials submitted in support of human NDAs.

Despite these constraints, the same statutory requirements regarding the demonstration of product safety and effectiveness apply to the regulation of both human and veterinary drug products. Therefore, innovative application of the principles of pharmacology and research study design is important in meeting the challenge of developing cost-effective ways to generate the data necessary to meet the statutory requirements of the FFDCA. Pharmaceutical companies are encouraged to consult closely with CVM to develop study designs and assays that maximize the value of the collected data to support their drug applications.

REGULATORY BASIS OF VETERINARY DRUG EVALUATION

The approval process is linked to the legal prohibition of adulteration or misbranding of food, drugs, or devices in interstate commerce. The specific requirements for gaining an approval are in Sections 512 (New Animal Drugs) and 571-573 (New Animal Drugs for Minor Use and Minor Species) of the FFDCA.

RECENT AMENDMENTS TO THE FFDCA

The Animal Medicinal Drug Use Clarification Act of 1994 (AMDUCA). Prior to the enactment of the AMDUCA of 1994, the FFDCA prohibited veterinarians from prescribing new animal drugs for any indications other than the specific conditions of use on the approved labeling. This extralabel use restriction precluded veterinarians from using an approved new animal drug for an unapproved animal species, for an unapproved indication, or for an approved species at dosage levels higher than that stated on the label. Prior to 1994, the use of human drugs for treating animals was also illegal.

In 1996, Title 21 of the Code of Federal Regulations was amended to add part 530, entitled "Extralabel Drug Use in Animals." This action served to implement AMDUCA to permit veterinarians to prescribe extralabel uses of certain approved animal and human drugs to treat animals under certain conditions. These regulations gave veterinarians the flexibility to meet patient needs in the practice of veterinary medicine (21 CFR §530; http://www.fda.gov/cvm/Images/530.pdf). Under AMDUCA, the key constraints are that any extralabel use must be by or on the order of a veterinarian within the context of a veterinarian-client-patient relationship; the use must not result in violative residues in food-producing animals; and certain listed compounds are prohibited from extralabel use in food-producing animals (http://www.fda.gov/ohrms/dockets/98fr/020602b.htm). The Agency may establish safe and violative levels for residues for extralabel use and may require development of analytical methods for residue detection. If, after affording an opportunity for public comment, FDA finds that an extralabel animal drug use presents a risk to public health or that no analytical method has been developed and submitted, the Agency may prohibit the extralabel use. The Agency has prohibited the extralabel use of the following drugs in food-producing animals:

- Chloramphenicol
- Clenbuterol
- Diethylstilbestrol (DES)
- Dimetridazole
- Ipronidazole
- Other nitroimidazoles
- Furazolidone (except for approved topical use)
- Nitrofurazone (except for approved topical use)
- Sulfonamide drugs in lactating dairy cattle (except approved use of sulfadimethoxine, sulfabromomethazine, and sulfaethoxypyridazine)

Neither AMDUCA nor the implementing regulations lessen the responsibility of the manufacturer, the veterinarian, or the food producer to prevent risks to public health from drug residues in animal-derived foods.

Updates on issues pertaining to the Animal Medicinal Drug Use Clarification Act of 1994 and its implementation by CVM can be found at http://www.fda.gov/cvm/amducatoc.htm.

The Animal Drug Availability Act of 1996 (ADAA). In an effort to increase the number of animal drugs on the market and to reduce regulatory burdens on the animal health industry without undermining the safety of animal drug products, the ADAA was signed into law on October, 1996 (http://www.fda.gov/cvm/adaatoc.html). The current study requirements associated with NADAs reflect changes instituted by this Act. In brief, the ADAA provides for the following (Annon 1996):

- An amendment to the definition of substantial evidence of effectiveness that provided CVM with greater flexibility to make case-specific scientific determinations regarding the number and types of adequate and well-controlled studies that will provide, in an efficient manner, substantial evidence that a new animal drug is effective (21 CFR Part 514 [Docket No. 97N-0435] Substantial Evidence of Effectiveness of New Animal Drugs. Notice of proposed rulemaking. http://www.fda.gov/cvm/Regulatory_Notice_Letters/fr971105.pdf).
- Greater direct interaction between animal drug sponsors and the FDA during the drug development process. The law requires a presubmission conference, held at the sponsor's discretion, to discuss the drug development at its earliest stages. The goal is for the FDA and the manufacturers to reach a common understanding regarding what data will be needed to establish safety and effectiveness, and what types of studies can be conducted to generate such data.
- The ability to market an animal drug with a range of acceptable/recommended doses on animal drug product labeling, rather than as one optimum dose. In addition, the law directs FDA to broaden the approval process to make available more animal drugs to treat minor species.
- A new category of drugs, "Veterinary Feed Directive Drugs" (VFD), that allows approval and use of new animal drugs in animal feed, on a veterinarian's order, while incorporating safeguards to ensure the safe use of such drugs. This new category of drug is discussed below.

The Veterinary Feed Directive (VFD). Before the passage of the ADAA, the FFDCA provided FDA only two options for regulating the distribution of animal drugs: over-the-counter (OTC) and prescription (Rx). A product can be approved as OTC if adequate directions for use can be written for the layperson. In contrast, use of Rx products requires veterinary intervention with respect to diagnosing the disease and monitoring the response to therapy, as well as monitoring the potential for adverse effects in the patient.

The prescription legend invoked the application of state pharmacy laws, and the pharmacy laws in a significant number of states prohibited feed manufacturers from possessing and dispensing prescription animal drugs and medicated feed containing those drugs. Pharmacy laws in other states required the presence of a pharmacist at the feed manufacturing facility that uses prescription drugs in the manufacture of medicated feeds. As a practical matter, the application of state pharmacy laws to medicated feeds would burden state pharmacy boards and impose costs on animal feed manufacturers to such an extent that it would be impractical to make these critically needed new animal drugs available for animal therapy. For this reason, through the ADAA, Congress enacted legislation to create the VFD, providing a new class of restricted feed use drugs that may be distributed without invoking state pharmacy laws. Although statutory controls on the distribution and use of VFD drugs are similar to those for prescription animal drugs regulated under section 503(f) of the FFDCA (21 U.S.C. 353(f)), the VFD regulations are tailored to the unique circumstances relating to the distribution of animal feeds containing a VFD drug. Unlike prescription drugs, VFD drugs are not be regulated by state pharmacy bodies (page 35966 Federal Register/Vol. 64, No. 127/ Friday, July 2, 1999). No extralabel use of a VFD drug is permitted, and a veterinarian may issue a VFD only if a valid veterinarian-client-patient relationship exists, as defined in 21 CFR §530.3(i). More information regarding VFD is available from the FDA on the web (http://www.fda.gov/cvm/vfd.html).

COMPONENTS OF NADAs AND ANADAs

Regulatory Overview. The legal requirements for NADAs are detailed in 21 CFR §514.1. Required infor-

mation for evaluation of the NADA is grouped into technical sections listed on Form FDA 356V (Figs. 55.2A, B) and includes the following:

- Target Animal Safety
- Effectiveness
- Human Food Safety
- Chemistry, Manufacturing, and Controls
- Environmental Impact
- All Other Information
- Labeling

The Office of New Animal Drug Evaluation (ONADE) within CVM is responsible for the review of information submitted by drug sponsors to obtain approval to manufacture and market animal drugs. Highlights for each of these technical sections are provided in the next several sections of this chapter.

Technical Sections of NADAs

Target Animal Safety (TAS). The purpose of the TAS studies is to evaluate potential harmful effects associated with use of a new animal drug in a controlled setting, as a prediction of product safety in the larger patient population. The regulation for TAS, 21 CFR §514.1(b)(8)(i), requires "adequate tests by all methods reasonably applicable to show whether or not the new animal drug is safe and effective for use as suggested in the proposed labeling." The FDA develops guidance documents (http://www.fda.gov/cvm/Guidance/published.htm) to summarize recommendations and suggestions for efficiently carrying out these studies. The FDA is also currently participating in the international harmonization of guidelines for TAS testing.

As with human pharmaceuticals, published literature, preliminary studies (including pharmacokinetics and pharmacodynamics, and extrapolation from toxicity testing in laboratory animals), and safety observations in clinical effectiveness trials are considered in the safety evaluation. But for new animal drugs, safety is also directly assessed in the target species through laboratory-based (overdose) studies. These nonclinical laboratory studies must be conducted in accordance with Good Laboratory Practices (GLP) regulations (21 CFR Part 58). FDA does not require that domestic animals be maintained under the conditions required for laboratory animals during GLP testing. Although clinical effectiveness studies contribute data to the overall safety assessment of a drug, GLP regulations do not apply to clinical studies. Furthermore, the product evaluated in the TAS studies should be identical to the product intended to be marketed, i.e., same chemical, same particle size and formulation, and manufactured in conformity with the principles of Good Manufacturing Practices (GMP).

Although the specific information needed to assess TAS in a particular NADA depends on a variety of factors (e.g., proposed usage regimen and dose, type of drug, pharmacokinetics, chemistry and manufacturing considerations, claims, previous use history, and animal species including class and breed), the underlying scientific approach, as outlined in FDA guidance documents, is common to all. Studies generally compare healthy control animals with small numbers of healthy animals of the target species treated with multiples of both the recommended dose and duration of administration of the product. Appropriate observations, physical examinations, clinical pathology tests (hematology, blood chemistry, urinalysis, fecal analysis, etc.), necropsy, and histopathology should be conducted to identify possible adverse effects. Additional specialized studies, such as evaluation of injection sites, topical administration sites, reproductive safety, and mammary gland safety, may be needed depending on the conditions of use and the characteristics of the drug. There may also be additional species-specific study requirements based upon unique physiology and or husbandry practices. For example in fish, target animal safety can change as a function of water temperature, ionic strength and composition, and life stage (Storey 2006).

Effectiveness. 21 CFR §514.4(b)(2) requires that a sponsor submit data generated from well-controlled studies of a new animal drug to distinguish the effect of the new animal drug from other influences, such as spontaneous change in the course of the disease, normal animal production performance, or biased observation. The data provided for substantial evidence of effectiveness must permit qualified experts to conclude that a new animal drug will have the effect it purports or is represented to have under the conditions of use suggested in the proposed labeling (21 CFR §514.4(b)(3)(i)(C)). Generation of these data represents a significant component of drug development time and cost such that the amount and nature of the evidence needed can be an important determinant of whether and when new animal drugs become available to the public. If there is a lack of substantial evidence that the new animal drug will have the effect it purports or if the proposed labeling is false or misleading as it relates to

CERTIFICATIONS

I certify that:

- I have personally reviewed this submission (or received assurances from qualified personnel) and determined that this submission and all supporting data, to the best of my knowledge and belief, are true, accurate, and complete,
- All copies (paper or electronic) of the submission are identical,
- For any information submitted by reference to a master file, investigational file, or application, the reference was made with the belief that the information contained in the referenced file is true, accurate, and complete,
- The services of any person debarred under section 306(a) or (b) of FFDCA have not been used in any capacity related to this submission, and
- I am aware that there are significant penalties for submitting false information, including the possibility of fine and imprisonment for knowing and willful violations (18 U.S.C. § 1001).

If this application is approved, I agree:

- To submit safety update reports as requested by FDA under its statutory authority or as provided for by regulation,
- To comply with all applicable statutes and regulations that apply to approved applications,
- Not to market this drug product until the Drug Enforcement Administration makes a final scheduling decision if this application applies to a drug product that FDA has proposed for scheduling under the Controlled Substances Act, and
- To notify FDA of any change to the conditions established in this approval.

FIG. 55.2—*continued*

INSTRUCTIONS FOR COMPLETING AND SUBMITTING FORM FDA 356v

GENERAL INSTRUCTIONS

Applicant Information

Provide your name, address, and telephone and facsimile numbers (including the country code if needed). This address will be the address of record we use for all contacts initiated by us and not directly related to a submission. Also provide the name of the individual who will serve as your contact (i.e., your authorized representative or U.S. agent). If you or your authorized representative do not reside or have a place of business within the United States, you must provide the name and address of a U.S. agent as your contact. A U.S. agent is a person who is a permanent resident of the United States and acts as your agent. Your U.S. agent must also sign your application (see 21 CFR § 14.1(a)).

Product Description

Include all of the information necessary to identify the drug product that is the subject of your submission. The manufacturer or sponsor of a new animal drug for a minor use or use in a minor species may request designation under section 573(a) of FFDCA. Indicate whether your drug has been declared a designated new animal drug and, if so, the date of designation.

Application Description

Type of Application:

- If you are submitting an application, check the appropriate box to identify whether you are submitting a new animal drug application (NADA), an abbreviated NADA (ANADA), or application for conditional approval. Please check whether the application is an administrative application. If this is an ANADA, identify, for the reference listed new animal drug, the proprietary name of the reference listed drug, its NADA number, and the name of the holder of the approved NADA for the referenced listed drug.

- **DO NOT** check a box under Type of Application if you are submitting information or data to an investigational file or master file. Instead, check the "submission of data or information to an investigational file," "submission to a master file," or "other" under type of submission and the appropriate item(s) from the Submission Content list of items.

Type of Submission: Check the appropriate box.

- **Submission of Data or Information to an Investigational File:** Data or information (including amending data or information) supporting a single technical section submitted for phased review. This submission should include labeling language, and may include Freedom of Information (FOI) information, relevant to the specific technical section.

- **Submission to a Master File:** Data or information submitted to a master file that may be referenced (by the owner or a person granted a right of reference) to support the approval of a new animal drug.

- **Original Application:** A complete application (i.e., containing all applicable technical sections or copies of technical section complete letters for all applicable technical sections) that you have not submitted before.

- **Supplement Requiring Review of Safety or Effectiveness Data:** A supplemental application (21 CFR § 14.8(a)) requesting a change to an approved application that requires FDA to review safety or effectiveness data (e.g., the addition of a new claim or species). Note: An applicant may not supplement an application for conditional approval to add indications of use (section 571(g) of FFDCA).

- **Chemistry, Manufacturing, and Controls - Supplement or Report:**

  – **Prior approval:** A supplemental application for any change in the drug, production process, quality controls, equipment, or facilities that has a substantial potential to have an adverse effect on the identity, strength, quality, purity, or potency of the drug as these factors may relate to the safety or effectiveness of the drug (21 CFR § 514.8(b)(2)).

  – **Changes being effected (CBE) in 30 days**: A supplemental application for any change in the drug, production process, quality controls, equipment, or facilities that has a moderate potential to have an adverse effect on the identity, strength, quality, purity, or potency of the drug as these factors may relate to the safety or effectiveness of the drug. (See examples in 21 CFR § 14.8(b)(3)(ii)). You may commercially distribute the drug made using the change 30 or more days after FDA receives your supplemental application unless FDA informs you otherwise within 30 days of its receipt of the application.

  – **Changes being effected (CBE):** A supplemental application for certain changes in the drug, production process, quality controls, equipment, or facilities that have a moderate potential to have an adverse effect on the identity, strength, quality, purity, or potency of the drug as these factors may relate to the safety or effectiveness of the drug (for examples, see 21 CFR § 514.8(b)(3)(vi)). You may

FIG. 55.2—*continued*

commercially distribute the drug when FDA receives your supplemental application.

– **Minor changes and stability report (MCSR):** An annual report that documents changes in the drug, production process, quality controls, equipment, or facilities that have a minimal potential to have an adverse effect on the identity, strength, quality, purity, or potency of the drug as these factors may relate to the safety or effectiveness of the drug (21 CFR § 14.8(b)(4)).

- **Labeling Supplement:**

  – **Prior approval:** A supplemental application requesting labeling changes that requires approval before the drug may be distributed (for examples, see 21 CFR § 14.8(c)(2)).

  – **Changes being effected (CBE):** A supplemental application requesting labeling changes that can be placed into effect before approval. These supplements request changes in labeling that increase the assurance of drug safety (21 CFR § 14.8(c)(3)(i)) or that do not decrease the safety of drug use (21 CFR § 14.8(c)(3)(ii)).

- **Amendment to a Pending Application, Supplement, or MCSR:** Any submission that provides additional information to an application or report while it is under review.

- **Reactivation of an Application, Supplement, or MCSR:** Resubmission of an application or report to address the deficiencies described in an incomplete letter from FDA.

- **Other:** Any submission that does not fit within one of the types of submissions described above.

Submission Content: Please check each box that describes a type of information that is included in your submission. Note that items 1-7 apply to the submission of NADAs and applications for conditional approval (or to their supporting investigational files), item 8 applies specifically to NADAs, and items 9-11 apply to ANADAs (or to their supporting investigational files).

- A complete NADA and application for conditional approval must include information and any right(s) of reference to information for items 1-7 (21 CFR § 14.1; section 571(a)(2)(A), (B) and (C) of FFDCA). A supplemental NADA may omit statements made in the application concerning which no change is made. If you are submitting information required by sections 571(a)(2)(D) - (F) of FFDCA to support conditional approval, check "other" and describe the information you are submitting. Indicate the order in which these sections appear in your submission in your table of contents. A completed User Fee Cover Sheet (item 8) should accompany each NADA and supplemental NADA subject to fees. To determine if your NADA or supplemental NADA is subject to an application fee, see section 740(a)(1) of FFDCA.

- For submissions other than applications (e.g., a submission to an investigational file for phased review), check only those items that apply and indicate the order in which these sections appear in your submission in your table of contents. Do not check Labeling or Freedom of Information Summary if the submission contains such information only as it relates to a technical section. For administrative applications, submit a copy of your FOI technical section complete letter.

- A complete ANADA should include items 9-11. A supplemental ANADA may omit statements made in the approved application concerning which no change is made.

- The "other" category should be checked and include a description of the submission when you are submitting certain information supporting a conditional approval (see instructions above) or when your submission does not fall into the above categories.

Description of Submission

Enter the number of volumes you are submitting. Describe any electronic media in your submission.

Cross References

List all investigational new animal drug files (INADs, JINADs), new animal drug applications (NADAs, ANADAs, applications for conditional approval), master files (VMFs, DMFs, PMFs), or other applications or files referenced in your current submission, including by "right of reference." If you reference data or information in any file you don't own, make sure a copy of your authorization to reference such data or information is included with your submission or has already been submitted to the file in which you referenced it.

Signature

After carefully reading the certifications, sign and date the form. Ordinarily only one person must sign the form, i.e., the applicant, or the applicant's attorney, agent, or other authorized official. However, if you do not reside or have a place of business within the United States, your U.S. agent must also sign the application.

INSTRUCTIONS FOR SUBMITTING AN APPLICATION

1. Include a completed and signed Form FDA 356v (pages 1 through 3) with all submissions relating to

FIG. 55.2—*continued*

new animal drug approval (i.e., NADAs, ANADAs, applications for conditional approval, submissions of data or information to an investigational file, supplements, amendments, reactivations, and MCSRs). The completed form should be placed before the cover letter, table of contents, and submission.

2. Submit three identical copies of your submission (21 CFR § 14.1(b)). A copy of the Form FDA 356v should accompany each copy of your submission.

3. Place the applicant's name and address and the proprietary name(s) (if available) and established name(s) of the new animal drug on the front cover of each copy of your submission (21 CFR § 14.1(b)).

4. Fully describe the submission in your cover letter (e.g., for a supplemental application, describe the change(s) you are seeking to the approved application).

5. Include a comprehensive table of contents in your submission (21 CFR § 14.1(b)(2)).

6. Format your submission so each of your sections begins on a new page.

7. Sequentially number the pages of the submission.

8. Send your submission and copies to:

   Document Control Unit (HFV-199)
   Center for Veterinary Medicine
   Food and Drug Administration
   7500 Standish Place
   Rockville, MD 20855

This space intentionally left blank.

FIG. 55.2—*continued*

the demonstration of effectiveness of the new animal drug, CVM is required to issue an order refusing to approve the NADA (21 CFR §514.4; [Docket No. 97N-0435] Substantial Evidence of Effectiveness of New Animal Drugs. Notice of proposed rulemaking. http://www.fda.gov/cvm/Regulatory_Notice_Letters/fr971105.pdf).

The availability of certain approved new animal drugs for use in livestock, poultry, pets, and other animals is vital to protecting the health of animals and the health of humans who consume the products of food-producing animals. The availability of other approved new animal drugs is vital to increasing the efficiency of food production in the United States. The changes made to the definition of *substantial evidence* by the ADAA and by the further definition of that term provided CVM with greater flexibility to make case-specific scientific determinations regarding the number and types of adequate and well-controlled studies that will provide, in an efficient manner, substantial evidence that a new animal drug is effective.

One or more adequate and well-controlled studies are required to establish, by substantial evidence, that a new animal drug is effective. These trials are intended to demonstrate that a new animal drug is effective for each proposed intended use and the associated conditions of use (21 CFR §514.4). The intended use includes the dose or dose range, frequency, duration, timing (e.g., in relation to the onset of clinical signs), animal species, age, gender, class, and breed of animal for which the new animal drug is intended for use. Subsequent to the enactment of the ADAA, the specific number and types of adequate and well-controlled studies for providing substantial evidence of effectiveness depend upon the number of intended uses, how narrowly or broadly each intended use is defined, and the conditions of use in the proposed labeling. When a proposed therapeutic indication is associated with a dose range, substantial evidence of effectiveness is demonstrated for the lowest proposed dose. The highest dose within the dose range is contingent upon a demonstration of target animal safety (FR Notice Vol. 64, No. 144, July 28, 1999, Substantial Evidence of Effectiveness of New Animal Drugs. Docket Number 97N-0435. http://www.fda.gov/ohrms/dockets/98fr/072899a.pdf). Sponsors also need to justify the intended dose. The basis of this justification can include pharmacokinetic/pharmacodynamic relationships, literature, and laboratory tests.

The effectiveness studies are designed to test the product under actual conditions of use. In contrast to studies conducted under controlled laboratory settings, the clinical trial provides information pertaining to how the product will perform under real-world conditions in the patient population. The effectiveness studies are typically designed with a negative (placebo) control or an active control. An active control is an approved product of established effectiveness for the same indications as the proposed product under development, with a known margin of superiority relative to a placebo (Piaggio et al. 2006). The evaluation of the active control study should explain why the new animal drugs should be considered effective in the study, for example, by reference to results in previous placebo-controlled studies of the active control (21 CFR §514.117(b)(3)(iii)). The study is typically masked, and patients are randomized to treatment groups. In so doing, the investigator can evaluate the drug effects with minimal bias. The study is typically a multicenter and multiinvestigator design to increase the likelihood that the product will perform as expected in the broader population postapproval. The study is testing whether the product will perform in the hands of multiple investigators under a variety of husbandry conditions, clinical practice settings, different breeds and ages of the patient populations, and perhaps different stages of the disease or condition. The proposed indication drives the design of the effectiveness study. Likewise, the results of the effectiveness study drive the wording of the indication. The final approved indication and dosage are confirmed by the results of the effectiveness studies. The effectiveness studies also provide important safety information about the use of the product in the patient population.

The manufacturing characteristics of the product used in the efficacy study must be provided as part of the study results in order to provide CVM with an assurance that the test article used is representative of the product intended for marketing (21 CFR §514.117).

Human Food Safety (HFS). By the general safety provisions of Sections 409, 512, and 706 of the Federal Food, Drug, and Cosmetic Act (http://www.accessdata.fda.gov/scripts/cdrh/cfdocs/cfcfr/cfrsearch.cfm), FDA must determine for each food additive, new animal drug, or color additive proposed for use in food-producing animals whether the edible products derived from treated animals are safe for human consumption. Accordingly, the sponsor must demonstrate *reasonable certainty of no harm* to human health for all drug products intended for use in food-producing animals.

A human food safety evaluation focuses on residues that are present in the intended type of food animal following intended use of the drug. A *residue* is "any compound present in the edible tissues of the target animal which results from the use of the sponsored compound, including the sponsored compound, its metabolites, and any other substances formed in or on food because of the sponsored compound's use" (21 CFR §500.82 (B)).

The information needed to demonstrate human food safety for a NADA generally includes the following:

- *Evaluation of carcinogenicity:* To establish the safety of veterinary drug residues in human food, a number of toxicological evaluations are recommended, including an assessment of the potential to induce neoplasia. Exposure to residues of veterinary drugs will usually occur at extremely low levels, but for potentially long periods. To ensure that substances that could pose carcinogenic potential at relevant exposure levels are adequately assessed, a number of issues should be considered, including genotoxicity, metabolic fate, species differences, and cellular changes. As part of the human food safety package, sponsors must determine whether carcinogenicity testing should be conducted. The decision to undertake carcinogenicity testing should take into consideration 1) the results of genotoxicity tests, 2) structure-activity relationships, and 3) findings in systemic toxicity tests that may be relevant to neoplasia in longer-term studies. It should also take into consideration any known species specificity of the mechanism of toxicity. Any differences in metabolism between the test species, target animal species, and human beings should be taken into consideration. For additional information, refer to CVM Guidance #141 (http://www.fda.gov/cvm/Guidance/guide141.pdf).
- *Toxicological assessment:* Toxicology tests are conducted in laboratory animals to determine the dose at which the compound produces an adverse effect and a dose that produces a no observed effect level (NOEL).
- *Determination of an Acceptable Daily Intake (ADI):* The acceptable daily intake (ADI) is derived from the results of the study illustrating the most sensitive endpoint in the most appropriate species. The ADI is the highest dose used in the study that demonstrates a no-observed-effect-level (NOEL) divided by an appropriate safety factor. As a general rule, CVM will use the safety factors indicated below for the various types of studies

TABLE 55.2 Safety factors associated with the different kinds of toxicology investigations

Type of Study	Safety Factor
Chronic	100
Reproduction/Teratology	100 or 1000; 100 for a clear indication of maternal toxicity, 1000 for other effects
90-Day	1000

The ADI is estimated as

$$\text{ADI}\,(\mu\text{g/kg/day}) = [(\text{NOEL}\,(\mu\text{g/kg}))/(\text{Safety Factor}\,(\text{day}^{-1}))]$$

The appropriate safety factor depends upon the type of study being used for establishing the ADI, as described in Table 55.2.

- *Determination of a safe concentration:* The safe concentration is, by definition, the amount of residue that can be eaten in any edible tissue each day for an entire lifetime without exposing the consumer to residues in excess of the ADI. To estimate the safe concentration, FDA considers the ADI, the weight in kg of an average adult human (60 kg), and the amount of the product that may be consumed in grams per day (where consumption values, in grams consumed per day, are 300 for muscle, 100 for liver, 50 for kidney and 50 for fat):

$$\text{safe concentration}\,(\mu\text{g/g}) = \frac{\text{ADI}\,(\mu\text{g/kg/day}) \times 60\,\text{kg}}{\text{grams consumed per day}}$$

Once a safe concentration has been determined, methods are developed and validated that will allow future testing of animal tissues to monitor for residues. Withdrawal times are determined to allow use of the drug, with any residues expected to be below the safe concentration.

- *Selection of a marker residue:* The marker residue is a residue used to monitor the depletion of total residues in edible tissues in a food animal. The marker residue must have a demonstrated relationship with the total radiolabel drug residues such that when the concentration of the marker residue is less than a specific value (the tolerance) in the target tissue, the total residues in all the edible tissues are less than their respective safe concentrations.
- *Development and validation of an analytical method to measure the marker residue:* This method serves as the

regulatory method for determining the withdrawal time and for assessing whether animal-derived products contain residue concentrations in excess of the established limit (violative residues of meats and animal-derived food products). This method will be used after a drug is approved by validated analytical laboratories during inspections, insuring the absence of violative residues in marketed human food products derived from animal sources.

- *Establishment of a tolerance:* A tolerance (the FDA maximum concentration of the marker residues within the target tissue) or the European version of a tolerance, the maximum residue limit (MRL) is determined based on the marker residue (http://www.fda.gov/cvm/index/vmac/fried_files/fried_text.htm). The target tissue for the tolerance is generally the edible tissue from which residues most slowly deplete.
- *Establishment of a withdrawal time:* The withdrawal time is the time interval between the last administration of the drug to the food animal and the time when the animal can be slaughtered, or products, such as milk or eggs, can be used for food, without incurring violative drug residues in the food product. The regulatory objective of the FDA is to predict a time when we can be 95% certain that the tissue residue concentrations in 99% of the animal population receiving the drug product (when dosed in accordance to the approved product label) will be at or below tolerance. Generally, multiple animals are sampled across at least four time points and regression methods with tolerance limits are used to set the withdrawal time. Concentrations of the marker residue must be measured with the same FDA-approved analytical method that will be used for the regulatory inspections.

  For antibacterial drugs, additional information is assessed as part of the human food safety section. Two types of potential effects of the new animal drug on bacteria of human health concern are considered (see below).
- *Microbiological Effects on Bacteria of Human Health Concern:* The level of antimicrobial residues present in food should not have clinically relevant effects on the human intestinal microflora. In addition, consideration is given to potential microbiological effects on foodborne bacteria of human health concern (FDA/CVM Guidance for Industry [#144], Pre-Approval Information for Registration of New Veterinary Medicinal Products for Food-Producing Animals with Respect to Antimicrobial Resistance VICH GL27. Finalized 04-27-04. http://www.fda.gov/cvm/guidance/guide144.doc). FDA/CVM has published a guidance document (#152) that serves as an initial step in developing internationally harmonized technical guidance for characterization of antimicrobial resistance selection in bacteria of human health concern in the European Union, Japan, and the United States. This includes a qualitative risk assessment approach for characterizing the potential risk to human health of a proposed use of the antimicrobial new animal drug. FDA/CVM then uses the resulting risk estimation ranking, along with other data and information submitted in support of the NADA, to determine if the drug is approvable under specific risk management conditions.

Details regarding human food safety assessments are provided in CVM Guidance #3 (*General Principles for Evaluating the Safety of Compounds Used in Food-Producing Animals,* http://www.fda.gov/cvm/Guidance/GFI003.htm) For more information on issues pertaining to HFS, the reader is referred to Chapter 61 of this textbook.

Chemistry, Manufacturing, and Controls. Several pivotal considerations go into the evaluation of the chemistry and manufacturing of a new animal drug product. These considerations are intended to ensure the quality and performance of the product, both prior to and subsequent to marketing. CVM requires that sponsors provide the information needed to ensure that each lot of the product released to consumers performs in a consistent manner, and that consumers have the necessary information with regard to product storage conditions so that product quality and performance are maintained (21 CFR §514.1).

A full description of the methods used in, and the facilities and controls used for, the manufacture, processing, and packaging of the new animal drug must be provided in the new animal drug application. This description should include full information with respect to any new animal drug in sufficient detail to permit an evaluation of the adequacy of the described methods of manufacture, processing, and packing, and the described facilities and controls. This information is evaluated by CVM's Division of Manufacturing Technologies to determine the identity, strength, quality, and purity of the new animal drug. Information is also needed with regard to the methods used in the synthesis, extraction, isolation, or purification of any new animal drug and the precautions being taken to ensure proper identity, strength, quality, and purity of the raw materials, whether active or not. Sponsors must provide

CVM with the instructions used in the manufacturing, processing, packaging, and labeling of each dosage form of the new animal drug, and precautions being taken to ensure batch-to-batch product uniformity.

To ensure adequate performance as the product ages, the sponsor also must conduct studies of the stability of the new animal drug in the final dosage form. Expiry dates represent the duration of time for which product quality and performance can be assured if the product is stored in accordance with label recommendations. The time for expiry is based upon extensive stability testing that is conducted by the drug sponsor on the product intended for marketing, and these data are evaluated by the Division of Manufacturing Technologies at CVM.

Additional information pertaining to current good manufacturing practices (cGMPs), including a listing of current guidance documents on this subject, can be obtained at http://www.fda.gov/cder/gmp/. Pertinent guidance documents include

Guidance for Industry #42: Animal Drug Manufacturing Guidelines, Dated 1994. http://www.fda.gov/cvm/Guidance/Guideline42.htm

Guidance for Industry #48: Guidance for Industry: Submission Documentation for Sterilization Process Validation in Applications for Human and Veterinary Drug Products, Dated 1994. http://www.fda.gov/cvm/Guidance/cmc2.pdf

Guidance for Industry #57: Guidance for Industry for the Preparation and Submission of Veterinary Master Files, Dated 1995. http://www.fda.gov/cvm/Guidance/Guideline57.htm

Environmental Impact. Statutory data requirements associated with Environmental Impact are defined in 21 CFR §514.50(D)(8). Every application or supplemental application must contain either an environmental assessment under 21 CFR §25.31, or a request for categorical exclusion under 21 CFR §25.24. Categorical exclusions are generally granted for ANADAs and for NADAs intended for use in companion animals.

Environmental documentation addresses the potential impact of the manufacturing and use of the product if the application were approved. The FDA *Environmental Assessment Technical Handbook* is available through the National Technical Information Service (NTIS) to assist in determining the contents of environmental documents (NTIS, 5285 Port Royal Road, Springfield, VA 22161, (703) 605-6000; order number PB 87-175345/AS; http://www.ntis.gov). GLP compliance is required for all environmental laboratory studies. Preapproval GMP inspections are used to confirm the contents of environmental documents that apply to manufacturing environmental permits and controls.

The overall target of the assessment is the protection of ecosystems. The field of ecotoxicology is a complex science and gaps in data and knowledge exist. Nevertheless, CVM and the International Veterinary Cooperative and Harmonization (VICH) have developed guidance (CVM Guidance #166 dated 1/09/2006) that describes the kinds of information needed as part of the Environmental Impact Assessment (EIA) of veterinary medicinal products (VMPs).

The goal of the EIA is to assess the potential for VMPs to affect nontarget species in the environment, including both aquatic and terrestrial species. It is not possible to evaluate the effects of VMPs on every species in the environment that may be exposed to the VMP following its administration to the target species. The taxonomic levels tested are intended to serve as surrogates or indicators for the range of species present in the environment. Impacts of greatest potential concern are usually those at community and ecosystem function levels, with the aim being to protect most species. However, it may be important to distinguish between local and landscape effects. There may be some instances where the impact of a VMP at a single location may be of significant concern, for example, for endangered species or a species with key ecosystem functions. These issues are handled by risk management at that specific location, which may even include restriction or prohibition of use of the product of concern in that specific local area. Additionally, issues associated with cumulative impact of some VMPs may be appropriate at a landscape level.

The route and quantity of a VMP entering the environment determines the risk assessment scenarios that are applicable and the extent of the risk assessment. The EIA is based on the accepted principle that risk is a function of the exposure, fate, and effects assessments of the VMP for the environmental compartments of concern. While emission can occur at various stages in the life cycle of the product, with the exception of certain topicals or those added directly to water, most VMPs first pass through the animal to which it is administered. Generally the most significant environmental exposure results from excretion of the active substance(s).

All Other Information. The *All Other Information* section must include all other information, not included in any of the other technical sections, that is pertinent to an evaluation of the safety or effectiveness of the new animal drug for which approval is sought, 21 CFR §514.1(b)(8)(iv). All other information includes, but is not limited to, any information derived from other marketing (domestic or foreign) and favorable and unfavorable reports in the scientific literature.

Product Labeling. The ability to interpret and understand drug labels is essential in ensuring that use of a particular drug achieves the intended outcome and minimizes unintended effects. The product labeling is the avenue through which CVM communicates instructions about product use and storage conditions to veterinarians, as well as communicating the benefits and risks associated with the use of a drug product.

Section 201K of the FFDCA defines *label* as a display of written, printed, or graphic matter upon the immediate container of any article. A drug's "labeling" includes all labels and other written, printed, or graphic matter, such as package inserts, on the drug, its containers or wrappers, or accompanying the drug. Labeling information is derived from studies submitted by the pharmaceutical sponsor to the FDA to support new animal drug approval and is developed as a collaboration between FDA and the drug sponsor.

Through the product label, the FDA provides the practitioner with a thorough understanding of the benefits and risks associated with the use of a drug product in the animal patient. The concept of "safe use" includes safety to the animal patient, safety to the person administering the product, the safety of food derived from the treated animal, and environmental safety issues associated with use or disposal of the product. Safety information on the labeling can be derived from studies conducted by the pharmaceutical sponsor, studies from peer-reviewed scientific literature, or from extrapolation from human drug labeling information that reasonably applies to the target species. Safety information is provided throughout the package insert under several different headings, including Contraindications, Warnings, Precautions, Adverse Reactions, and Animal Safety. No doubt, each veterinary student has heard the advice, "Above all, do no harm." Therefore, it is extremely important that the practitioner become familiar with all sections of the package insert in order to better understand both the risks and benefits associated with use of the product. The safety information can be viewed from the perspective of a hierarchy of severity, with Contraindications being the most serious, followed by Warnings and Precautions. The Animal Safety section is generally derived directly from laboratory target animal safety studies. The Adverse Reactions section is developed directly from the preapproval field effectiveness studies and the postapproval experience after the drug is marketed to the larger population. The Contraindications, Warnings, and Precautions statements can be modified by new findings from the postapproval surveillance of product use. The following are typical sections/information found on a package insert:

- Product identification, description, and prescription legend
- Indications
- Dosage and administration
- Contraindications
- Warnings
- Precautions
- Adverse reactions
- Information for the owner or person treating the animal
- Clinical pharmacology
- Effectiveness
- Target animal safety
- Storage information
- How the product is supplied
- NADA or ANADA number and FDA approval statement

The following describes these sections in detail:

- **Product Identification, Description and Prescription Legend** provides the product's brand name (often indicated by ®), generic name (the name give to the chemical entity), the dosage form (e.g., tablet, sterile solution, oral suspension, etc.), and the prescription legend (OTC, Rx, or VFD). The regulatory decision for designating a product as Rx, OTC, or VFD takes into consideration the need for veterinary involvement in the safe and effective use of the product. Considerations include the potential toxicity or other harmful effects of the product, its method of administration, collateral measures necessary for its use (e.g., accurate diagnosis of a disease with reasonable certainty), and all types of potential safety

risks. The labeling for all veterinary prescription products contains the following statement: "Caution: Federal law restricts this drug to use by or on the order of a licensed veterinarian.

- **Indications** lists the specific disease(s) or conditions(s) for which a particular drug product is approved. The specific wording in this section depends upon the data contained in the effectiveness technical section of the approved new animal drug application.
- **Contraindications** defines the known circumstances under which a product should not be used because the risk associated with drug use clearly outweighs the possible benefit. Contraindications are based upon reasonable evidence that a drug caused a specific adverse reaction. Use of the drug in the situations described in the Contraindications section is likely to result in a serious adverse event that is fatal; life-threatening; requires professional intervention; or causes an abortion, stillbirth, infertility, congenital anomaly, or prolonged or permanent disability or disfigurement to the treated animal.
- **Warnings** describes serious adverse reactions and potential safety hazards to the animal being treated. Although the adverse reactions may be serious, FDA has determined that the benefit of using the drug outweighs the risk of the adverse event.

  The Warnings section may also describe potential actions that could be taken by the veterinarian to mitigate the adverse reaction should it occur, or to decrease the likelihood of the adverse reaction occurring, such as avoiding use in a predefined high-risk population. Warning statements are based on evidence indicating an association of a serious hazard with a drug, but not necessarily proof that the drug caused the reaction. Significant problems that may lead to death or serious injury may require a "boxed warning" on the package insert.

  The Warnings section may also include a user safety (Human Warnings) or human food safety section. The user safety section provides information regarding hazards to human health by contact, inhalation, ingestion, injection, or by other exposure to the product. The human food safety (Residue Warnings) section states the withdrawal time for use of the product in a food animal species. This section also warns against use of the drug in animals for which a withdrawal time has not been determined.
- **Precautions** includes additional information to enhance the safe use of the product by the practitioner. The Precautions section includes any additional information that is important for the safe use of the product that has not been included in the Contraindications or Warnings sections. The Precautions section may include recommendations for screening or diagnostic tests, information about drug-drug interactions, carcinogenesis, reproductive safety, adverse reactions in species other than the target species, or use in particular subpopulations of the target species, such as pediatric, geriatric, or animals with a particular disease.
- **Adverse Reactions** lists undesirable effects reasonably associated with the use of the drug that may occur as part of the pharmacological action of the drug or that may be unpredictable in their occurrence. The Adverse Reactions section is developed from the field effectiveness studies conducted by the pharmaceutical sponsor to support new animal drug approval. This section may also include a postapproval experience section, reporting any additional undesirable effects reported from the postapproval surveillance of the product in the larger population. The Adverse Reactions section includes a toll-free number for the practitioner to call for technical assistance from the pharmaceutical sponsor.
- **Information for Owner or Person Treating Animal** contains specific information for the owner or person treating the animal regarding the safe and effective use of the product. This information is designed to be conveyed by the prescribing veterinarian to the animal owner. Some products have a separate client information sheet (CIS) in addition to the package insert. The CIS sheet is designed to be given to the animal owner every time the product is dispensed. The CIS is typically required by the FDA when there is a need to give the animal owner detailed information about the potential for serious adverse reactions from the drug. The CIS may include information to help the animal owner recognize and report to the veterinarian any early signs of problems following the use of the product in the individual patient.
- **Clinical Pharmacology** is a concise summary of the pharmacology, pharmacokinetics, and pharmacodynamics of the drug in the target species. This section may also provide information about the drug class, potential drug-drug interactions, and the effect of food on product

bioavailability. For an antimicrobial agent, this section often includes a microbiology section with susceptibility data for the specific pathogens for which the product is approved.

- **Effectiveness** contains an abstract of the results from the effectiveness studies published in the FOI summary. The abstract provides a concise summary of the pivotal effectiveness studies and includes information such as the number and geographic location of study sites; the age, sex, and total number, etc., of animals in the study; a brief description of the study design; and the study results. The abstract describes how the effectiveness studies were conducted and how well the treated animals fared as compared to the control animals. This information can be considered from the perspective of the similarity between the study population versus the potential patient undergoing treatment (where the "patient" can represent an individual animal or a group of animals). For example, relevant questions may include whether the patient and the study population are of a similar age, class, and level of morbidity. This kind of information may be particularly useful when choosing between similar products that are approved and available for the same indications.With regard to the database supporting product approvals, more detailed information than provided by the abstract can be obtained in the FOI summary. These summaries are easily accessed from CVM's website (http://www.fda.gov/cvm/FOI/efoi.html) by simply inserting the NADA or ANADA number (another piece of information found on the package insert) for that product.
- **Animal Safety** provides an abstract of the results from the TAS studies that are required for FDA approval of the new animal drug. This information demonstrates the margin of safety for the drug. It also allows the reader to see what types of signs were observed in animals that received the drug at higher doses and for longer times than the intended dosage. It should help the practitioner decide whether to use the drug in animals that may be old or young or have compromised organ function. If adverse signs in a treated animal are observed, the package insert provides information regarding whether similar signs were noted during the safety testing of this application.
- **Storage Information** describes the recommended storage conditions that are needed to maintain the potency of the drug within acceptable limits before the established expiration date. When applicable, this includes practical information for shipping, warehouse storage, and storage by the user. Any mandatory storage conditions are described, e.g., "Store at controlled room temperature, 20–25°C (68–77°F)". When the drug is to be mixed with a diluent before use, this section describes the storage conditions for the diluted drug and also the time limitations for use of the diluted drug.
- **How the Product Is Supplied** can include a description of the delivery device, the number of units per package, and the dosage strengths.
- **NADA or ANADA Number** and **FDA Approval Statement:** The NADA or ANADA number can be used for searching the FDA/CVM website or for reporting product-specific adverse reactions.

The ANADA. In 1984, Congress signed into law the Drug Price Competition and Patent Term Restoration Act (Waxman Hatch Act, Public Law #98-14). This legislation created a system for the review and approval of generic versions of post-1962 human "pioneer" drug products through the use of ANADAs. In 1988, the Generic Animal Drug and Patent Term Restoration Act (GADPTRA) was signed into law (Public Law #100-670), amending section 512 of the FFDCA (21 U.S.C. 360b). GADPTRA provides statutory authority to approve ANADAs for generic copies of off-patent animal drugs approved for safety and efficacy.

Prior to GADPTRA, the FDA could approve abbreviated applications only for copies of animal drugs approved prior to 1962 and found to be effective under the DESI (drug efficacy study implementation) program. The intent of GADPTRA was to encourage competition and lower animal drug prices by allowing abbreviated applications for copies of previously approved drugs, without the generic drug sponsor duplicating the safety and efficacy studies that were required for the original NADA approval. GADPTRA permits an ANADA for an animal drug product that is the same as an animal drug product listed in the approved animal drug product list published by the Agency (listed new animal drug) with respect to conditions of use recommended in the product labeling, active ingredient(s), dosage form, strength, and route of administration.

An ANADA applicant may petition the Agency under Section 512(n)(3) of the FFDCA for permission to file an ANADA for a new animal drug product with certain

defined changes from an approved pioneer product. The changes are limited to the following:

- A change of one active ingredient in an approved combination product
- A change in dosage form
- A change in dosage strength
- A change in route of administration
- A change in one active ingredient in a feed mixed combination

A generic sponsor may file a suitability petition to request that the specific change in the pioneer product be allowed. The petition must follow the format and content described for a Citizen Petition (21 CFR §10.20), which is a public document filed with the FDA. The FDA response to the petition is also a public document. The Agency determines whether to deny or approve the petition.

ANADAs need to address all the technical sections applicable to NADAs, but in some cases, the information needed to fulfill these requirements is different. For example, target animal safety and effectiveness are evaluated through the demonstration of product bioequivalence between the pioneer and generic products. The focus of bioequivalence studies is to determine whether differences in product manufacturing and formulation will affect the rate and extent of drug absorption. The fundamental assumption of all bioequivalence testing is if the rate and extent of drug absorption are comparable, the products will be medically indistinguishable and therefore interchangeable. Bioequivalence studies (i.e., blood level, pharmacologic endpoint, and clinical endpoint studies) and tissue residue depletion studies are conducted in accordance with GLP regulations (21 CFR Part 58). When absorption of the drug is sufficient to enable the quantification of drug concentrations in the blood (or other appropriate biological fluid or tissue) and if systemic absorption is relevant to drug action, a blood (or other biological fluid or tissue) level bioequivalence study should be conducted.

For certain generic drug products, the Agency may waive the requirement for demonstration of bioequivalence to the pioneer product. In general, the bioequivalence between solutions is considered to be self-evident for solutions with the same active and inactive ingredients in the same concentrations and with the same pH and physicochemical characteristics as the pioneer product. Categories of products that may be eligible for waivers include parenteral solutions intended for injection by the intravenous, subcutaneous, or intramuscular routes of administration, oral solutions or other solubilized forms, topically applied solutions intended to produce local therapeutic effects, and inhalant volatile anesthetic solutions.

When using serum or blood concentrations of drug in the evaluation of product bioequivalence, the principles underlying this assessment reflect a blending of pharmacokinetics and biostatistics. In addition to its use in generic drug product applications, bioequivalence studies may be used to support the approval of proposed changes in the manufacturing of a generic version of an approved off-patent product or to cover the safety and/or effectiveness of a sponsor's own drug. Blood level bioequivalence studies compare a test formulation to a reference formulation using parameters derived from the concentrations of the drug moiety and/or its metabolites (as a function of time) in the plasma, serum, or other appropriate biological fluid. This approach is applicable to dosage forms intended to deliver the active drug ingredient(s) to the site of action by way of the systemic circulation. Although usually conducted as a comparison of blood levels following single-dose administration, a multiple-dose study may be appropriate when there are concerns regarding poorly predictable drug accumulation. For details regarding the assessment of product bioequivalence, readers are referred to CVM Guidance #35 (*Bioequivalence Guidance*). Further discussion of the pharmacokinetic and statistical basis for bioequivalence determinations are provided later in this chapter in the section "The Use and Application of Pharmacokinetic Information."

Since veterinary generic drug products must contain all the same indications, warnings, cautions, directions for use, etc., that are associated with the approved pioneer product (except as deemed appropriate on the basis of the Suitability Petition, 21 CFR §512(n)(1)(F)), a bioequivalence study is generally needed for each species for which the pioneer product is approved (with the exception of "minor" species. See the section "The Office of Minor Use and Minor Species Animal Drug Development" of this chapter for additional information).When the product in question is a generic product intended for use in a food-producing animal, sponsors are required to conduct both bioequivalence and tissue residue studies unless blood concentrations of the active drug can be measured out to the withdrawal

time of the pioneer product. The requirement is based upon the conclusion that tissue residue depletion of generic products is not adequately addressed through blood level bioequivalence studies. Differences that may go undetected in a blood level study (and which would be without clinical significance) could impact the withdrawal time because the latter is based on extremely low drug concentrations in the tissue (see earlier section, Human Food Safety [HFS]). A tissue residue study should generally accompany clinical endpoint and pharmacologic endpoint bioequivalence studies, 21 USC 360 b (n) (1) (A) (ii).

The sponsor of the generic product application uses the existing tolerance, marker residue, target tissue, and analytical method (as contained within the pioneer product's approved NADA) to determine the withdrawal time for the generic product (FDA/CVM Guidance For Industry [#35]). Accordingly, generic sponsors need only monitor the depletion of the unlabeled marker residue in the target tissue to establish a withdrawal time for the generic product. However, for reasons explained above, there is a risk that the generic formulation will be associated with a withdrawal time that differs (longer or shorter) from that of the pioneer product. For this reason, the end users of generic products should carefully read each product label to avoid the potential for incurring violative residues.

The Phased Review Process. Sponsors may submit a complete technical section for review during the investigation of the new animal drug under a process called *phased review*. The same requirements under 21 CFR §514.1 apply to all NADAs whether for phased review or not. Phasing of NADA submissions is a voluntary program. The option to phase the review of data submissions applies to all original NADAs and ANADAs and can be exercised up to the point at which the sponsor submits an NADA or ANADA. If a sponsor exercises the option to use the phased review process:

- Submissions relating to technical sections should be submitted during the investigation of the new animal drug and filed in an Investigational New Animal Drug (INAD) file established by CVM for the new animal drug.
- Each submission should contain information and data relating to only one technical section and should be under a separate cover. Sponsors are encouraged to contact the reviewing division regarding what information and data should be submitted together.

For additional information about the Administrative NADA process, refer to CVM Guidance #132 (*Guidance for Industry:* FDA/CVM Guidance for Industry, *The Administrative New Animal Drug Application Process*).

THE OFFICE OF MINOR USE AND MINOR SPECIES ANIMAL DRUG DEVELOPMENT

OVERVIEW. The Minor Use and Minor Species Animal Health Act of 2004 (the MUMS Act) provided for the establishment of the Office of Minor Use and Minor Species Animal Drug Development (OMUMS) (refer to FFDCA Title 21, Section 571, Subchapter F—New Animal Drugs for Minor Use and Minor Species). OMUMS reports directly to the director of CVM, and is responsible for overseeing the development and legal marketing of new animal drugs for minor uses (disease conditions that are rare) in major species (cattle, swine, chickens, turkeys, dogs, cats, and horses) and for minor species that fall under the category of "all other animals," including sheep, goats, game birds, emus, ranched deer, alpacas, llamas, deer, elk, rabbits, guinea pigs, pet birds, reptiles, ornamental and other fish, shellfish, wildlife, zoo animals, aquarium animals, and bees.

Because the markets are small and profit margins low for new animal drugs intended for minor uses in major species or for minor species, there are often insufficient economic incentives to motivate sponsors to develop the data necessary to support FDA approvals. In addition, some minor species populations are too small or their management systems too diverse to make it practical to conduct traditional studies to demonstrate safety and effectiveness. Consequently, manufacturers have not, in many cases, been willing to fund research to collect these data. Accordingly, very few new animal drugs intended for minor uses or for minor species have been approved and are legally marketed.

The limited availability of approved new animal drugs intended for minor uses or minor species has limited the availability of options for treating these sick animals. In many cases, the choices are to leave a sick animal untreated or to treat the animal with an unapproved drug. Failure to treat sick animals appropriately may increase public

health hazards. For example, the transmission of disease from animals to humans or the shedding of disease-producing organisms by untreated animals into the environment may increase health risks to humans as well as to other animals. Treating an animal with an unapproved drug introduces questions of effectiveness and safety to the animal, to the environment, and to the public (e.g., human food safety).

Enactment of the 1996 ADAA reflected Congress' concerns about the lack of availability of approved new animal drugs. Among other things, the legislation recognized particular problems relating to the availability of approved new animal drugs for minor uses in major species and for use in minor species. The ADAA directed the Secretary of Health and Human Services to consider legislative and regulatory options for facilitating approval under section 512 of the Federal Food Drug and Cosmetic Act (FFDCA) (21 U.S.C. 360b) of new animal drugs intended for use in minor species or for minor uses. The ADAA further required the secretary to announce proposals for legislative or regulatory change to the approval process for new animal drugs intended for use in minor species or for minor uses. The MUMS Act is intended to amend the FFDCA to address the critical shortage of approved animal drugs for minor species and for minor uses in major species. It is intended to increase the availability of new animal drugs for minor species and for minor uses, while still ensuring appropriate safeguards for animal and human health.

The MUMS legislation modifies provisions of the FFDCA in three key ways, providing for

- **Conditional Approval**: The sponsor of a veterinary drug can ask CVM for conditional approval, which allows the sponsor to market the drug after proving the drug is safe and establishing a reasonable expectation of effectiveness, but before collecting all of the effectiveness data needed to support a full approval. The drug sponsor can keep the product on the market for up to 5 years, through annual reviews, while gathering the required effectiveness data.
- **Indexing:** The implementation of this regulation allows the FDA to add a minor species drug to an index of unapproved new animal drugs that may be legally marketed when the potential market for the drug is too small to support the costs of the drug approval process, even under a conditional approval. This provision is especially helpful to veterinarians treating zoo or endangered animals, and to owners of minor pet species such as ornamental fish or caged reptiles, birds, or mammals.
- **Designation**: This legislation provides incentives for approvals, such as grants to support safety and effectiveness testing. Sponsors must apply for designation prior to filing a new animal drug application for FDA approval. At the time that a designated drug gains approval or conditional approval, it is awarded 7 years of exclusive marketing rights. This means that FDA will not approve another application for the same drug in the same dosage form for the same intended use until after the 7 years have elapsed. This is 2 to 4 years longer than the protection provided from generic copying of nondesignated drugs. The MUMS marketing exclusivity also protects against approval of another pioneer (nongeneric) application for the same drug, in the same dosage form, for the same intended use.

GRANTS. The legislation also includes a provision that will allow Congress to appropriate funds for grants to defray the costs of safety and effectiveness testing for designated drugs.

IMPLEMENTING REGULATIONS FOR THE MUMS ACT. Both designation and conditional approval became available to sponsors when the bill was signed. Drugs could not be indexed until regulations implementing that provision were finalized (http://www.fda.gov/cvm/CVM_Updates/proMumsDes.htm). Those regulations were published December 6, 2007, and the agency started accepting indexing submissions in February 2008.

ADDITIONAL INFORMATION. For additional information regarding drug use in minor species, the reader is referred to Chapters 52 and 53 of this book.

INTERNATIONAL HARMONIZATION

Historically, the FDA has been concerned with the safety and effectiveness of animal drugs produced or marketed within the U.S. The FFDCA requires that exported pharmaceuticals meet or exceed the standards for approval in the U.S. *or* for the country to which they are being

exported. It also requires that animal drugs marketed in interstate commerce in the U.S. be approved through the same process by the FDA, regardless of where they are manufactured. In addition to the US FDA, other countries have independently developed regulations and regulatory agencies that review safety, effectiveness, and purity of drugs that are intended for marketing within their specific jurisdiction for use in humans and/or animals. Although, internationally, the regulations share the common goal of protection of public health, the specific requirements and methodologies used in the evaluations of these products may diverge.When pursuing a broad international market, products may undergo multiple complete and autonomous reviews by regulating agencies in different countries or regions, and differences in the regulatory requirements between these agencies can retard the development of new drugs and drug products. Regulatory differences can also increase product development expenses, complicate international trade (both of products and of foods derived from animals consuming these products), and lead to duplication of animal studies. Growing globalization, emergence and spread of new animal diseases, and the international nature of the scientific community make it important to share innovation in animal treatment across borders, while maintaining standards for safety, quality, and effectiveness.

Internationally, formation of the European Community (EC) and later the European Union (EU) served as an impetus for the development of a shared regional process for the approval of new animal drugs. This set a pattern for harmonizing separate and diverse regulations among member countries. In 1990, the International Conference on Harmonisation of Technical Requirements for Registration of Pharmaceuticals for Human Use (ICH) was formed. This was followed by formation of the VICH in 1996. The VICH initially included the U.S., EU, and Japan, with the addition of Canada and New Zealand/Australia as observers.The objectives of the VICH (http://vich.eudra.org/htm/what.htm) are to:

- Establish and monitor harmonized regulatory requirements for veterinary medicinal products in the VICH regions, which meet high quality, safety, and efficacy standards and minimize the use of test animals and costs of product development.
- Provide a basis for wider international harmonization of registration requirements.
- Monitor and maintain existing VICH guidelines, taking particular note of the ICH work program and, where necessary, update these VICH guidelines.
- Ensure efficient processes for maintaining and monitoring consistent interpretation of data requirements following the implementation of VICH guidelines.
- By means of a constructive dialogue between regulatory authorities and industry, provide technical guidance enabling response to significant emerging global issues and science that impact on regulatory requirements within the VICH regions.

VICH Expert Working Groups, composed of scientific and technical experts representing each region, meet regularly to develop recommendations for more uniform standards for collection of preapproval and postapproval safety, purity, and effectiveness data. The goals of these working groups are to evaluate requirements of member agencies (within the context of current and emerging scientific knowledge), and to craft harmonized, science-based standards wherever possible. These standards are intended to maintain or enhance animal and public health and well-being. Despite the challenges of reaching scientific and regulatory harmony, this process has led to a long list of approved and draft guidances (http://vich.eudra.org/htm/guidelines.htm), with more documents currently in development. These guidances are intended to allow the same studies to be used during the animal drug approval process of different regulatory agencies.

The FDA also participates in other international activities with a goal of protecting human and animal health in the global economy. During the early 1960s, the Food and Agriculture Organization (FAO) Conference and the World Health Organization (WHO) launched a joint effort to "protect the health of the consumers and ensure fair practices in the food trade." The primary product resulting from this program is the *Codex Alimentarius*, which literally means the food code (http://www.cfsan.fda.gov/~cjm/codex.html). This code represents a collection of food standards and guidance documents published jointly by the FAO and the WHO. Among these standards are maximum residual limits (MRLs) for veterinary drugs (MRLVD), as well as documents related to their use and control. The Codex Committee on Residues of Veterinary Drugs in Foods (CCRVDF) is specifically responsible for addressing the MRLVD (http://www.codexalimentarius.net/web/index_en.jsp). Additional information pertaining

to WHO initiatives can be found elsewhere (Martinez et al. 2004).

The FDA also participates in General Subject Committees, Commodity Committees and Task Forces that determine standards and codes of practice for international trade (http://vich.eudra.org/htm/what.htm.; Castle 2005).

ADVERSE DRUG EXPERIENCE REPORTS

The primary purpose for maintaining the Food and Drug Administration—Center for Veterinary Medicine (FDA/CVM) Adverse Drug Experience (ADE) database is to provide an early warning or signaling system for adverse effects not detected during premarket testing of FDA-approved animal drugs and for monitoring the performance of drugs not approved for use in animals. The FDA/CVM ADE reporting system depends on the detection of an adverse clinical event by veterinarians and animal owners, the attribution of the clinical event to the use of a particular drug ("suspect" drug), and the reporting of the ADE to the manufacturer of the suspected drug or directly to FDA. Data from these ADE reports are coded and entered into the computerized FDA/CVM ADE database.

It is important to remember certain caveats when using data from the FDA/CVM ADE database:

- For any given ADE report, there is no certainty that the suspected drug caused the adverse event. This is because veterinarians and animal owners are encouraged to report all suspected ADEs, not just those that are already known to be caused by the drug. The adverse event may have been related primarily to an underlying disease for which the drug was given or to other concomitant drugs, or may have occurred by chance at the same time the suspect drug was administered.
- Accumulated ADE reports should not be used to calculate incidence rates or estimates of drug risk. The Division of Surveillance is responsible for consolidation of all drug experience reports, necessary referrals and consultations, and preparation of the summary reports. The division's ADE scoring system uses a modified Kramer scoring system (Bataller and Keller 1999). In this system, each sign is separated from the other signs and scored according to previous experience with the drug, alternative etiologic candidates (other causes), timing of the event, whether there was an overdose, whether the reaction continued or subsided with withdrawal of the drug, and whether a reaction recurred on reintroduction of a drug. Additional information on the criteria and responsibilities for the consolidation, screening, review, and evaluation of drug experience reports is further detailed in the CVM Program Policy and Procedures Manual section 1240.3522, Review and Evaluation of Drug Experience Reports (http://www.fda.gov/cvm/Policy_Procedures/3522.pdf).

Veterinarians and animal owners are encouraged to report adverse experiences and product failures to the government Agency that regulates the product in question. To access the FDA/CVM website for information and forms that are needed to report adverse experience with veterinary drugs, the reader is referred to http://www.fda.gov/cvm/adereporting.htm. Pretesting by the manufacturer and review of the data by the government does not guarantee absolute safety and effectiveness due to the inherent limitation imposed by testing the product on a limited population of animals. CVM encourages veterinarians and animal owners to contact the manufacturer of a suspect product. Withdrawal of an approved drug may be recommended if it is determined to be unsafe or ineffective.

The drug company marketing the drug product in question should be notified of the need to report an ADE for an FDA-approved animal drug. Drug company phone numbers can usually be obtained from product labeling. Technical services will ask a series of questions about the event, complete the FDA 1932 form, and forward the report to CVM. Alternatively, the report may be submitted directly to the FDA on Form 1932a.

Reports should preferably include a good medical history, all concomitant drugs the animal has been given, any recent surgical procedures, and as much in the way of clinical findings as is possible. Clinical findings may include veterinary exam, clinical chemistries, complete blood counts, urinalysis, fecal exams, radiographic results, and hemodynamic data such as blood pressure, any other pressure measurements in or around the heart, and neurological assessments.

"Veterinary Adverse Experience, Lack of Effectiveness or Product Defect Report," form *FDA 1932a*, is a preaddressed, prepaid postage form (Figs. 55.3A, B) that can be completed and dropped in the mail. This form may be

A

FOLD, SEAL, AND RETURN

VETERINARY ADVERSE DRUG REACTION, LACK OF EFFECTIVENESS OR PRODUCT DEFECT REPORT

DATE REPORTED

Form Approved: OMB No. 0910-0284
Expiration Date: January 31, 2010

NOTE: This report is authorized by 21 U.S.C 352(a) and (f). While you are not required to report, your cooperation is needed to assure comprehensive and timely assessment of product labeling.

If you do NOT want your identity disclosed to the manufacturer, place an "X" in this box. ☐

1. VETERINARIAN'S NAME AND ADDRESS

TELEPHONE (Include Area Code) ___ — ___ — ____

2. OWNER'S NAME OR CASE ID *(In Confidence)*

3. NADA NUMBER (For FDA Use)

4. SUSPECTED DRUG AND DOSAGE FORM

5. MANUFACTURER'S NAME

6. DIAGNOSIS AND / OR REASON FOR USE OF DRUG

7. ADMINISTERED BY
☐ VETERINARIAN
☐ OWNER

8. DOSAGE ADMINISTERED AND ROUTE *(Ex. 250 mg. q 12h, 5 days, orally)*

9. DATE(S) OF ADMINISTRATION

10. SPECIES	11. BREED	12. AGE	13. SEX	14. WEIGHT
				LBS.

15. CONCURRENT CLINICAL PROBLEMS
☐ NONE

OVERALL STATE OF HEALTH WHEN SUSPECTED DRUG GIVEN:
☐ GOOD ☐ FAIR ☐ POOR ☐ CRITICAL

16. CONCURRENT DRUGS ADMINISTERED
☐ NONE

17. REACTION INFORMATION

a. TIME BETWEEN INITIATION OF THERAPY WITH SUSPECTED DRUG AND ONSET OF REACTION WAS
b. TIME BETWEEN LAST ADMINISTRATION OF SUSPECTED DRUG AND ONSET OF REACTION WAS
c. OUTCOME: ☐ RECOVERED FROM REACTION ☐ DIED FROM REACTION ☐ OTHER *(Comment Below)*
d. WAS THE REACTION TREATED? ☐ NO ☐ YES *(Comment Below)*
e. WHEN THE REACTION APPEARED, TREATMENT WITH SUSPECTED DRUG:
☐ HAD ALREADY BEEN COMPLETED
☐ WAS DISCONTINUED DUE TO REACTION
☐ WAS DISCONTINUED AND REPLACED WITH ANOTHER DRUG
☐ WAS DISCONTINUED AND REINTRODUCED LATER
☐ WAS CONTINUED AT ALTERED DOSE
☐ OTHER *(Comment Below)*

AND THE REACTION

☐ CONTINUED
☐ STOPPED
☐ RECURRED
☐ OTHER *(Comment Below)*

f. LEVEL OF SUSPICION THAT DRUG CAUSED THE REACTION: ☐ HIGH ☐ MEDIUM ☐ LOW

18. DESCRIBE THE REACTION, ADD DETAILS ABOUT CASE HISTORY AND OUTCOME *(Include numbers if group of animals involved)*, GIVE COMMENT ON POSSIBLE CONTRIBUTING FACTORS. DESCRIBE LACK OF EFFECTIVENESS OR PRODUCT DEFECT *(Include Expiration Date and Lot No.)*

NOTE: Triple fold as marked, seal with tape, no postage required, additional space on back, if needed.

The CVM can also be reached by phone at 800-FDA-VETS.

The Center may occasionally need more detailed information about an incident and the reporter may be called by a CVM staff veterinarian. The identities of all persons and animals is held in strict confidence by FDA and protected to the fullest extent of the law. The reporter's identity may be shared with the manufacturer or distributor unless requested otherwise. However, FDA will not disclose the reporter's identity to a request from the public, pursuant to the Freedom of Information Act. Information requested includes the reporter's name, address, phone number and the brand name of the drug involved. For information regarding CVM's surveillance program, the reader is referred to Chapter 58 of this textbook.

Additional contact information includes:

- Animal biologics: vaccines, bacterins and diagnostic kits: U.S. Department of Agriculture. 800-752-6255.
- Pesticides: topically applied external parasiticides: U.S. Environmental Protection Agency, 800-858-PEST.

LEVERAGING WITH THE FDA

Over the last few years, the FDA has emphasized the value of collaborating or partnering with outside parties as a primary strategy to more effectively accomplish its mission of promoting and protecting the public health. This concept of collaboration and partnership in FDA is generally known as *leveraging*. Within the framework of leveraging activities, collaborators work synergistically to achieve goals that neither party could achieve on its own. Examples include joint workshops to assess particular public health challenges, cosponsored training sessions, consensus standard setting, and mission-related research (Batson and Starinsky 2002).FDA/CVM partnerships reflect the creative thinking and initiative of our outside stakeholders, frontline employees, managers, and others. It is from these ideas that formal agreements and informal collaborative relationships have flourished. Formal agreements may include the following (Batson and Starinsky 2002):

- **Cooperative Agreement:** This involves a collaborative effort between the FDA and the partner in which substantial technical expertise is anticipated between both parties and FDA will provide at least part of the funding for the project.
- **Cost-Sharing Contract:** A cost-sharing contract is one under which the federal government contracts for goods or services and the contractor absorbs a portion of the total cost of the effort. These arrangements are usually appropriate when the contractor is able to apply or market the developed product for the benefit of their business.
- **Cooperative Research And Development Agreement (CRADA):** CRADAs involve collaborative efforts between the FDA and one or more partners (academia, industry, not-for-profit, for-profit, and state and local government organizations). From the FDA perspective, the CRADA is intended to help develop FDA technology, inventions, training programs, etc., that will facilitate achievement of mission-related goals. The CRADA partner, in return, receives some benefit from the establishment of this collaboration. The CRADA partner may provide funds to be used for the CRADA project. FDA and the partner may each contribute staff time and expertise, equipment, supplies, and facilities. Both parties are expected to make significant intellectual contributions to the objectives of the project.
- **Interagency Agreement (IAG):** The purpose of the collaboration is the sharing of knowledge, personnel, or other resources to strengthen programs of mutual concern between two or more federal agencies. It is also used as a mechanism for eliminating overlap or duplication of effort. Within the framework of the IAG, the parties may either contribute or receive funds, services, staff, property, facilities, or equipment, or exchange information to forward the common project goal.
- **Cosponsorship Agreement:** This can involve activities such as the joint development of a conference, seminar, symposium, educational program, or public information campaign that is related to the mission of the Agency. This kind of cooperative agreement involves the FDA and one or more nonfederal entities that share a mutual interest in the subject matter. As part of this cooperation, each party provides its own funding or staffing.

Potential leveraging opportunities should be brought to the attention of FDA/CVM program personnel or CVM Leveraging Points of Contact. After the idea or concept is discussed and a decision made with respect to moving forward, the appropriate mechanism for implementing the collaboration can be determined. Additional information on FDA leveraging activities can be obtained from the FDA's Leveraging Handbook, which is available on the FDA website http://www.fda.gov/oc/leveraging/default.htm

THE USE AND APPLICATION OF PHARMACOKINETIC INFORMATION

Since this is a pharmacology textbook, we would like to take this opportunity to discuss the potential value of pharmacokinetics for understanding product *in vivo* performance characteristics and how use of the pharmacokinetic information provided on a product label can address questions that may arise within the context of clinical practice situations. The basic pharmacokinetic principles being applied in this section have been discussed elsewhere in this textbook. Readers are referred to Chapters 2 and 3 for in-depth discussions of these basic pharmacokinetic principles. Many animal drug labels contain specific pharmacokinetic information that can assist veterinarians in their judgments regarding drug selection and dosage. Furthermore, there is a growing effort to characterize the impact of variables such as age, weight, gender, breed, diet, etc., on the rate and extent of systemic drug exposure. Therefore, to efficiently use such information, it is important that veterinarians understand how to interpret and apply this information and such variables as terminal elimination half-life, bioavailability, systemic clearance, and volume of distribution.

Pharmacokinetics has been used in many different aspects of drug development. Examples of possible uses of pharmacokinetics in the new animal drug development process are provided in Table 55.3. In some circumstances, drug concentrations in other matrices (such as

TABLE 55.3 Applications of pharmacokinetics in a regulatory environment

Purpose	Type of Studies	Relevant Examples or Published Guidance Documents
Bridging between formulations	Bioequivalence studies for generic drug approvals	CVM Bioequivalence Guidance (Guidance #35)
	Relative bioavailability studies to bridge between safety and/or effectiveness data contained in a sponsor's NADA	CVM Guidance #82 (Development of Supplemental Applications for Approved New Animal Drugs)
Bridging between animal species	Relative bioavailability studies to provide substantial evidence of effectiveness for minor species	CVM Guidance #61 (Guidance for industry: FDA approval of new animal drugs for minor uses and for minor species)
Dose justification/dose rationale	Blood levels that may help in dose selection when there is information available on pharmacokinetic-pharmacodynamic relationships	e.g., FOI for NADA 141-081; NADA 141-232
Information to assist in protocol development	Target animal safety and/or clinical effectiveness studies	e.g., Guidance 123 (Development of target animal safety and effectiveness data to support approval of nonsteroidal antiinflammatory drugs (NSAIDS) for use in animals)
For setting *in vitro* release specifications	Correlation of *in vitro* release characteristics with *in vivo* bioavailability.	e.g., see Shah 2005
For conveying information to the veterinarian on variables that may affect systemic drug exposure	Studies to characterize the drug's pharmacokinetics (e.g., clearance, volume of distribution, protein binding, metabolism, and route of elimination). Additional information may include dose proportionality, potential food effects or drug/drug interactions, and influence of age, gender or disease on dose-exposure relationships.	See discussion on pharmacokinetic information that may be provided in the package insert.

cerebrospinal fluid, bronchial secretions and urine) may provide valuable information regarding in vivo product performance.

Pharmacokinetic information is only as good as the experimental design and analytical method used to generate these data. For example, in the 1970s a pharmacokinetic study was conducted to determine whether cephalothin might be a good candidate for the treatment of bacterial meningitis in humans. Based on bacterial susceptibility and drug concentrations achieved in cerebrospinal fluids (CSF), as measured by bioassay, cephalothin appeared to achieve the concentrations in the CSF needed to treat bacterial meningitis. However, this drug was a clinical failure. The reason for this conflict was that the bioassay of CSF drug concentrations was actually measuring the cephalothin metabolite, desacetylcephalothin. Although the organism used in the bioassay, *Sarcina lutea,* was highly susceptible to both the parent and the metabolite, the targeted pathogens, *S. pneumoniae* and *N. meningitidis* were resistant to the metabolite (Nolan and Ulmer 1980). Because of the importance of using a validated analytical method for assaying drug concentrations in biological matrices, CVM provides recommendations on the methods assessments that should accompany the submission of pharmacokinetic datasets (FDA/CDER/CVM Guidance for Industry: Bioanalytical Method Validation Dated 05-2001. http://www.fda.gov/cder/guidance/4252fnl.htm).

Examples of other points that may be important during analysis of pharmacokinetic data include the following:

- Did animals vomit following administration and when did the event occur relative to dosing?
- Were the pharmacokinetic data generated with the final product formulation?
- Were animals fed or fasted prior to dosing?
- For some topically administered products, were the animals able to lick the product? (Laffont et al. 2003; Bousquet-Melou et al. 2004).
- Are there active metabolites?
- Does the drug exhibit stereospecific pharmacokinetics? For example, ketoprofen has been shown to have stereospecific pharmacokinetics (Lees al. 2003; Landoni et al. 2003).
- What is the magnitude of protein binding?

Table 55.3 provides examples of how pharmacokinetics has been applied in the evaluation of animal drug products.

In determining what type of studies may be appropriate, CVM recommends that factors such as the proposed conditions of use, release characteristics of the dosage form, the intended target animal species, and the drug's therapeutic uses be considered.

INTERPRETING THE PHARMACOKINETIC INFORMATION PROVIDED IN THE PACKAGE INSERT.

Types of pharmacokinetic information that a sponsor may choose to convey in the clinical pharmacology portion of the package insert include the basic pharmacokinetic parameters such as volume of distribution (V), systemic clearance (CL), terminal elimination half-life (T1/2), AUC, Cmax, time to Cmax (Tmax), mechanisms of elimination, magnitude of protein binding, and factors that may influence systemic drug exposure (e.g., food effects, influence of age, gender, altered hepatic or renal function). By the inclusion of labeling information on these variables, the veterinarian is informed of those clinical factors that may necessitate dose adjustments.

Terminal Elimination Half-life (T1/2). The T1/2 provides a clinician with an estimate of the time it will take to totally eliminate the drug from the body or the duration of dosing needed to attain steady-state conditions. As a general rule of thumb, when there are no saturable kinetic processes, veterinarians can multiply the half-life by 10 to estimate the duration of time it will take to effectively eliminate the active moiety from the systemic circulation. From a regulatory perspective, this information can be used when evaluating protocols for clinical safety and/or effectiveness studies, as well as for estimating the duration of washout needed between periods of a bioequivalence trial employing a crossover study design. It should be noted that 10 times the plasma or serum half-life value often differs from the withdrawal time established for human food safety. This difference may be because the tissue half-life and blood half-life differ, because the moiety being measured may differ, or because the endpoint (time to some established tolerance, as previously defined) differs. Furthermore, withdrawal time includes an additional factor to account for population variability. As previously mentioned, it is a statistical calculation of the time it takes to be 95% certain that 99% of the animals will have tissue concentrations of the marker residue that are at or below tolerance. There are some additional rules of thumb that

can be applied to predict a likely withdrawal time for many compounds, as discussed in Chapter 61.

T1/2 can also be a valuable tool for estimating the time it will take to reach 90% steady-state blood levels of the drug (e.g., approximately 4 times the T1/2 under conditions of linear pharmacokinetics). When a drug can be described by a single exponential and it is administered via intravenous injection (or when the product is rapidly absorbed relative to the time it takes to eliminate the compound from the blood), T1/2 can be used to estimate the accumulation at steady-state using this equation (Gibaldi and Perrier 1982):

$$R = \frac{1}{1 - \exp^{-\lambda_z \times \tau}}$$

where R = the accumulation index, λ_z = the slope of the depletion phase (also referred to as *Kel* for a one-compartment model), and τ = the dosing interval (e.g., q24hr, q12hr, etc.).

Therefore, if we are dosing once daily (i.e., $\tau = 24$ hr) and the half-life for that compound is 15 hr, then

$$\lambda_z = 0.693/15 \text{ hr} = 0.0413 \text{ hr}^{-1}, \text{ and}$$

$$R = \frac{1}{1 - \exp^{-0.0413 \times 24}} = 1.49$$

The accumulation index provides information on the ratio of Cmax values (comparing steady-state Cmax values to that observed following a single dose). It can also be used to predict the Cmin ratios (steady-state versus dose 1) or the ratio of AUC values estimated over a single dosing interval at steady-state versus the AUC estimated over the first dosing interval ($AUC_{0-\tau ss}/AUC_{0-\tau dose1}$) (Gibaldi and Perrier 1982).

This equation can also be used to provide a close approximation of the magnitude of accumulation that will occur for drugs that follow a two-compartment open body model. Errors can occur when there is a deep peripheral compartment. An important caveat is that this equation provides a good approximation of the magnitude of accumulation at steady-state primarily when the rate-controlling step in drug elimination is its CL. Overestimation of the magnitude of drug accumulation is likely to occur when the rate of absorption is slower than the rate of elimination. Situations that fall within this category include sustained-release products. To illustrate this point, we provide the following example of the relationship between estimates of T1/2 (based on the use of noncompartmental methods), dosing interval, and predicted versus actual level of drug accumulation. Drug profiles were simulated under a variety of conditions, including a drug that follows a one-compartment body model (i.e., the rate of depletion is best described by a single exponential), a drug that follows a two-compartment model and the majority of the AUC is associated with the β elimination phase, and a third compound exhibiting a slowly depleting compartment that is responsible for only a small portion of the overall AUC value (refer to Chapter 2 of this book for information on the pharmacokinetic characteristics of drug absorption, metabolism, distribution, and clearance). A comparison of the single dose profiles for these drugs is provided in Figure 55.4.

In this example, the fundamental difference in the profiles of the compounds following a one- versus two-compartment model is the "nose" representing the distribution phase of the drug associated with two compartments. In the case of the deep compartment, there is a very rapid initial distribution phase (α), a slower secondary depletion phase (β) and a very slow third depletion phase (γ). The vast majority of the profile is associated with the β elimination phase. Therefore, marked overestimations will occur if the γ elimination phase is used to estimate the magnitude of accumulation at steady-state. Although kinetic distinctions can be readily identified in these simulated examples, factors such as within and between subject pharmacokinetic variability, the selection of blood sampling times, and analytical method limitations can occasionally obstruct the identification of drug kinetic properties from actual datasets.

Another factor that can influence our ability to predict steady-state concentrations is the presence of an absorption rate constant that is less than the elimination rate constant of a drug when that drug is administered in an immediate release dosage form. This phenomenon is coined "flip-flop kinetics." Thus, as the absorption rate constant approaches or is less than the elimination rate constant, there is an increase in the magnitude of error associated with the predictions or R. The influence of pharmacokinetic model or rate of absorption on the accuracy of our estimates of steady-state drug concentrations is provided in Table 55.4.

The estimates for $AUC_{0-\tau ss}/AUC_{0-\tau dose1}$ and Cmax ratios were generally similar (except for the very slow absorption situation where there was a marked underestimation of the amount of drug absorbed after dose 1). However, dissimilar conclusions were derived from steady-state versus dose

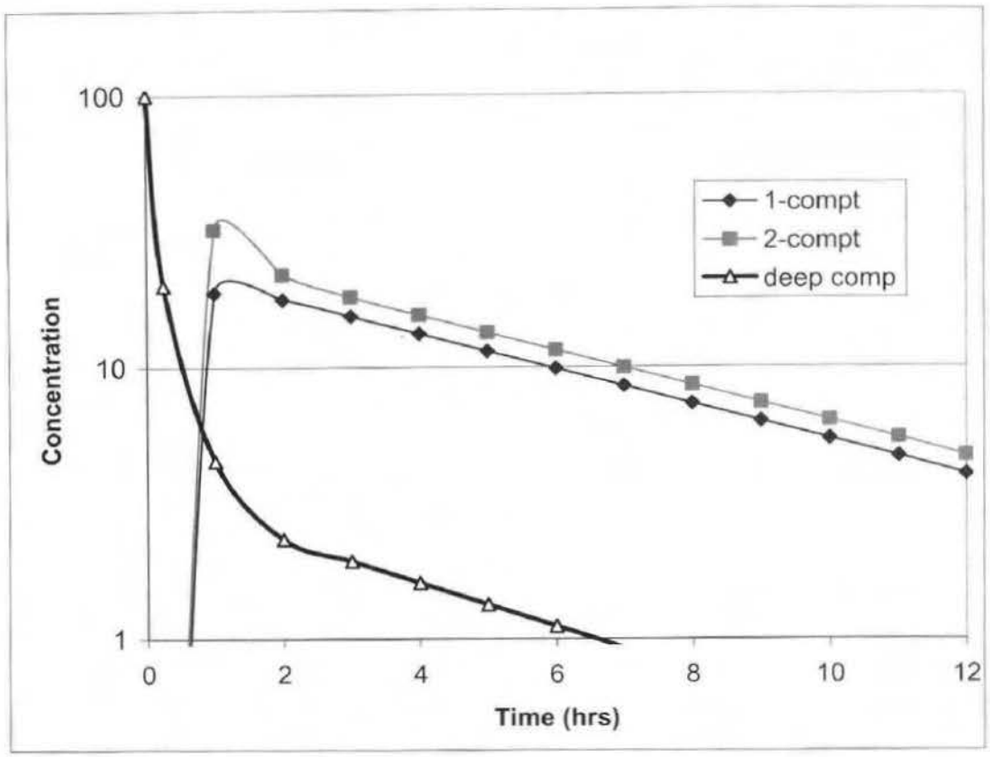

FIG. 55.4 Profile of the three kinds of compounds used in these simulations.

TABLE 55.4 Accuracy of estimating steady-state drug concentrations based upon the arithmetic estimate of R when applied to various pharmacokinetic situations. Doses were administered either once daily (two-compartment drug) or every 6 hours (deep-compartment drug)

Model	Absorption Rate Constant, Ka (hr^{-1})	Estimated Terminal Slope (λ_z), Dose 1 (hr^{-1})	Estimated Terminal Slope at Steady-State (λ_{ss}, hr^{-1})	R-Estimated	Observed Accumulation Based upon Observed Parameter Values		
					AUC Ratios*	Cmin Ratios**	Cmax Ratios***
1-compt	0.01	0.0036		11.95	6.25	4.78	5.18
			0.0084	5.48			
	0.149	0.0986		1.10	1.15	1.06	1.14
			0.1057	1.09			
	0.5	0.149		1.03	1.04	1.03	1.04
	2.5	0.149		1.03	1.03	1.03	1.03

*AUC ratio = $AUC_{0-\tau}/AUC_{0-24}$.

**Cmin ratios = Cmin at steady-state versus the concentration at hr 24 postdose. ***Cmax ratios = Cmax at steady-state versus Cmax after dose 1.

1 ratios based upon AUC and Cmax versus Cmin values when there was a deep compartment or when the absorption phase encompasses a large portion of the dosing interval. When there is a deep compartment, slow depletion from the deep compartment will have a substantial effect on Cmin values. However, if this deep compartment provides only a small contribution to the total AUC (e.g., less than 10%), this accumulation will have negligible impact on either steady-state AUC or Cmax values. This is graphically shown for the simulated example in Figure 55.5. In this case, $AUC_{0-\tau ss}/AUC_{0-\tau dose1}$) ~1.0 and only minimal accumulation was seen in Cmax (due to the slight elevation in Cmin values relative to Cmax), despite the substantial increase in Cmin.

Assessments of the likely magnitude of prediction error should be based on our understanding of the pharmacokinetics of the drug in question. When absorption is rapid and the majority of the AUC is associated with the depletion phase being used in our estimates of λ_z, R can serve as a valuable tool for predicting steady-state drug exposure.

The accuracy of our predictions of time to at least 90% steady-state concentrations was likewise dependent upon our ability to accurately capture half-life. The presence of flip-flop kinetics of a deep tissue compartment influences the accuracy not only of the predictions of steady-state drug accumulation but also the time to reach steady-state (Table 55.5).

Food Effects. Numerous products, when administered orally to monogastric species, have been found to have altered bioavailability when administered with food (Persson et al. 2005; Kung et al. 1995). This can be both drug-specific and formulation-specific (Jinno et al. 2006). For example, highly lipophilic compounds may have enhanced bioavailability when administered with food.

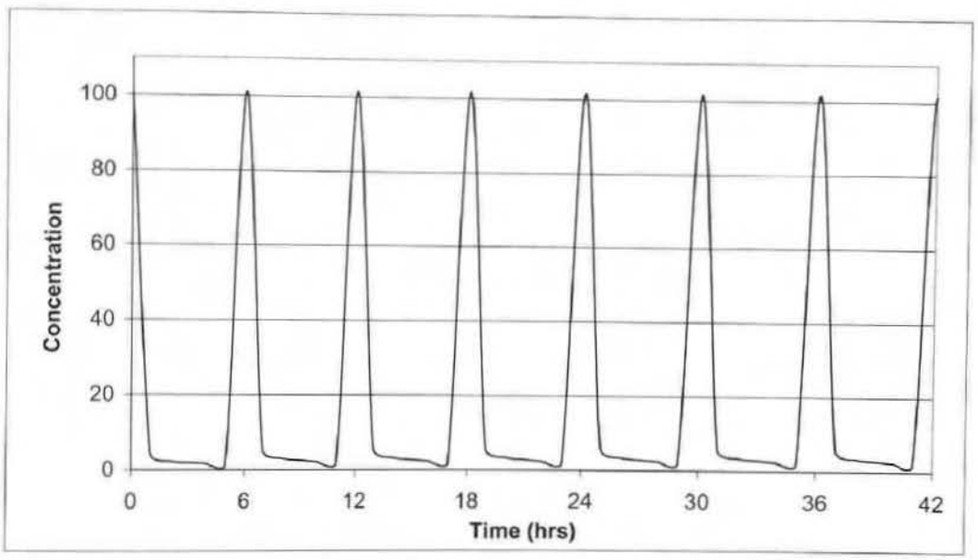

FIG. 55.5 Accumulation with repeated administrations.

TABLE 55.5 Accuracy of estimating time to at least 90% steady-state concentrations estimated on the basis of T1/2 values (where time to 90% accumulation is approximately equal to 4 × T1/2)

Model	Absorption Rate Constant, Ka (hr^{-1})	Using First Dose T1/2 (hr)	Using Last Dose T1/2 (hr)	Actual Dose When $AUC_{0-\tau}/AUC_{0-inf} > 0.9$
2-compartment	0.01	644 (dose 27)	311 (dose 13)	216 hr (dose 9)
	0.149	35	34	By dose 2
	0.5	23	—	By dose 2
	2.5	23	—	By dose 2
Deep compartment		19	—	By dose 2 (hr 12)

Acid labile products may be degraded by stomach acids when retention time is increased due to the intake of a meal. Changes in retention time are likely to influence the dissolution and hence alter drug absorption for drugs with either pH-dependent dissolution or for those compounds for which absorption rate is determined by the rate of gastric emptying. Information on the product package insert will indicate whether an effect of food has been evaluated and needs to be considered when the drug is being administered (e.g., NADA 141-151).

Effect of Age. There is little published information available on the influence of age on drug pharmacokinetics in veterinary species. The age of animal for which the product can be labeled is usually determined on the basis of the population of animals evaluated in the target animal safety and effectiveness studies. The package insert will indicate whether there are recommended age restrictions in product use due to lack of adequate safety information in that age group (e.g., NADA #111-798), whether there are recognized safety concerns associated with its use in very young animals (e.g., NADA #141-081), whether there are use restrictions due to the absence of a withdrawal period established in very young animals (e.g., preruminating calves) (e.g., NADA #141-061).

It is only recently that age has been an important focus within the context of human pharmaceutics (de Zwart et al. 2002). Certain differences, such as those seen in preruminating versus ruminating calves, bring obvious differences in drug bioavailability. Other less obvious differences are seen in drug metabolism. Renwick (1998) observed the following general trends in humans:

- Children tend to eliminate drugs more rapidly than do adults.
- For renally cleared compounds, elimination is markedly slower in neonates as compared to other age groups.
- There are some drugs that show age-related shifts in body weight adjusted clearance (such as amrinone, meropenen, midazolam, and cefotaxime). However, other drugs reach adultlike clearance values after the first few months of life (such as zidovudine, amikacin, and ketamine).

Clark University, in cooperation with the Connecticut Department of Public Health, created an extensive pediatric database containing published information across a wide range of pharmaceutical substances (Hattis et al. 2001).

In veterinary medicine, Sequin et al. (2004) observed that feline enrofloxacin pharmacokinetics was markedly influenced by animal age. They noted that the T1/2 was shorter in kittens 2 to 8 weeks of age as compared to adult cats and that the apparent volumes of distribution were lower at 2 to 4 weeks of age and greater at 6 to 8 weeks of age. The greater volume of distribution and clearance in kittens 6 to 8 weeks of age resulted in lower plasma concentrations, and the authors concluded that doses may need to be increased to achieve therapeutic drug concentrations when enrofloxacin is administered to kittens 6 to 8 weeks of age. In terms of geriatric animals, practitioners need to consider the possible decrease in renal and/or hepatic function as these could lead to substantial increases in drug exposure (remember that AUC = Dose × F/CL. Therefore, a change in CL is equivalent to a commensurate change in dose). Similarly, old age may be associated with changes in volume of distribution, thus influencing free drug concentrations (Crome 2003; Steinmetz et al. 2005).

Effect of Body Weight. For highly lipophilic compounds, animal weight may influence volume of distribution and therefore T1/2. In dogs, the proportion of body adipose tissue per unit body weight was significantly increased in animals less than 4 weeks of age as compared to adults (Kienzle et al. 1998). Gender differences may occasionally be attributable to differences in the proportion of body fat per unit weight. For example, significant weight effects were observed when oral moxidectin was administered to beagle dogs (Vanapalli et al. 2002). Along with this finding, the terminal half-life was statistically significantly longer in females as compared to males. To some degree, this problem is less dramatic in veterinary medicine as compared to human medicine because most veterinary compounds are prescribed on a mg/kg basis. Nevertheless, practitioners may find it helpful to consider the potential impact of body composition when prescribing medications.

Gender Effects. For some compounds, differences have been observed between the pharmacokinetics in males versus females (Harris et al.. 1995; Lin et al. 1996; Parkinson et al. 2004; Ohhira et al. 2006). Related concerns associated with gender effects in human medicine can be found at the CDER website (http://www.fda.gov/cder/reports/womens_health/women_clin_trials.htm). If

present, the label will indicate whether the dosing recommendations differ between males and females.

Change of Pharmacokinetics in Pregnancy and Lactation. Numerous changes in pharmacokinetics can occur during pregnancy (FDA/CDER Draft Guidance for Industry: Pharmacokinetics in Pregnancy—Study Design, Data Analysis, and Impact on Dosing and Labeling: Draft dated 10/2004). These pharmacokinetic alterations can be due to such factors as the following:

- Changes in total body weight and body fat composition
- Delayed gastric emptying and prolonged gastrointestinal transit time
- Increased extracellular fluid and total body water
- Increased cardiac output, increased stroke volume, and elevated maternal heart rate
- Decreased albumin concentration with reduced protein binding
- Increased blood flow to the various organs (e.g., kidneys, uterus)
- Increased glomerular filtration rate
- Changed hepatic enzyme activity, including phase I CYP450 metabolic pathways (e.g., increased CYP2D6 activity), xanthine oxidase, and phase II metabolic pathways (e.g., N-acetyltransferase)

Clinically important changes in drug pharmacokinetics can also occur during lactation (Petracca et al. 1993; Hossaini-Hilali and Olsson 1993; Soback et al. 1994; Cao et al. 2001; Mottino et al. 2002). These changes may be the result of extensive partitioning of the drug into milk (increasing drug clearance and, if there is transfer between milk and blood, increasing the volume of distribution), differences in transporter activity or metabolism caused by endogenous hormonal changes, altered body fat proportion, and changes in weight or muscle mass (FDA/CDER Guidance for Industry: Clinical Lactation Studies—Study Design, Data Analysis, and Recommendations for Labeling. *Draft Guidance* dated 02/2005). These changes may influence the safety and effectiveness of the drug in the patient or, if pregnant or nursing, may pose risks in the fetuses/nursing animals. Therefore, the product label will generally state whether CVM has evaluated the safety and effectiveness of that product for use in reproducing and lactating animals (e.g., NADA #141-075). In terms of lactating dairy cattle, it is important not to use a product that has not been approved for this purpose as violative residues in milk may result (e.g., June 21 2004 CVM update http://www.fda.gov/cvm/CVM_Updates/milkresup.htm).

Breed Effects. There are recognized breed differences in metabolism, disease response and kinetics in cattle (Elsasser et al. 2005). Similarly, metabolic differences have been observed across breeds of dogs (http://omia.angis.org.au/). There are over 350 inherited disorders that have been described in the purebred dog population (Patterson et al. 1988). Breed-related differences in drug absorption have been correlated with differences in intestinal transit time (Meyer et al. 1993; Weber et al. 2002, 2003) and potential differences in intestinal permeability (Randell et al. 2001; Weber et al. 2002). An example of breed effect that has been included in product labeling is the warning associated with use of ivermectin-containing compounds in some sensitive collies (e.g., NADA 140-971). An extensive review of breed effects in dogs has recently been published elsewhere (Fleischer et al. 2008).

Protein Binding. For certain compounds (specifically, those associated with low renal or hepatic extraction ratios), protein binding can significantly affect the total systemic clearance. Furthermore, when evaluating the pharmacokinetic-pharmacodynamic relationship of antimicrobial compounds, it is generally appropriate to base these evaluations on free (unbound) rather than total (free plus bound) drug concentrations (Liu et al. 2002; Drusano 2004; Müller et al. 2004). This is because the pharmacodynamic component is expressed relative to drug antimicrobial activity that is usually estimated in protein-free media. In disease states associated with altered plasma protein binding, changes in total drug concentrations may occur for highly protein bound drugs (e.g., >90%). For certain drug moieties, such as propofol, altered protein binding can have clinically relevant effects (Hiraoka et al. 2004). However, in most cases, altered protein binding will not influence the AUC of the free drug moiety, although total drug concentrations may change (Benet and Hoener 2002; Toutain and Bousquet-Melou 2002). The potential disparity between free and total drug concentrations should be considered if one is doing therapeutic drug monitoring because in many situations, adjustments in dose, when based solely upon total plasma concentrations, can lead to higher than desired free drug concentrations and, possibly, drug toxicity. For additional information on therapeutic drug monitoring, the reader is referred to Chapter 51 in this textbook.

Protein binding information can be found in the clinical pharmacology portion of the product label (e.g., see NADA # 140-684).

Michaelis Menton Kinetics. When there are saturable processes associated with either the absorption or elimination of a compound, it is no longer appropriate to predict dose-proportional changes in drug exposure with changes in a dosage regimen. When there are saturable absorption processes, the increase in drug exposure will be less than that expected on the basis of the magnitude of increase in administered dose. This may impact product effectiveness. Conversely, if there are nonlinear elimination processes, the increase in drug exposure will exceed what is anticipated on the basis of the increase in delivered dose. This may impact target animal safety. Therefore, any known information regarding nonlinear kinetics will be described on the package insert (e.g., NADA # 141-075).

TYPES OF MEANS USED IN PRODUCT LABELING.

An aspect of pharmacokinetic information that may be unfamiliar to users is that parameter values provided in the package insert are listed as arithmetic means, least square (LS) means, harmonic means, or geometric means (Zar 1998). The question is how do these various means differ? To address this question, Table 55.6 lists 10 estimates of half-life. These initial values are then manipulated as indicated in this table. From the change in the value associated with each mean, we see that identical values can result in differing mean estimates, depending on how these means were calculated.

Another question pertains to the difference between LS means and arithmetic means. Arithmetic means and LS means are identical when groups contain an identical number of observations across animals with differing characteristics. However, when there are inequalities in the numbers of these disparate subjects, the arithmetic and LS means can differ. For example, if the half-life of a drug is longer in females than males, the arithmetic means would be higher for a group composed of 7 females and 3 males than for a group containing 5 females and 5 males. In contrast, the LS means would adjust for the differences in these ratios. This point is illustrated in Table 55.7.

To provide an example of how the method of calculation can influence our interpretation of the study data, let's consider the following hypothetical everyday situation:

A survey was being conducted to determine the number of individuals that arrived by bus or by car to a particular tourist destination and to determine whether the duration of the journey was generally shorter when the travelers arrived by car or by bus. The survey resulted in the following table of values (Table 55.8).

The tourist company found that only slightly more people arrived by bus (73) as compared to by car (70) and that most of the tourists lived more than 300 miles away. When examining the arithmetic mean, they concluded that the time for arrival to destination was similar when the tourists arrived by car or by bus. While that was a true

TABLE 55.6 Comparison of various kinds of means used with pharmacokinetic data

	T1/2	Ln-Transformed	Reciprocal T1/2	0.693/T1/2 (= λ_z)

	7.00	1.95	0.14	0.10
	8.00	2.08	0.13	0.09
Arithmetic mean	6.44	1.83	0.17	0.12
Geometric mean[1] [exp (Ln T1/2)]		6.21		
Harmonic mean[2]			5.95	
T1/2 based on $0.693/\lambda_z$[3]				5.95

[1]Geometric mean = the back-transformed mean of the log-transformed variables

[2]Harmonic mean = the reciprocal of the arithmetic mean of reciprocals

[3]$T1/2 = Ln(2)/\lambda_z = 0.693/\lambda_z$. T1/2 can also be expressed as $Ln(1/2)/-\lambda_z = -0.693/-\lambda_z$.

TABLE 55.7 An example of differences in the LS mean versus the arithmetic mean

Subject #	Gender	$T^1/_2$ (hr)
1	Male	2
2	Male	3
3	Male	4
4	Female	7
5	Female	8
6	Female	9
7	Female	9
8	Female	7
9	Female	6
10	Female	8
Arithmetic mean		6.3
LS mean		5.3

TABLE 55.8 Survey results from a tourist company

Length of Journey	Bus	Car
>300 miles	38 travelers, average = 7.9 hr	22 travelers, average = 9.7 hr
200 to 300 miles	28 travelers, average = 6.3 hr	12 travelers, average = 7.7 hr
<200 miles	7 travelers, average = 3.4 hr	36 travelers, average = 4.8 hr
Arithmetic mean	6.64 hr	6.56 hr
LS means	5.86 hr	7.37 hr

statement, it is also evident that there is bias in the arithmetic mean. When considering that more folks used the bus when traveling from further distances, it became clear that in part, the arithmetic mean was confounded by the distance traveled. To correct for this imbalance, the LS mean was evaluated. When corrected for distance, the conclusion was actually quite different, and it was evident that the trip was generally more rapid when individuals took the bus (5.86 hr) as compared to the car (7.37 hr).

ASSESSING PRODUCT RELATIVE BIOAVAILABILITY. The pharmacokinetic and statistical considerations that are involved in the design and analysis of in vivo bioequivalence trials are described in CVM's Guidance #35 (Bioequivalence Guidance). The pivotal blood level parameters for supporting product comparability are the AUC measured from time zero to the last quantifiable drug concentration (for a single dose study), and the Cmax (FDA/CVM Guidance #35). When blood levels are measured under steady-state conditions, the AUC is measured over a single dosing interval ($AUC_{0-\tau}$). Prior to initiating any bioequivalence trial, CVM protocol concurrence is always strongly encouraged.

Ordinarily, studies are conducted with healthy animals that are representative of the species, class, gender, and physiological maturity for which the pioneer drug product is approved. The assumption is that the potential for formulation effects on drug absorption will be the same in the healthy animal and in the targeted patient population.

When using a bioequivalence trial to compare formulation effects, a basic tenant is that there is no difference in either the volume of distribution or the clearance of drug between administrations. For example, when comparing estimates of AUC, we are actually comparing the following:

$$\text{Relative bioavailability} = \frac{\frac{F_{test} \times D_{test}}{CL_{test}}}{\frac{F_{ref} \times D_{ref}}{CL_{ref}}}$$

where D_{test} = dose of the test product; D_{ref} = dose of the reference product; F_{test} = fraction absorbed of the test product; F_{ref} = fraction absorbed of the reference product; CL_{test} = total systemic clearance of the test product; CL_{ref} = total systemic clearance of the reference product.

It is only when $D_{test} = D_{ref}$ and $CL_{test} = CL_{ref}$ that our comparisons provide an unbiased estimate of the product ratio of fraction absorbed. Therefore, we cannot use traditional *in vivo* bioequivalence studies to compare two dosage forms that may differ in terms of the actual dose administered to or consumed by the patient. For example, a product approved for administration in drinking water may have a different pattern of intake as compared to the same drug in medicated feed. Therefore, even if the two dosage forms are found to have no pharmacokinetic differences (e.g., as shown by a comparison of equal gavage doses), potential differences in "D" under clinical conditions confound our ability to declare the two dosage forms as being bioequivalent.

Cmax is a parameter that reflects both the rate and extent of absorption. This point can be seen in the equation that describes Cmax for a drug that follows a one-compartment body model:

$$C\max = \frac{Ka \times F \times D}{V(Ka - Kel)} \times \left(e^{-Kel \times T\max} - e^{-Ka \times T\max}\right)$$

where Ka = the absorption rate constant, $Kel = \lambda_z$ = the terminal elimination rate constant (where Kel = CL/V), $Tmax$ = the time to Cmax, and V = the volume of distribution. Therefore, any change in F will influence both AUC and Cmax. However, changes in Ka affect only Cmax values.

Similar to AUC, to obtain an unbiased estimate of the influence of formulation on Cmax, we need to have a comparison where the values of D, V, and Kel are equal across treatments.

The ability to declare products as equivalent depends upon the number of subjects included in the investigation, the magnitude of difference in the pharmacokinetic parameter, and the variability associated with that parameter. When a crossover design is used, intersubject variability is removed from the statistical model, leaving only the variability that cannot be explained by either period or treatment effects. When a parallel study design is used, intersubject variability cannot be removed from the effects associated with treatment effects. Since between-subject variability is generally larger than within-subject variability, it is frequently more difficult to determine product bioequivalence when using a parallel as compared to crossover study design.

Statistically, CVM advocates use of the 90% confidence intervals (the one-sided test procedure originally described by Schuirrman (1987)). Within the U.S., the limits necessary to define bioequivalence are generally 0.80–1.20 (untransformed data, based upon treatment differences and expressed relative to the reference mean) or 0.80–1.25 (Ln-transformed data, expressed as the ratio of the test/reference means). While alternative statistical methods are described in CDER guidance documents (FDA/CDER Guidance for Industry, Statistical Approaches To Establishing Bioequivalence, Finalized 01/2001), use of these alternative methods has not been described in CVM's Guidance #35. When using the 90% confidence interval approach to declare two products as being bioequivalent, we are stating that we are 90% certain that the interval from X to Y contains the true ratio of treatment means across the population of individuals. For any level of certainty, the width of the interval can decrease by the following:

- Decreasing the variability in estimates of the treatment means. Therefore, study design and analytical method are important points of consideration. Whenever possible, crossover studies are generally preferred to parallel designs.
- An increase in subject numbers. The larger the sample size, the greater the representation of the true population. The better the representation of the population, the smaller the intervals need to be to achieve the same level of certainty.

To demonstrate the latter point, we simulated a parallel study that employed two identical populations of subjects. The parameter values for the two treatments were identical and each input parameter was generated with identical amounts of variability. In this simulation, the distribution of AUC values for the test and reference products were identical (and therefore, the two products were in fact equivalent). However, the AUC values for these two products had a coefficient of variation equal to ~30%. Using this information, we explored the frequency of simulating a bioequivalence trial that succeeded in demonstrating that the two products were indeed bioequivalent as a function of the number of subjects included in the study. The result of this exercise is provided in Table 55.9.

From this table, it is seen that despite the large variability, as study size increases, there is an increase in ability to accurately declare these two products as bioequivalent. With very large sample sizes, bioequivalence is declared despite the high level of variability associated with these two simulated datasets.

In a typical two-period crossover design, subjects are randomly assigned to either sequence A or sequence B with the restriction that equal numbers of subjects are initially assigned to each sequence. The design is as follows:

TABLE 55.9 Relationship between the numbers of subjects included in a simulated bioequivalence trial versus the frequency of correctly declaring these two products as being bioequivalent (e.g., 0.48 means that equivalence criteria were met in 48% of the simulations)

# Subjects	10	15	20	24	30	40	100	1000
Declare equivalence	0.48	0.57	0.65	0.70	0.73	0.78	0.97	1.00

Sequence A	Sequence B
Period 1 Test	Reference
Period 2 Reference	Test

A critical assumption in the two-period crossover design is that there is an equal magnitude of physiological and pharmacological carryover between periods 1 and 2, regardless of the order of treatment administration. This carryover is also termed *residuals* or *residual effects*. Unequal residual effects may result, for example, from an inadequate washout period. A one-period parallel design may be preferable when the drug induces physiological changes in the animal (causing a physiological carryover effect); when the drug has a very long terminal elimination half-life, creating a risk of residual drug present in the animal at the time of the second period dosing; and when the duration of the washout time for the two-period cross-over study is so long as to result in significant maturational changes in the study subjects.

Another assumption inherent in bioequivalence trials is that there is no subject by formulation interaction. In other words, the assumption is that the population of all potential drug recipients will exhibit similar relative bioavailability of the test and reference products. If this is not the case, it would be possible to overlook the presence of a small subpopulation for which the two products may not perform in an equivalent manner (Meyer 1995). Fortunately, subject-by-formulation interactions are rarely observed.

When a generic drug sponsor seeks the approval of a multistrength solid oral dosage form product, waiver of *in vivo* bioequivalence study requirements may be granted if *in vivo* bioequivalence has been demonstrated between the highest strengths of the generic and pioneer products, the lower dosage strengths exhibit in *vitro* dissolution characteristics comparable to that of the corresponding strength of the pioneer product, and the generic product formulations are dose-proportional with respect to the ratio of active and inactive ingredients. In cases where the active drug has poor water solubility, manufacturing and tableting conditions may alter product bioavailability and *in vivo* bioequivalence studies of both the highest and lowest dosage strengths may be needed. A bioequivalence waiver may be granted on the basis of *in vitro* dissolution if minor changes in the composition or manufacturing method of an approved product are proposed (refer to FDA/CVM Guidance #83: Chemistry, Manufacturing and Controls Changes to an Approved NADA or ANADA: Guidance). Most recently, the mechanism for granting waivers for Type A medicated articles has been established for active ingredients that are soluble in aqueous fluids across a pH range of 1.2 (0.1N HCl) to 7.5 (FDA/CVM Guidance for Industry #171).

UNDERSTANDING THE RELATIONSHIP BETWEEN DOSE AND DRUG EXPOSURE. Examples of the many variables that can potentially influence drug exposure were described in the previous section "Interpreting the Pharmacokinetic Information Provided in the Package Insert."

Much of the information generated on the safety of products under the intended dosing conditions are derived from the TAS study (refer to the previous section "Technical Sections of NADAs/Target Animal Safety (TAS)." The use of exaggerated doses and duration of dosing during the TAS study accommodates the variability in animal sensitivity to the drug and its metabolites. In addition to difference in kinetics that can occur across animal breeds, there can also be changes in CL that occur as a consequence of disease (Kraemer et al. 1982; Abdullah and Baggot 1986, 1988; Monshouwer et al. 1996a,b; Renton 2001). Since TAS studies are typically conducted in healthy animals, blood samples taken during the TAS study can help identify the potential risk of toxicity if/when some pharmacokinetic parameters change under disease conditions.

To illustrate how blood level data may be helpful in the interpretation of target animal safety data, let's take a hypothetical example of a drug that exhibits nonlinear absorption. For simplicity, let's assume that our orally administered drug follows a one-compartment open body model with the following mean pharmacokinetic parameters: ka = 1.25 hr^{-1}, kel = 0.05 hr^{-1}, and V/kg = 1.0 l. In this example, F is ~100% below a 100 mg dose, but declines to ~28% at a 500 mg dose. The actual mg dose absorbed in this example is provided in Figure 55.6.

Although we administered a 1X, 3X, 5X dose (100, 300, and 500 mg dose), the drug exposure reflected the absorption of only a 90 mg, 132 mg, and 140 mg dose (i.e., F = 0.9, 0.44, and 0.28 for a 1X, 3X, and 5X dose, respectively). Such nonlinearity may occur with some drugs, particularly those orally administered drugs that either are absorbed via carrier-mediated pathways or are highly lipophilic in nature (therefore, in vitro dissolution may be problematic at exaggerated doses). Generally, the animals

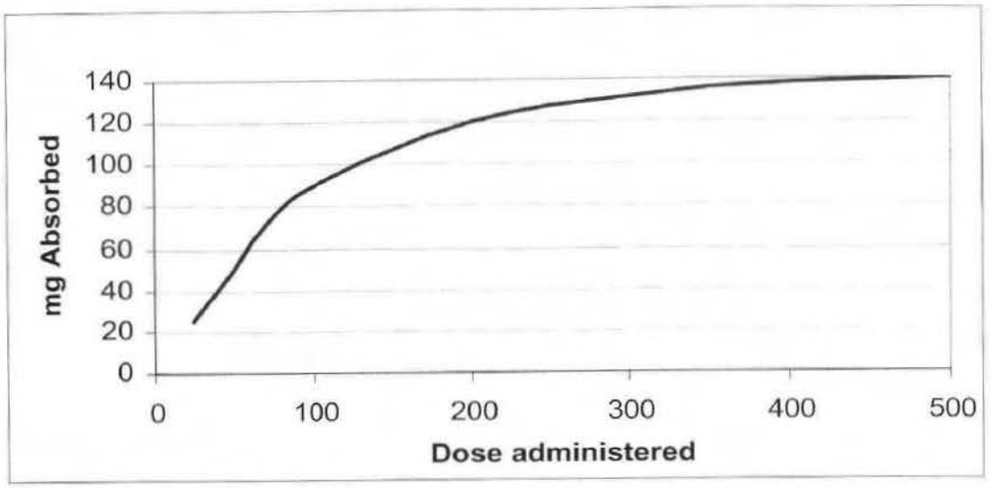

FIG. 55.6 Nonlinear absorption.

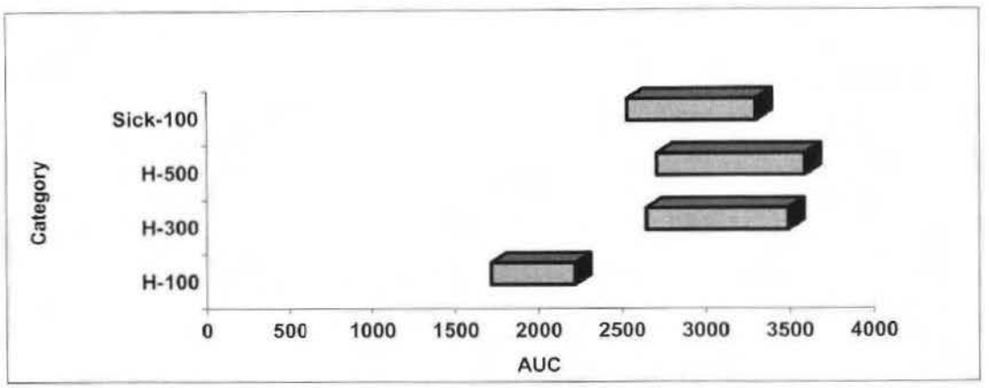

FIG. 55.7 Simulated example of a potential relationship between dose and AUC in healthy versus diseased animals.

enrolled in the TAS trial are of a single breed, healthy, and are maintained under well-controlled conditions. The laboratory setting tends to minimize between-subject variation. To accommodate the potential differences in pharmacokinetics in laboratory animals versus the targeted animal patient, our simulations include a 50% reduction in CL and an increase in the variability of that CL to 40% CV. For the sake of simplicity, we will assume that there is no change in either F, Ka, or V. The resulting AUC values (mean ±1 standard deviation) are provided in Figure 55.7.

In this illustration, there is a substantial difference in the AUC of the 1X versus the 3X and 5X groups during the TAS study. However, under the simulated conditions for diseased animals, there is an overlap between the AUCs associated with a 1X dose in diseased subjects versus the 3X and 5X drug exposure generated with parameters representing laboratory animals. Thus, in this example, it would be preferable to consider the margin of safety from a perspective of drug exposure rather than of dose.

CONCLUSION

The Center for Veterinary Medicine is a consumer protection agency, fostering public and animal health by approving safe and effective products for animals and by enforcing other applicable provisions of the Federal Food, Drug, and Cosmetic Act and other authorities. CVM works to safeguard the health and increase productivity of food-producing animals in the United States—97 million cattle,

59 million pigs, 8.8 billion chickens, 272 million turkeys, and 7 million sheep. CVM also evaluates the safety and effectiveness of drugs used to treat more than 100 million companion animals (http://www.fda.gov/opacom/factsheets/justthefacts/6cvm.html). The regulation of new animal drugs represents an interaction of science, statistics, veterinary practice, and law. These efforts are complicated by an ever-changing scientific, political, and veterinary medical landscape. As these changes occur, regulators work diligently in an effort to accommodate new issues, concerns, and technologies.

INTRODUCTION

A pharmacist's responsibility for providing patients with high-quality pharmaceutical care extends beyond the human species. Although colleges of pharmacy and licensing boards have focused almost exclusively on human pharmacotherapy, society expects an equally competent quality of pharmaceutical care and products to be provided for non-human family members. Veterinarians are well schooled in providing quality care and products to animal patients, but few pharmacists are. It behooves all pharmacists to be equipped with a working knowledge of veterinary pharmacotherapy and to develop a clinically and legally sound algorithm for processing veterinary prescriptions. Because this process is very slowly evolving in the pharmacy profession, veterinarians should be well versed in pharmacy issues related to veterinary medical therapy. Although several of these issues have been introduced or discussed in previous chapters, this chapter describes a variety of pharmacy-related topics of which all veterinarians should be aware.

REGULATORY REQUIREMENTS FOR USE OF DRUGS IN ANIMAL PATIENTS

Unlike human patients, some animals or their by-products have potential to end up in the human food chain. Drug use and consequential drug residues in animal tissue pose a human health hazard through allergic reactions, bacterial resistance due to chronic exposure to drugs, and carcinogenicity. Because of these hazards, the Animal Drug Amendment to the Food Drug and Cosmetic Act imposed

a strict regulation on the use of drugs in animal patients stating that drugs must be used as labeled in the approved species, for the approved indication, and at the approved dose. All animal patients were included in this ruling because it was increasingly difficult to categorize food animals strictly by species. Traditional food animals in the United States include cattle, pigs, poultry, fish, shellfish and their meat, milk, and eggs. However, animals such as dogs, rabbits, ostriches, and alligators can be considered pets, food animals, or exotic animals, depending on cultural or philosophical preference.

REGULATORY DISCRETION FOR EXTRALABEL USE

Advances in medical knowledge occur at a much faster rate than do drug product approvals. Since it is impossible for a drug company to test marketed drugs in all species at all doses and for all indications, very few approved drug products can be used by veterinarians to achieve therapeutic successes strictly as described on the product label. Passage of the Animal Drug Amendment in 1968 significantly restricted use of drugs in animals to use only in those species for which the product was labeled with strict adherence to the labeled indication, dose, route of administration, and duration of therapy. Any use of a human-labeled drug in animals, for example, would be illegal. Pursuant to enactment of this legislation, veterinarians were forced to break the law most of the time when using drugs in their patients. Physicians, on the other hand, were still allowed to use any drug at any dose for any indication in human patients.

Realizing the impracticality of strict interpretation of this law for veterinarians, the Food and Drug Administration published compliance policy guidelines (CPGs) in 1993 to show veterinarians the boundaries for regulatory discretion by FDA inspectors. Four main CPGs provided the boundaries for drug use by veterinarians: Extralabel Drug Use, Human Label Drug Use, Use of Drugs in Food Producing Animals, and Compounding for Animals (see www.fda.gov for summaries of these CPGs).

NEED FOR LEGAL EXTRALABEL USE—AMDUCA

Although these CPGs provided veterinarians with a higher comfort level for using drugs in animal patients, extralabel use of drugs in animals was still illegal. The law did not change. CPGs only informed veterinarians of occasions when FDA inspectors would exercise regulatory discretion with respect to interpreting and enforcing extralabel drug use. In 1993, veterinarians, tired of being forced to break the law, demanded the same legal right physicians had in treating their patients. On October 22, 1994, the Animal Medicinal Drug Use Clarification Act (AMDUCA) was passed allowing veterinarians to legally use drugs off label under certain circumstances. AMDUCA went into effect December 9, 1996. Concurrently, Congress passed the Animal Drug Availability Act, significantly expediting the process by which FDA approved products intended for use in animals. Passage of both laws was intended to significantly improve the ability of veterinarians to best treat nonfood-producing animal patients.

ANIMAL MEDICINAL DRUG USE CLARIFICATION ACT. On October 22, 1996, the Animal Medicinal Drug Use Clarification Act of 1994 was enacted into law, allowing veterinarians to prescribe extralabel use of veterinary and human drugs for animals under specific circumstances

TABLE 56.1 Requirements for extralabel drug use (ELDU) in animals

- ELDU is permitted only by or under the supervision of a veterinarian.
- ELDU is allowed only for FDA-approved animal and human drugs.
- A valid veterinarian/client/patient relationship is a prerequisite for all ELDU.
- ELDU is for therapeutic purposes only (animal's health is suffering or threatened), not for production use.
- Rules apply to dosage for drugs and drugs administered in water. ELDU in feed is prohibited.
- ELDU is not permitted if it results in a violative food residue, or any residue that may present a risk to public health. FDA prohibition of a specific ELDU precludes such use (Table 56.2).

TABLE 56.2 Drugs prohibited for extralabel use in food animals

- Chloramphenicol
- Clenbuterol
- Diethylstilbestrol (DES)
- Dimetridazole
- Ipronidazole
- Other Nitroimidazoles
- Furazolidone (except for approved topical use)
- Nitrofurazone (except for approved topical use)
- Sulfonamide drugs in lactating dairy cows (except approved use of sulfadimethoxine, sulfabromomethazine, and sulfaethoxypyridazine)
- Fluoroquinolones
- Glycopeptides (example: vancomycin)
- Phenylbutazone for female dairy cattle over 20 months of age

TABLE 56.3 Record requirements for drugs dispensed for animals

- Identify the animals, either as individuals or a group.
- Animal species treated.
- Numbers of animals treated.
- Condition being treated.
- The established name of the drug and active ingredient.
- Dosage prescribed or used.
- Duration of treatment.
- Specified withdrawal, withholding, or discard time(s), if applicable, for meat, milk, eggs, or animal-derived food.
- Keep records for 2 years.
- FDA may have access to these records to estimate risk to public health.

TABLE 56.4 Label requirements for drugs prescribed for animals

Name and address of the prescribing veterinarian.
Established name of the drug.
Any specified directions for use including the class/species or identification of the animal or herd, flock, pen, lot, or other group; the dosage frequency and route of administration; and the duration of therapy.
Any cautionary statements.
Your specified withdrawal, withholding, or discard time for meat, milk, eggs, or any other food.

and also codified compounding for animal patients provided the starting ingredients were FDA-approved drug products. The key extra-label provisions of the Animal Medicinal Clarification Act are provided in Table 56.1. (A copy of the AMDUCA Extra Label Drug Use Guidelines Brochure is available in the February 15, 1998, issue of JAVMA or may be obtained from the AVMA website: www.avma.org.) Some drugs are strictly prohibited from administration to food animals because a safe level of residue in food products cannot be identified (Table 56.2).

Additional provisions of the AMDUCA legislation require proper dispensing and labeling of prescribed drugs for animals (Tables 56.3 and 56.4).

CLASSIFICATION OF DRUGS

DRUG. A chemical can be considered a drug if is meets one of the following criteria:

1. It is an article recognized in one of the official compendia, i.e., the *United States Pharmacopoeia/National Formulary* or the official *Homeopathic Pharmacopoeia* of the United States or their supplements.

TABLE 56.5 A valid veterinarian-client-patient relationship (VCPR)

- The veterinarian has assumed the responsibility of making medical judgments regarding the health of the animal(s) and the need for medical treatment, and the client (owner or other caretaker) has agreed to follow the instructions of the veterinarian.
- There is sufficient knowledge of the animal(s) by the veterinarian to initiate at least a general or preliminary diagnosis of the medical condition of the animal(s). This means that the veterinarian has recently seen and is personally acquainted with the keeping and care of the animal(s) by virtue of an examination of the animal(s), and/or by medically appropriate and timely visits to the premises where the animal(s) are kept.
- The practicing veterinarian is readily available for follow-up in case of adverse reactions or failure of the regimen of therapy.

2. It is an article intended for use in the diagnosis, cure, mitigation, treatment, or prevention of disease in man or other animals.
3. It is an article other than food intended to affect the structure or any function of the body of man or other animals.
4. It is an article that is intended to be used as a component of an item falling into one of the three categories above.

This definition does not differentiate between prescription drugs and nonprescription drugs, nor does it distinguish legal or lawful drugs from illicit ones. Because of this broad definition, *any substance that is used to treat an animal can be ultimately considered to be a drug and can be regulated and actionable as such.*

LEGEND ("PRESCRIPTION") DRUGS. Prescription drugs are limited to dispensing by or upon the order of a licensed prescriber ("prescription") because they are habit forming, are toxic, or have potential for harm. These drug labels contain the following warnings identifying them as legend drugs:

- *Veterinary Legend*: "Caution: Federal law restricts this drug to use by or on the order of a licensed veterinarian."
- *Human Legend:* "Rx only."

Legend (prescription) drugs *cannot* be dispensed without a prescription and may only be prescribed and dispensed within the confines of a valid veterinarian-client-patient relationship (VCPR) (Table 56.5). Because of the requirement of a valid VCPR, if a veterinarian has not examined the animal, he/she cannot prescribe legend drugs for use in that animal. Likewise, a veterinarian cannot "fill a prescription" for an animal unless he/she has a valid

veterinarian-client-patient relationship with that animal. Veterinarians filling prescriptions for other veterinarians are considered to be practicing "pharmacy" and are subsequently subject to action by state pharmacy regulatory boards.

OVER-THE-COUNTER ("NONPRESCRIPTION") DRUGS. Over-the-counter (OTC) drugs are also considered "nonprescription" drugs. These are familiar to veterinarians and pet owners because they are available for human use in retail outlets such as pharmacies, markets and grocery stores. Such OTC products can also be found for animals in the same retail outlets as for humans as well as in pet and feed stores. These drugs have been recognized by experts as safe and effective and bear extensive labeling which renders them safe for use by laypersons and are sold "over the counter," without a prescription.

All OTC products must be used *precisely* as labeled just as legend drugs. Use outside of these specifications constitutes extralabel use and the aforementioned guidelines should govern this use. Veterinarians should avoid repackaging OTC medications for dispensing because reproducing the required labeling that is comprehensive enough for safe use by a layperson is difficult and dangerous.

CONTROLLED SUBSTANCES. Controlled substances ("narcotics") are defined and monitored by the Drug Enforcement Authority (under jurisdiction of the Controlled Substances Act of 1970) and are divided into five schedules according to potential for abuse. An example of the schedules used for opiate drugs is provided in Chapter 12. These drugs are strictly controlled by federal and state law and specific requirements for administering, dispensing, and prescribing are addressed later in this chapter.

COMPOUNDED DRUGS. Compounded drugs are mixtures of approved dosage forms or drugs formulated from bulk chemicals that are not approved by FDA for use as drugs in the United States. Veterinarians may compound items for their own use or write prescriptions for their patients for some of these chemicals to be filled by licensed pharmacists. These chemicals (e.g., potassium bromide, cisapride, phenylpropanolamine, diethylstilbestrol) are recognized by FDA to be essential in the treatment of some companion, nonfood animals. As many of these chemicals have been withdrawn from the market due to human hazards, the FDA has published a "negative" list for human compounding describing the chemicals that are either prohibited for use in humans or are restricted to small dosages. Note that some of the chemicals (e.g. cisapride and diethylstilbestrol) may still be compounded for nonfood animals such as companion animal pets but never for food animals or humans.

CURRENT STATUS OF COMPOUNDED VETERINARY DRUGS

Drug compounding has always been an important component of veterinary medicine. Historically, veterinarians have prepared concoctions, mixtures, and remedies for their patients because there were few approved formulations on the market for animals. Now, there are more available drugs for animals, and pharmaceutical science has provided for a better understanding of the risk factors contributing to poor drug bioavailability, instability and physical incompatibility. Over the last several years, questions concerning the practice of compounding have been raised, particularly with respect to stability, purity, and potency when the original dosage form of the drug is altered.

Compounding is the alteration of the original drug dosage form for the purposes of ease of administration or because the original dosage form is unsuitable for the purpose intended. According to the *United States Pharmacopeia* (USP), compounding involves the preparation, mixing, assembling, packaging, and labeling of a drug or device in accordance with a licensed practitioner's prescription. The USP chapter on pharmacy compounding states that "compounding is an integral part of pharmacy practice and is essential to the provision of health care" (USP [795]).

Further defined by the FDA in an early Compliance Policy Guideline (FDA-CVM 1996), "compounding is any manipulation to produce a dosage form drug other than that manipulation that is provided for in the directions for use on the labeling of the approved drug product." Compounding does not include the preparation of a drug by reconstitution or mixing that is according to the manufacturer's instructions on an approved human or veterinary drug product.

In 1993, a symposium on compounding in veterinary medicine was held by the American Academy of Veterinary Pharmacology and Therapeutics (AAVPT) (JAVMA 1994). This symposium had representatives from AVMA, FDA/CVM, pharmacology and pharmacy groups, and USP. From this symposium emerged a Task Force Report

TABLE 56.6 Compounding Compliance Policy Guideline (Federal Register, July 3, 1996)

1. The FDA lists three criteria that must be met before compounding is deemed necessary and acceptable.
   (1) A legitimate medial need is identified (the health of animals is threatened and suffering or death would result from failure to treat the affected animals),
   (2) There is a need for an appropriate dosage regimen for the species, age, size, or medical condition of the patient, and
   (3) There is no marketed approved animal drug which when used as labeled (or in an extra-label manner in conformity with criteria listed in CPG 615.100, or human-label drug, when used in conformity with criteria listed in CPG 608.100) may treat the condition diagnosed in the available dosage form, or there is some other rare extenuating circumstance. (For example the approved drug cannot be obtained in time to treat the animals in a timely manner, or there is a medical need for different excipients.)
2. All drugs dispensed to the animal owner by the veterinarian or pharmacist bear labeling information which is adequate to assure proper use of the product. The following label information should be included:
   (a) name and address of the veterinary practitioner;
   (b) active ingredient(s) or ingredient(s),
   (c) the date dispensed and the expiration date, which should not exceed the length of the prescribed treatment except in cases where the veterinarian can establish a rationale for a later expiration date,
   (d) directions for use specified by the practitioner, including the class/species or identification of animals; and the dosage, frequency, route of administration, and duration of therapy,
   (e) cautionary statements specified by the veterinarian and/or pharmacist (this would include all appropriate warnings necessary to ensure safety of human operators handling the finished drug, especially if there are potential hazards of exposure to any components,
   (f) the veterinarian's specified withdrawal/discard time(s) for meat, milk, eggs or any food which might be derived from the treated animal(s). (While the veterinarian must set the withdrawal time, he may in doing so use relevant information provided by a dispensing pharmacist although the veterinarian retains the ultimate responsibility),
   (g) if dispensed by a licensed pharmacist, the name and address of the dispenser, serial number and date of order or its filling,
   (h) if dispensed by a veterinarian, the serial number, and
   (i) any other applicable requirements of state or federal law.

that summarized the presentations and resulted in the Compliance Policy Guide published in 1996, summarized in Table 56.6 (FDA 1996). The proceedings from this symposium are very informative and contain 115 pages of presentations, which cannot be adequately summarized here. The FDA revised this Compliance Policy Guide (CPG) for compounding drugs for use in animals in 2003 (FDA-CVM 2003). The 2003 version of the CPG provides guidance to FDA's staff with regard to the compounding of animal drugs by veterinarians and pharmacists for use in animals. This CPG is available from the FDA, or on the Internet at this address: http://www.fda.gov/ora/compliance_ref/cpg/default.htm or http://www.fda.gov/OHRMS/DOCKETS/98fr/03d-0290-gd10001.pdf. At the time of this writing, the FDA is apparently revising the CPG for a third iteration, but that document is not yet available for public view.

The FDA recognizes the importance of compounding in veterinary practice, but also must ensure that compounded drugs do not cause harm to the treated animals or their caregivers, that compounded preparations are bioavailable, effective, stable and potent, and that compounded preparations do not cause drug residues in food animals. FDA regulations permit the compounding of formulations from approved animal or human drugs under the current federal code: 21 *CFR* 530.13 (AMDUCA). The FDA is concerned that some compounding by veterinarians and pharmacists is performed to circumvent the usual drug approval process. Some activities performed under the guise of compounding (e.g., mass preparation of compounds that are wholesaled to veterinarians with no patient identified at the time of compounding, *dispensing* of compounds intended only for *administration* by the veterinarian in the office, or compounding less expensive copies of commercially available approved drugs) mimics exactly the manufacturing and distribution of what FDA defines as "new animal drugs." A court ruling by the 5th Circuit of Appeals (*Medical Center Pharmacy vs. Mukasey*, July 2008) reasserted that compounds prepared for animals outside of the provisions of AMUDCA definitely fit the description of new animal drugs. New animal drugs must undergo the long and arduous FDA approval process to ensure the safety of the public health. Compounds have clearly not undergone this scrutiny to determine the safety, efficacy, potency, purity, and stability required of drug manufacturers in order to receive FDA approval for marketing. Pharmacies are held to Good Compounding Practices as adopted by their state boards of pharmacy; however, compounds, under no circumstances, can be manufactured or wholesaled. Licensed veterinary distributors who wholesale compounds from compounding pharmacies are in direct violation with licensure as granted by state licensing agencies (usually the Department of Agriculture). Compounds must be prepared pursuant to a valid prescription

order for an individual patient or for use in a veterinary practice ("office use") in the few states where this is permitted according to state law. At the time of this writing, only 20 states allow compounding for office use and all 20 states specifically prohibit dispensing of "office use" compounds to be used outside of the veterinary practice.

The CPG published in July 2003 specifically was intended to clarify the regulations on compounding from unapproved or bulk chemicals. *Bulk chemicals* are defined as active ingredients used in the manufacture of finished dosage forms of the drug. Bulk chemicals are also referred to as *active pharmaceutical ingredients (APIs)*. Compounding from APIs or unapproved drug substances is not allowed except for a few chemicals provided in Appendix A of the 2003 version CPG for Compounding For Animals. Compounding with these chemicals is allowed in instances where the health of the animal is at risk and there are no other remedies. The list includes antidotes such as methylene blue, sodium thiosulfate, or sodium nitrite. (A complete list of bulk chemicals tolerated for animal compounding is listed in the FDA document cited earlier.) Chemicals used for compounding that are not listed in Appendix A are subject to FDA regulatory discretion. The FDA has seized compounds prepared from bulk chemicals and issued warnings to pharmacies when there have been violations (http://www.fda.gov/foi/warning.htm). At the time of this writing, a legal battle initiated by compounding pharmacies challenging FDA's right to regulate compounding pharmacies has been heard and successfully appealed in the 5th District Circuit of Appeals. While this ruling is in direct conflict with a previous ruling by the 9th Circuit Court of Appeals in 2001 regarding compounding for humans, the legality of compounding with bulk chemicals for human patients must be decided by either the Supreme Court or codified through legislation. As the rulings by the 5th and 9th Circuit Courts of Appeals did not apply to compounding for animals, this too must be challenged at the level of the Supreme Court or codified through legislation.

POTENTIAL PROBLEMS FROM COMPOUNDED DRUGS

Because many drugs are not in a form that is ideal for the species being treated, either due to body size, taste preferences, or species-specific metabolic intolerances, commercially available drug products have been altered to make a more convenient and palatable oral dose form. However, when protective coatings on tablets or capsules are disrupted, and suspending or solubilizing vehicles are diluted or changed, the bioavailability and stability of the product may be compromised. In some instances, the only change is a slight alteration of pH. But, according to the USP (2008), "improper pH ranks with exposure to elevated temperature as a factor most likely to cause a clinically significant loss of drug. A drug solution or suspension may be stable for days, weeks, or even years in its original formulation, but when mixed with another liquid that changes the pH, it degrades in minutes or days. It is possible that a pH change of only one unit could decrease drug stability by a factor of ten or greater." Addition of a water-based solution to a product to make a liquid solution or suspension can hydrolyze some drugs (beta-lactams, esters). Some drugs undergo epimerization (steric rearrangement) when exposed to a pH range higher than what is optimum for the drug (for example, this occurs with tetracycline at a pH higher than 3). Other drugs are oxidized, catalyzed by high pH, which renders the drug inactive. Drugs most likely to be subject to oxidation are those with a hydroxyl group bonded to an aromatic ring structure. Oxidation may occur from exposure to light and oxygen during reformulation and mixing. Oxidation is catalyzed by high pH and usually leads to drug inactivation. Other factors contributing to instability and decrease in bioavailability may be through the addition of sugars and starches to an oral suspension. For example, it is well documented that the presence of sugar significantly decreases the stability of oral suspensions of atenolol and pyrimethamine, and the addition of methylcellulose to solutions of pyridostigmine will significantly decrease the oral bioavailability of pyridostigmine resulting in potential harm to the patient receiving these medications.

Veterinarians and pharmacists are obligated to be cognizant of the potential for interactions and interference with stability (Table 56.7). Oxidation is often visible through a color change (color change to pink or amber, for example). Loss of solubility may be observed through precipitation. Some drugs are prone to hydrolysis from moisture. A rule-of-thumb for veterinarians is that if a drug is packaged in blister packs or moisture-proof barrier, it is probably subject to loss of stability and potency if mixed with aqueous vehicles. If compounded formulations of solid dose forms show cracking or "caking," or swelling, the formulation has probably accumulated moisture and may have lost potency. Another rule-of-thumb is that if the original packaging of a drug is in a light-resistant or amber container it is prob-

TABLE 56.7 Signs of drug instability of compounded formulations

Liquid Dose Forms
Color change (pink or amber)
Signs of microbial growth
Cloudiness, haze, flocculent or film formation
Separation of phases (e.g., oil and water, emulsion)
Precipitation, clumping, crystal formation
Droplets or fog forming on inside of container
Gas or odor release
Swelling of container
Solid Dose Forms
Odor (sulfur or vinegar odor)
Excessive powder or crumbling
Cracks or chips in tablets
Swelling of tablets or capsules
Sticking together of capsules or tablets
Tackiness of the covering of tablets or capsules

ably prone to inactivation by light. Vitamins, cardiovascular drugs, and phenothiazines are labile to oxidation from light during compounding. Also, as a general rule, if an antibiotic is available in a powder that must be reconstituted in a vial or oral dispensing bottle prior to administration, it is probably unstable for long periods of time and should also not be mixed with other drugs.

EXAMPLES OF POTENTIAL PROBLEMS. There are very few published studies in which drugs for veterinary patients have been tested for stability under the conditions used during compounding. In a commercial formulation, the inactive ingredients and excipients added to drug formulations are done so as to ensure the stability of the drug; provide an optimum chemical environment, pH; or increase the ease of packaging or handling. However, adding other chemicals, flavorings, or vehicles, or interfering with protective coatings of tablets may affect the stability of the drug, decreasing potency, oral absorption, and efficacy. There are published formulas in compounding journals, and texts, but few of these formulations have been tested for safety, efficacy, bioavailability, stability, potency, and purity for use in the target species. As the responsibility for risk when using compounded preparations rests squarely on the shoulders of prescribing veterinarians, they have an obligation to request evidence from compounding pharmacists about the stability and potency of formulations prepared for their patients. When veterinarians compound formulations in their own practices, they should be cognizant of the potential interactions and alterations that may compromise the stability and potency of the active ingredient and should not attempt compounding without proper training, equipment, and quality assurance techniques.

There are published examples in which drug stability and efficacy have been compromised through compounding. For example, when omeprazole was compounded for oral use in horses, it was not as effective for treating gastric ulcers as the commercial formulation registered for horses (Gastroguard) (Nieto et al. 2002). Systemic bioavailability and potency of the compounded formulation was not as high as for the proprietary product. Omeprazole is known for its instability unless administered in the original formulation intended for horses or people.

Fluoroquinolone antibiotics are frequently modified for administration to exotic animals and horses. The compatibility of enrofloxacin and orbifloxacin with flavorings, vehicles, and other ingredients has been evaluated. With few exceptions, this class of drugs is compatible with most mixtures and remarkably stable. A notable exception is the chelation of enrofloxacin with iron and aluminum-containing products (e.g., antacids, sucralfate, mineral supplements, iron-containing molasses), in which a significant portion of the medication may become unavailable for absorption. It has also been observed that certain mixtures and flavorings may be incompatible with fluoroquinolones if they contain metal ions that are known to cause chelation. For example, when crushed orbifloxacin tablets were mixed with a vitamin and mineral supplement (Lixotinic) that is sometimes used as a flavored vehicle for oral administration of drugs, the potency of orbifloxacin was decreased from its original concentration by 50%. (Lixotinic contains 2.5 mg/ml iron.) Other flavorings and vehicles (for example, corn syrup, regular molasses, fish sauce, and Syrpalta) had no effect.

Antifungal drugs are subject to instability if not maintained at an optimum pH and formulation conditions. Itraconazole is frequently compounded from the bulk chemical or the proprietary capsules. However, itraconazole must be complexed onto cyclodextran in order to be orally bioavailable, and as bulk chemical preparations of itraconazole are not complexed in this fashion, they have not been found to be orally bioavailable in animal patients. Itraconazole may also adsorb to plastic and glassware during compounding, decreasing the predicted potency of the finished preparation.

Aminoglycoside antibiotics (gentamicin, tobramycin, kanamycin) are inactivated when admixed with other

antibiotics, particularly beta-lactams. This interaction is greatest from carbenicillin, followed by ticarcillin, penicillin G, and ampicillin. Loss of potency by as much as 50% can occur within 4 to 6 hours. This interaction is a potential problem when antibiotic mixtures are prepared in a vial or fluid administration set and dispensed to be used several hours later. This interaction does not occur intravascularly at therapeutic concentrations in the patient because the drugs are diluted out in plasma and body fluids, but visual precipitation of these agents in IV administration sets is commonly reported when they are mixed.

Drugs formulated as acids—such as the hydrochloride form of basic drugs—are formulated to maintain their solubility in aqueous solutions. However, when these formulations are mixed with other drugs that are more basic, or added to basic vehicles, drug precipitation may occur.

Several drugs are not soluble in aqueous vehicles. Therefore they are dissolved in organic solvents (propylene or ethylene glycol, for example) or alcohols. These are notoriously unpalatable to some animals, particularly cats. However, if these formulations are diluted in aqueous fluids, precipitation may occur. When these are stored at home by the pet owner, precipitation of the drug to the bottom of the container results in dilute oral dosing when the container is sampled from the top, and highly concentrated formulation when the container is sampled from the bottom (assuming that the precipitate at the bottom can be resuspended). This also may be observed when mixing some drugs in aqueous fluids. For example, if diazepam solution (which contains propylene glycol and alcohols) is diluted in saline solution or Lactated Ringer's solution, precipitation occurs.

COMPOUNDED TRANSDERMAL MEDICATIONS FOR PETS. Because of convenience, ease of administration, and therapeutic success with some transdermal drugs (antiparasitic agents and fentanyl), there is considerable interest in formulating a wide range of other drugs for use by this route. Historically, transdermally administered drugs were formulated for single-dose delivery in a liquid preparation, or for continuous delivery out of a drug-releasing matrix or "patch." A compounding pharmacist (Marty Jones, PharmD) discovered a penetration-enhancing drug vehicle in the 1990s, and application of this delivery system to drugs used in animals rapidly caught on. A quick Internet search of "compounding pharmacy + transdermal" will reveal over 11,000 advertisements from compounding pharmacies who provide drugs in transdermal delivery gels. Noninvasive, nonstressful, palatable drug delivery is ideal for many veterinary patients, especially cats. Consequently, many veterinarians are eager to try this dosage form on fractious or fragile patients who should not be (or do not want to be) stressed during medication. While transdermal drug delivery is appealing, there are still many questions to be resolved regarding its use in veterinary medicine. The skin is a formidable barrier to drug penetration, and drug absorption into systemic circulation is a predictably tricky feat. In order to facilitate drug transport across skin, drugs need to be small in molecular weight and placed in a biphasic vehicle that can propel the drug across the various lipophilic and hydrophilic layers of the skin. Passage of the drug across the skin relies on the thickness of the skin, the partition coefficient of the drug, the diffusion coefficient of the skin, and the concentration of drug in solution. The partition coefficient, the diffusion coefficient, and the thickness of the skin are not alterable, so transdermally applied drugs must be placed in high concentrations in vehicles that accommodate the various coefficients of diffusion. Drugs have been combined with penetration enhancers to facilitate transdermal absorption. One commonly used penetration enhancer is pleuronic lecithin organogel (PLO), which is lecithin (derived from eggs or soybeans) mixed with isopropyl palmitate and a poloxamer (Pluronic). The ingredients in PLO act as surfactants, emulsifiers, and solubilizing agents to escort drug across the skin into systemic vasculature. There are many other penetration-enhancing vehicles (e.g., Lipoderm, Van Penn) utilized to compound transdermal preparations, but at the time of writing, there are no commercially available formulations that utilize these penetration-enhancing vehicles to deliver systemic drugs. Most commercially available transdermal drugs are available as patch delivery systems or are single-dose applications of parasiticides. Compounded transdermal preparations are formulated in high concentrations so that a therapeutic dose may be delivered in 0.1–0.2 ml, which is applied to a hairless area and rubbed in until no residue remains on the skin surface. Because the drug must be in solution in order to penetrate skin, many drugs are logically precluded from transdermal administration because they are not soluble in concentrations high enough to deliver a dose in 0.1–0.2 ml (e.g., any drug dosed at 10 mg/kg requires a transdermal concentration of at least 500 mg/ml to deliver a 0.1 ml dose to a 5 kg cat). The majority of drugs are not soluble at these high concentrations.

At the time of this writing, there have been few published reports regarding compounded transdermally administered drugs. Single-dose pharmacokinetic studies for transdermally administered drugs have demonstrated that absorp-

tion was incomplete, nonexistent, or highly inconsistent among study cats, and that after single doses, bioavailability was low compared to a single oral dose. There have been an even smaller number of chronic dosing safety and efficacy studies for transdermally administered drugs, and few of those demonstrated positive evidence of efficacy. Incredibly, the stability or potency of the transdermal formulated for the study was not determined except in only two of the investigations, so it is difficult to draw conclusions from any study where the potency of the study drug was undetermined. Transdermally administered drugs examined so far have included methimazole, amlodipine, glipizide, dexamethasone, buspirone, amitriptyline, metoclopramide, atenolol, fentanyl, morphine, fluoxetine, and diltiazem. Methimazole was not absorbed well according to a pharmacokinetic study (Hoffman et al. 2002; Trepanier 2002), but produced clinical efficacy with repeated transdermal application in other studies (Hoffman et al. 2001). Transdermally administered amlodipine did effect a decrease in blood pressure in hypertensive cats and was found to be stable for at least 60 days when formulated in a transdermal gel (Helms 2007). Absorption of atenolol from a transdermal preparation in cats was low and inconsistent and did not produce therapeutic blood levels of atenolol after a week of chronic dosing at an equivalent oral dose. (MacGregor et al. 2008). The remaining drugs were examined as single-dose pharmacokinetic studies and showed poor bioavailability as compared to oral dosing and a high degree of intrasubject variation in drug absorption.

A major concern for use of transdermally administered drugs, for which there is no safety, efficacy, or potency evidence, is the risk of poor absorption or decreased stability of the formulated drug. For example, unstable or poorly absorbed transdermal antibiotics will surely result in subtherapeutic drug concentrations leading to therapeutic failure, and even worse, the development of antimicrobial drug resistance. Increased risk of toxicity also is a potential problem. Misinterpretation of single-dose pharmacokinetic studies might lead prescribers to increase transdermally administered drug doses, leading to accumulation of drug and severe toxicity. For example, the transdermal bioavailability of amitriptyline was 10% compared to oral dosing in a single dose pharmacokinetic study. Several veterinarians erroneously interpreted these results to mean that transdermal amitriptyline should effectively be administered at 10 times the oral dose. Obviously, there also is considerable risk for absorption by the human caregiver. Drugs toxic to humans (e.g., chloramphenicol, carprofen, digoxin) are extremely poor candidates for transdermal drug administration. Similarly, caregiver health and lifestyle must also be considered when prescribing transdermal drugs for pets. For example, a hypothyroid owner is a poor candidate to administer transdermal methimazole to her hyperthyroid cat, and a long-distance truck driver subject to periodic drug testing is a poor candidate for administration of transdermal opiates to his pet in pain.

COMPOUNDING GUIDELINES FOR VETERINARIANS AND VETERINARY PHARMACISTS. The FDA-CVM uses regulatory discretion to allow veterinary drug compounding within the scope of clinical veterinary practice through the Compliance Policy Guideline. However, there are still some restrictions that apply, and each state may have more restrictive requirements than federal law. The purity standard of the bulk chemical should be that of a USP- or an NF-grade substance. Compounded therapies should be prepared from a commercially available formulation, if a suitable approved product exists. Compounding from bulk chemicals is not allowed if a proprietary registered formulation is available unless the veterinarian can document a medically necessary reason (economic reasons are not valid) why the commercially available product is not appropriate. If bulk chemicals are utilized because there is no commercially available form (e.g., pergolide, potassium bromide, cisapride, or diethylstilbestrol), the pharmacist should use bulk chemicals obtained through an FDA-registered chemical supplier and accompanied by a valid certificate of analysis for that specific batch and lot number of chemical. It is absolutely critical that compounders examine the certificate of analysis for potency, because many bulk chemicals (e.g., aluminum hydroxide, doxycycline, and chloramphenicol palmitate) are not supplied as 100% potent powders and potency may be as low as 57% for some of these chemicals. If these bulk chemicals are used in compounding, appropriate mathematical conversions must be calculated to ensure expected potency of the final preparation.

It is the responsibility of the veterinarian and pharmacist to ensure that regulations and guidelines are being followed to ensure confidence in the compounded medication. The FDA website cited above lists the labeling requirements for compounded drugs. The United States Pharmacopeia (USP), a national standard-setting organization for pharmaceuticals, lists specific guidelines for pharmaceutical compounding in Chapters 795 Pharmaceutical Compounding—Non-Sterile Preparations, and 797 Pharmaceutical Compounding—Sterile Preparations,

(USP-NF 2008, http://www.usp.org). One important guideline for compounded preparations is that the final potency of the finished preparation is not less than 90.0% and not more than 110% of the theoretically calculated and labeled quantity of active ingredient per unit weight or volume. This is also the requirement for FDA-approved commercially available drugs, so the pharmacist may be starting with more or less of the active ingredient than is labeled on the commercially available product when utilizing approved products to compound. There are also guidelines available for stability considerations in the chapter on Observing Products for Evidence of Instability (Chapter 1191) (USP-NF 2008). Generally, the beyond-use dating (BUD) for a nonaqueous solid compounded dosage form should not be later than 25% of the time remaining until the expiration date of the shortest-dated ingredient or 6 months, whichever is shorter. For water-containing formulations the beyond-use date is not later than 14 days stored at cold temperatures, and for nonaqueous liquid formulations USP Chapter 795 allows for the beyond-use date to be no later than the intended duration of therapy or 180 days, whichever is earlier. These limits may be exceeded when there is supporting valid scientific data that applies to the specific compounded formulation.

The Society of Veterinary Hospital Pharmacists, an organization of academic veterinary teaching hospital pharmacists, has published a position statement on Compounding For Animal Patients that may be consulted by pharmacists or veterinarians for further guidance (http://www.svhp.org.).

Finally, veterinarians should seek the services of a Pharmacy Compounding Accreditation Board (PCAB) accredited pharmacy when prescribing compounds. Formed in 2004 by eight national pharmacy organizations, the nonprofit PCAB runs a voluntary accreditation program to ensure quality standards for compounding pharmacies. PCAB currently represents the only validated set of professional and ethical standards for compounding pharmacies. Once a pharmacy applies for PCAB accreditation, they must undergo a rigorous standards evaluation that is then validated by multiple site visits and inspections by PCAB surveyors. If a pharmacy meets the incredibly rigorous accreditation standards, a veterinarian can be assured that the pharmacy is legally and ethically impeccable and that its compounds are of the highest possible quality. At the time of this writing, PCAB has accredited 46 pharmacies in 40 states, and 40 more pharmacies are awaiting accreditation. PCAB maintains an interactive map of accredited pharmacies in each state list of accredited compounding pharmacies on their website, or veterinarians can contact PCAB's executive director to find an accredited pharmacy in their state. Further information regarding PCAB can be reached at http://www.pcab.org.

UNAPPROVED DRUGS AVAILABLE BY IMPORTATION

When a veterinarian requires a drug that is not approved for use in this country, but is available as an approved dosage form in other countries, he may obtain it through FDA's personal importation policy. These dosage forms may be obtained through importation from other countries by filing a Medically Necessary Personal Veterinary Import form with FDA CVM. This form may be obtained by contacting the FDA. The requesting veterinarian must complete information regarding intended use of the drug and quantities imported. Filing this form alerts the FDA to the fact that a veterinarian is importing a drug from out of the U.S. and will prevent the drug from being seized by U.S. Customs officials upon entry to the United States. Drugs deemed hazardous by FDA may still be seized.

PRESCRIBING CONTROLLED SUBSTANCES

A veterinarian who administers, dispenses, or prescribes controlled substances in the course of his practice *MUST* register with the Drug Enforcement Authority (DEA). This requires submission of an application, which may be obtained from the DEA. Practitioners must have a separate registration for every practice site employed. State regulations also must be followed and practitioners must contact their state authorities to determine the requirements.

Prescribing controlled substances requires submission of appropriate forms and maintaining records for controlled substances. Documentation must be made in the patient's medical record of all controlled substances administered, and such records must be stored in a readily retrievable fashion for 3 years. Appropriate entries must be made for waste or disposal of unused portions of controlled substance and witness is required for disposal. Records must be kept of all controlled substances dispensed, and such records must be stored in a readily retrievable fashion for 3 years. While the law does not specifically require a dispensing record separate from the medical record, a separate record-keeping system provides more readily retrievable dispensing

records than does the patient's medical record. A separate dispensing log does *NOT* replace the need to document dispensing of drugs in the medical record because these drugs are still restricted to the order of a licensed practitioner. It is also recommended that Schedule II dispensing records be maintained separately from other records.

PRESCRIBING RECORDS. Practitioners are not required to keep records of prescriptions written for controlled substances, but it is in the best interest of the veterinarian to make a note of such prescriptions in the patient's medical record to provide for a complete patient medical profile.

INVENTORY RECORDS. All DEA 222 order forms for Schedule II orders as well as other commercial invoices accompanying controlled drugs must be signed and dated, and items must be counted, noted, and stored in a readily retrievable file for 3 years. Schedule II records must be stored separately from Schedule III-V records.

A complete and accurate inventory of all stocks of all controlled substances must be taken every 2 years on the anniversary of the practitioner's initial DEA registration. The written inventory should contain the following information:

- The name, address, and DEA registration number of the registrant
- The date and time the inventory is taken
- The signature of the person taking inventory
- An indication that the inventory is maintained for at least 2 years at the location appearing on the registration
- An indication that inventory and other records of Schedule II drugs are maintained separately from other drugs

STORAGE AND SECURITY OF CONTROLLED SUBSTANCES. Controlled substances "must be stored in a securely locked, substantially constructed cabinet." If there is loss or theft, upon discovery of loss of theft of controlled substances, the registrant must immediately notify the region office of the DEA and then must complete DEA form 106 describing the loss. If a theft is verified, the local police department must also be notified.

DISPENSING MEDICATIONS INTENDED TO GO HOME WITH A PATIENT

Many state and federal legal requirements exist for the act of dispensing a drug to go home with a patient. Any prescription medications that leave a practice to go home with a patient must be labeled with the information indicated in Table 56.8.

Any medications that leave a practice to go home with a patient must be packaged in a child-resistant container

TABLE 56.8 Drug dispensing labeling requirements

- name, address, and phone number of the dispensing facility
- name of client
- animal identification (name and species)
- date dispensed
- full directions for use
- name, strength, and quantity of drug dispensed
- name of prescribing veterinarian
- for controlled substances, the label must also contain the message "Caution: Federal law prohibits transfer of this drug to any person other than the patient for whom it was prescribed."

TABLE 56.9 Requirements for writing a prescription for noncontrolled substances

The elements listed below are required by law to be included on the written prescription document:

- printed or stamped name, address, and telephone number of the licensed practitioner
- DEA registration number of the licensed practitioner
- legal signature of the licensed practitioner
- name and strength of drug
- directions for use
- full name and address of the client
- animal identification (name and/or species)
- cautionary statements including, if applicable, withdrawal times for food animals
- number of refills, if any

TABLE 56.10 Requirements for writing a prescription for controlled substances

The elements listed below are required by law to be included on the written prescription document:

- printed or stamped name, address, and telephone number of the licensed practitioner
- DEA registration number of the licensed practitioner
- legal signature of the licensed practitioner followed by printed name of the practitioner
- name and strength of drug
- directions for use
- full name and address of client
- animal identification (name and/or species)
- cautionary statements including, if applicable, withdrawal times for food animals

Note: No refills are allowed on Schedule II prescriptions and refills are limited to 5 times or 6. months (whichever comes first) on prescriptions for drugs in Schedules III–V.

TABLE 56.11 Officially recognized Latin abbreviations used in prescription writing

a.c.	before meals	ml	milliliter
a.d.	right ear	o.d.	right eye
a.s.	left ear	o.s.	left eye
a.u.	both ears	o.u.	both eyes
amp	ampoule	p.c.	after meals
b.i.d.	twice daily	p.o.	by mouth
cc	cubic centimeter	p.r.n.	as needed
c	with	q.	every
cap	capsule	q4h	every 4 hours, etc.
disp	dispense	q.i.d.	four times daily
g or gm	gram	q.s.	a sufficient quantity
gtt(s)	drop(s)	Sig.	directions to patient
h	hour	SQ	subcutaneously
h.s.	at bedtime	stat	immediately
IM	intramuscularly	susp	suspension
IP	intraperitoneally	tab	tablet
IV	intravenous	TBSP	tablespoonful (15 ml)
kg	kilogram	t.i.d.	three times daily
lb	pound	tsp	teaspoonful (5 ml)
m^2	meter squared	Ut. dict	as directed
mg	milligram		

Note: Do not use q.d., q.o.d., and s.i.d. because they are confused with other abbreviations. S.I.D. is unknown to health professionals outside of veterinary medicine. If in doubt about an abbreviation, write out the directions in plain English. Also, avoid using abbreviations such as b.i.d., t.i.d., q.i.d., as they are confusing to clients. Abbreviations such as q12h, q8h and q6h are much clearer.

as described by the Poison Prevention Packaging Act. Medications dispensed in non–child-resistant containers should be adequately labeled with auxiliary labels indicating "Caution: Package not child resistant" and "Keep out of reach of children." Other auxiliary labels detailing important information such as "shake well," "refrigerate," "not for injection," etc. should also be affixed to the container.

PRESCRIPTION WRITING

A prescription is a written order or other order, which is promptly reduced to writing for a controlled substance or for a preparation, combination, or mixture thereof, issued by a practitioner who is licensed in his state to administer and prescribe drugs in the course of his professional practice. A prescription does not include an order entered in a chart or other medical record for drugs administered. Always store blank prescription pads in a secure place with access limited to minimal personnel. The elements required in a valid prescription are provide in Tables 56.9 and 56.10. When writing a prescription, abbreviations are allowed. Some commonly accepted and recognized abbreviations are listed in Table 56.11. When in doubt about an abbreviation, *spell it out.*

Summary	**1429**

Horses and greyhounds frequently compete in athletic events in which the use of drugs and medications are regulated. The goals of these medication control programs are threefold: 1) assure a fair and level playing field for the competitors, 2) protect the health and welfare of the animal and human participants, and 3) safeguard the public interest whenever parimutuel wagering is involved. The actual rules for these programs can vary widely depending on the type of competition and the philosophy of the regulating authority. For example, some programs, such as that administered by the Fédération Equestre Internationale (FEI), which is considered to have one of the strictest rules, permit no medications to be present in the horse's system at the time of competition except for approved antiulcer therapies. Other programs allow horses to compete with pharmacologically significant concentrations of a limited number of therapeutic medications in their system. These permitted or authorized medications may include various nonsteroidal antiinflammatory drugs (NSAIDs), muscle relaxants such as methocarbamol, and corticosteroids such as dexamethasone. These rules usually limit the amount of a drug that can be administered to the horse by stipulating a maximum permitted serum concentration; the presence of the drug above that concentration is considered a violation of the rule. By most rules unless a medication is expressly authorized, its mere presence in any detectable amount is considered a violation. Regardless of their specifics, most regulations are enforced by collecting urine and/or blood samples from animals participating in a competition and testing those fluids for the presence of unauthorized drugs and medications and overages of permitted medications in forensic drug testing laboratories. Violations of the rules can be punishable by fines, suspensions, and in severe cases expulsion from the sport.

The testing process itself involves two steps. First, all samples are subjected to a series of screening tests. If the results of any of the screening tests suggest the presence of

a drug or an unauthorized medication or indicate an overage of a permitted medication, the sample in question undergoes a second confirmatory testing process. Because of recent advances in analytical chemistry it is now possible to detect drug substances that the animal may have been exposed to through its environment, as well as therapeutic medications at concentrations that could be considered pharmacologically insignificant. This has led many regulatory authorities to move toward the adoption of thresholds or regulatory limits for some environmental contaminants and therapeutic medications. If a substance is present in the serum or urine at a concentration below the regulatory limit or threshold, no action is taken by the regulatory authority (Table 57.1).

TABLE 57.1 Internationally accepted serum or urine threshold concentrations

Dimethyl sulfoxide	15 µg/ml in urine or 1 µg/ml in plasma
Arsenic	3 µg/ml in urine
Hydrocortisone	1 µg/ml in urine
Salicylic acid	625 µg/ml in urine or 5.4 µg/ml in plasma
Testosterone	0.02 µg (free and conjugated)/ml in urine from geldings, and 0.055 µg (free and conjugated)/ml in fillies and mares (unless in foal)
Theobromine	2 µg/ml in urine
Total carbon dioxide	36 millimoles/l in plasma
Boldenone (other than geldings)	Free and conjugated boldenone 0.015 µg/ml in urine or 1 µg/ml in plasma
Estranediol in male horses (other than geldings)	The ratio of the mass of 5a-estrane-3b,17a-diol (free and conjugated) and the mass of 5(10)-estrene-3b-17a-diol (free and conjugated) in urine must be less than 1.
Methoxytyramine	4 µg (free and conjugated) 3-methoxytyramine/ml in urine

DRUG AND MEDICATION RULES

THE RACING COMMISSIONER'S INTERNATIONAL (RCI). The Racing Commissioner's International (RCI) is an organization consisting of racing regulators primarily from the U.S., Canada, and the Caribbean. Although it has no direct role in enforcement of racing regulations, the organization encourages standardization within the industry by developing model rules and penalty guidelines covering a broad range of violations (Racing Commissioner's International Model Rules). The organization, which currently lists over 800 agents, has also adopted a Uniform Classification Guideline for Foreign Substances that consists of five classes (Racing Commissioner's International Model Rules). The classification scheme is based on a number of factors, including the potential for the agent to affect a horse's athletic performance, whether it has a recognized therapeutic use, and the frequency of that use in normal veterinary practice. Drugs listed in the Class 1 category are considered to have the most potential to affect racing performance and have no accepted medical use in racing animals. As shown in Table 57.2, this would include many agents that are also listed as Schedule 1 drugs in the U.S. Drug Enforcement Agency's drug classification system. Class 2 agents also have the potential to affect the performance of an animal, but less so than Class 1 agents. While some Class 2 agents have no recognized therapeutic use in veterinary medicine, others are therapeutic agents that have a high abuse potential in athletic competition. They include drugs used in human medicine as antipsychotics and antidepressants, as well as those used in veterinary medicine as general and local anesthetics (Table 57.2). The difference between drugs in Class 2 and Class 3 is often a question of the frequency of their use in veterinary medicine. For example, while most local anesthetics are in Class 2, the local anesthetic procaine is a Class 3 agent

TABLE 57.2 Examples of drugs and medications categorized in the Association of Racing Commissioner's Drug Classification Guideline

Class 1	Class 2	Class 3	Class 4	Class 5
Amphetamines	Barbiturates	Clenbuterol	Aspirin	Cromolyn
Apomorphine	Benzodiazepines	Detomidine	Betamethasone	Dicumarol
Cocaine	Fluphenazine	Glycopyrrolate	Boldenone	Dimethylsulfoxide
Etorphine	Ketamine	Ipratropium	Carprofen	Famotidine
Fentanyl	Lidocaine	Procaine	Flunixin	Nedocromil
Heroin	Mepivacine	Salmeterol	Stanozolol	Omeprazole
Morphine	Paroxetine	Xylazine	Prednisolone	Warfarin

primarily because it is commonly used in the slow release formulation of penicillin (procaine penicillin). Other Class 3 agents include bronchodilators and sedatives, such as acepromazine and detomidine that are commonly used in veterinary medicine (Table 57.2). Class 4 agents are commonly used therapeutic agents that have a limited capacity to affect racing performance such as isoxsuprine and methocarbamol. Class 5 agents are those that have very specific actions with little potential to alter athletic performance and include antiulcer medications, mast cell stabilizers, and anticoagulants (Table 57.2).

There are several controversial aspects to the RCI classification system. For example, one limitation of the classification system is that it is based on the effects of the drugs on healthy horses. Because of this approach the corticosteroid agents, such as methylprednisolone and triamcinolone, which are commonly used as intraarticular medications are listed in Class 4 indicating that they are therapeutic agents with limited ability to influence performance. While intraarticular administration of corticosteroids may have limited potential to alter the performance of a normal sound horse, they have enormous potential to alter the performance of a horse with an inflamed, arthritic joint (Shoemaker et al. 1992; Carter et al. 1996). In a similar manner NSAIDs, such as flunixin and naproxen, are included in Class 4, despite their significant analgesic and antiinflammatory effects. Finally, anabolic steroids, which are prohibited substances in most human athletic competitions, are also Class 4 agents. Several anabolic steroids are approved by the FDA for use in dogs and horses and some practitioners contend that there are legitimate therapeutic uses for these compounds. Whether anabolic steroids can alter athletic performance in horses and dogs has not been determined, and their class 4 designation reflects this uncertainty.

FÉDÉRATION EQUESTRE INTERNATIONALE (FEI). The FEI is the governing body recognized by the International Olympic Committee. It establishes the rules and regulations, including those for medication use, under which a number of different international equestrian disciplines compete, including Jumping, Dressage, Eventing, and Endurance Riding. The FEI drug and medication rule is one of the most conservative in equine sports and reflects the philosophy that the horse should compete on its own merits without any unfair advantage that might follow the use of drugs (FEI Veterinary Regulations 2005). The FEI considers a prohibitive substance as any agent capable at any time of acting on one or more of the following mammalian body systems: the nervous system, the cardiovascular system, the urinary system, the reproductive system, the musculoskeletal system, the blood system, the endocrine system, the immune system (other than licensed vaccines against infectious agents), the digestive system (other than orally administrated antiulcer medications) and the skin. An extensive list of specific prohibited agents is approved each year. The medication rule states that the finding of a prohibited substance means the detecting of the substance itself, a metabolite of the substance, an isomer of the substance, or an isomer of a metabolite (FEI Veterinary Regulations 2005). In addition, the finding of any biological or scientific indicator of administration or other exposure to a substance is equivalent to the detection of the substance itself. This latter aspect of the rule allows for methods of detection that do not specifically identify the substance itself, but rather detect some secondary physiological change that occurs following its administration. The list of medications not considered prohibited substances is quite short and includes antibiotics, with the exception of procaine penicillin; antiparasite drugs, with the exception of levamisole; and three agents commonly used to prevent or treat gastric ulcers—omeprazole, ranitidine, and cimetidine. In addition, mares with estrus-related behavioral problems can be treated with the substance altrenogest with certain limitations (FEI Veterinary Regulations 2005). Although the FEI has adopted thresholds on a number of different substances, unlike many other drug and medication rules, the FEI strictly limits the type of substances for which thresholds may be adopted. Their rule states that thresholds can be adopted only for substances endogenous to the horse, substances arising from plants traditionally grazed or harvested as equine feeds, and substances in equine feed arising from contamination during cultivation, processing, treatment, storage, or transportation (FEI Veterinary Regulations 2005).

UNITED STATES EQUESTRIAN FEDERATION (USEF). Formerly known as the American Horse Show Association, the U.S. Equestrian Federation (USEF) is the largest regulatory organization for show horses in the U.S. Numerous riding and breed disciplines compete under the USEF umbrella, including Arabian, Eventing, Connemaras, Reining, Vaulting, etc. USEF has two drug and

medication rules and each discipline chooses under which rule they want to compete (USEF 2005 General Rules). The No Foreign Substance Rule is very similar to the FEI medication rule, and currently only FEI and Endurance Riding events are conducted according to its provisions. The remaining disciplines compete under the Therapeutic Substance Rule, which is considered the more permissive of the two. Under this rule, forbidden substances are any stimulant, depressant, tranquilizer, local anesthetic, or psychotropic agent and/or drug that might affect the performance of a horse and/or pony or any metabolite and/or analogue of any such substance except where expressly permitted (USEF 2005 General Rules). The premise of the Therapeutic Substance Rule is that any drug or medication administered to a competing horse is to be used only for a legitimate, therapeutic purpose. This means that the drug is deemed to be necessary for the proper diagnosis and treatment of an existing illness or injury (USEF 2005 General Rules). Under the Therapeutic Substance Rule some medications are permitted to be present at concentrations likely to be pharmacologically significant. For example, the NSAIDs that are currently permitted and their respective maximum allowed plasma concentrations are shown in Table 57.3. Up to two of the NSAIDs listed may be present in a single plasma or urine sample, except the combination of flunixin and phenylbutazone, which is not permitted. NSAIDs other than those expressly allowed are considered prohibited substances and their presence in a sample collected during a competition would be considered a violation. The Therapeutic Substance Rule also allows the use of the muscle relaxant methocarbamol and the corticosteroid dexamethasone, as long as their plasma concentrations do not exceed 4.0 μg/ml and 0.003 μg/ml, respectively.

DRUG AND MEDICATION RULES IN RACING DOGS AND HORSES IN THE U.S. In the United States each racing jurisdiction adopts its own rules and regulations. Because parimutuel wagering is involved, it is the state governments that hold the ultimate authority, but that authority is often delegated to racing commissions or boards that are appointed by the governor of the respective state. In addition, there may be multiple boards within one state or racing jurisdiction. For example, different boards may oversee horse versus dog racing and/or Thoroughbred versus Standardbred racing. As mentioned previously the ARCI is a voluntary organization of racing commissioners that has attempted to standardize rules and regulations between the various jurisdictions without much success. In the U.S. there is little consistency in drug and medication rules and penalties among the different states, and therefore veterinarians need to familiarize themselves with the specific regulations in each jurisdiction in which they practice.

TABLE 57.3 Maximum permitted plasma concentrations of nonsteroidal antiinflammatory agents allowed by USEF under the Therapeutic Substance Rule

Diclofenac	0.005 μg/ml
Phenylbutazone	15 μg/ml
Ketoprofen	0.25 μg/ml
Meclofenamic Acid	2.5 μg/ml
Naproxen	40 μg/ml
Flunixin	1.0 μg/ml

In horseracing there are two medications that are regulated across the U.S. in a fairly consistent manner, the NSAID phenylbutazone and the diuretic furosemide. For example, in most jurisdictions phenylbutazone can be administered up to 24 hours before the post time of the race in which the horse is entered. Although doses and specific routes of administration are not mandated, most rules stipulate that the concentration of phenylbutazone cannot exceed 5 μg/ml in serum samples collected immediately following the race. In addition, other NSAIDs, such as flunixin meglumine and ketoprofen, are permitted by few racing jurisdictions as alternatives to phenylbutazone. The presence of more than one permitted NSAID in a single serum sample would be considered a violation in most jurisdictions.

In addition to phenylbutazone, most racing jurisdictions in the U.S. permit the administration of the diuretic furosemide to racehorses suffering from exercise-induced pulmonary hemorrhage (EIPH). Furosemide is a loop diuretic that induces natriuresis, chloruresis, increased hydrogen ion excretion, and a profound diuresis (Hinchcliff and Muir 1991). These effects are mediated by the inhibition of Na^+-K^+-$2Cl^-$ transporters in the thick ascending limb of the loop of Henle, although furosemide also has important extrarenal effects, including venodilation and prevention of bronchoconstriction (Broadstone et al. 1991; Wiemer et al. 1994). Whether or not furosemide is an effective therapy for EIPH, has not been proven. For example, Pascoe and colleagues (1985) concluded that furosemide decreased the severity of EIPH in racehorses. That study, however, used an admittedly subjective grading

scale to judge the severity of the disease, and therefore, the results were not considered conclusive. Nevertheless, if the pathogenesis of EIPH is associated with the unusually high pulmonary arterial pressures (>70 mm Hg) that develop in the horse during intense exercise, as has been proposed, there is evidence that furosemide may be effective at decreasing those pressures and thus could be therapeutic for EIPH (Manohar 1993; Gleed et al. 1999; Magid et al. 2000).

Even though furosemide is permitted in every racing jurisdiction in the U.S. its use remains controversial, primarily because there is some evidence that it can enhance the athletic performance of horses apart from any effects on EIPH. For example, it has been hypothesized that the diuretic-induced fluid losses associated with furosemide administration result in a moderate, but significant weight loss in the horse, which could enhance its athletic performance (Hinchcliff et al. 1993; Hinchcliff and McKeever 1998). In addition to the controversy regarding the effects of furosemide on equine athletic performance, it has been proposed that the dilute urine that follows furosemide administration may interfere with the detection of other drugs (Soma et al. 1984; Stevenson et al. 1990). For this reason, the dose and timing of furosemide administration are regulated to minimize the chance that that urine samples collected postrace will be dilute (i.e., urine specific gravity <1.010). Most commonly, furosemide administration is restricted to 250 to 500 mg, administered intravenously no closer than 4 hours before post time.

Unlike racing horses, there are no commonly accepted permitted medications for greyhounds racing in the U.S. Although there are many NSAIDs approved by the FDA for use in dogs, the detection of any of these medications in urine samples collected following a race would be considered a violation of most medication rules. In addition, because dogs do not suffer from EIPH to any significant degree, the administration of furosemide is also not permitted. Some states, however, do allow the administration of anabolic steroids to intact female greyhounds to prevent the onset of estrus.

THE DRUG TESTING PROCESS

The drug testing process aims to separate and identify nonendogenous components or drugs in biological matrixes, such as urine and plasma. The analytic process used to accomplish this goal can be separated into three components: extraction of the drug from the biological matrix, separation of the drug from other compounds, and detection and identification of the drug.

ANALYTICAL METHODS FOR EXTRACTION. The goal of the extraction process is to isolate and concentrate the drug, often referred to as an *analyte*, from the sample while removing endogenous matrix materials that could interfere with the detection process. One of the simplest and most traditional methods of sample preparation is liquid-liquid extraction (LLE). In LLE, an aqueous sample such as plasma or urine is mixed with an organic solvent that is not miscible with the sample. Most drugs are more soluble in the organic solvent than in the aqueous media of the sample, and therefore, they partition into and concentrate in the organic phase during the mixing process. The selection of optimal conditions, such as pH and solvent polarity, will result in the majority of any analyte present being extracted into the chosen solvent. To complete LLE, the two liquid layers are separated and the solvent layer is kept for further manipulation, such as concentration through evaporation and reconstitution, which improves the sensitivity of the method.

Solid-phase extraction (SPE) is another technique used to separate and concentrate analytes from aqueous samples. Where LLE uses a liquid solvent to separate the analytes from the sample matrix, SPE uses adsorption to a solid surface to achieve this same separation. Most commonly, SPE methods use prepackaged columns containing bonded silica sorbents to which functional groups, such as hydrocarbons or ion exchange groups have been bound. First, the column of material is washed and buffered to the desired pH to facilitate analyte binding, and then the liquid sample is passed through the bed of adsorbent particles. While the analytes are retained on the column, contaminating matrix material is removed by washing the column with water, buffer, or other solvents. In the final step the column is buffered to a specific pH to facilitate release of the analytes, which are then removed from the column with a small amount of elution solvent. The sample is then evaporated and reconstituted in a solvent amenable to analysis.

The third type of extraction process commonly used in forensic drug testing laboratories is separation by precipitation. This method relies on differences in the solubility of the analytes and the other compounds in the matrix. This method is commonly used to precipitate proteins from plasma or serum samples after which the resulting

supernatant is analyzed directly. This extraction method does not involve a concentration step, so the sensitivity is generally less than LLE or SPE.

ANALYTICAL METHODS OF SEPARATION. The goal of the sample separation process is to isolate analytes from each other after extraction and prior to the detection process. The most common method used in forensic drug testing laboratories for separation of analytes is chromatography. For a chromatographic separation, the analytes are dissolved in a mobile phase and passed through an immiscible stationary phase. Differences in the chemical characteristics, such as the polarity, size, and charge state of the analytes, will cause them to have different rates of migration through the stationary phase. These differences in migration rates result in separation of the components in time into a series of discrete bands or peaks that can be collected for further analysis. The two types of chromatography commonly used in forensic drug testing are planar and column chromatography.

One of the simplest types of chromatography is planar chromatography, where the stationary phase is bonded to a piece of paper or glass, and the mobile phase passes over it by either gravity or capillary action. One of the most common types of planar chromatography is thin layer chromatography (TLC), which utilizes a very thin coating of stationary phase on a flat surface called a *plate*. Because it is possible for different analytes to have very similar migration patterns, TLC provides only presumptive qualitative identification of the analyte. In addition, because it is difficult to completely recover the analyte from the plate, quantitative analysis is also problematic. Therefore, TLC is used as a general screening technique and the putative detection of any drug in a sample using TLC would be confirmed by a second analytical method that provides more definitive identification, such as mass spectroscopy.

In column chromatography, the stationary phase is contained within a tubular container (i.e., a column) and the mobile phase, either liquid or gas, is passed through it by either gravity or positive pressure. Liquid chromatography (LC) and gas chromatography (GC) are the two most common column chromatography techniques currently utilized by forensic drug testing laboratories.

In gas chromatography, samples are vaporized in a heated inlet kept in excess of 200°C and moved through the column by an inert carrier gas, such as argon, helium, or nitrogen. The carrier gas acts as the mobile phase and the stationary phase is contained within the column. Typical GC columns are several meters long with an internal diameter of 1 mm or less. One disadvantage of GC is that the majority of analytes of interest to forensic drug testing laboratories require a lengthy derivatization step before analysis. Derivatization is the process by which an analyte is modified by a chemical reaction to produce a new compound that is more amenable to separation by GC. Derivatization is used to increase the volatility and stability of compounds of interest. The advantages of using GC are that the systems are fairly simple to operate and the methods are relatively straightforward because few modifications of the stationary and mobile phases are possible.

In liquid chromatography, compounds in a sample are separated by utilizing the differences in polarity of the analytes, the liquid mobile phase, and the solid stationary phase contained within the column. Typical LC columns are 100–500 mm long with an internal diameter of 3 mm or less. Unlike GC, in LC the composition of both the mobile and stationary phases can be modified to optimize the analytical separation. Another advantage of LC separation methods is that they are accomplished using aqueous mobile phases at room temperature. Therefore, LC methods are not limited by the thermal stability or volatility of the compound, because vaporization of the sample is not required. Together these factors have made LC an increasingly popular technique for separation in forensic drug testing laboratories.

ANALYTICAL METHODS FOR DETECTION. While extraction and separation are essential components of the analysis, it is important to note that neither of these processes provide data sufficient to definitively identify a drug. The two most common methods used in forensic drug testing laboratories to identify analytes are absorption spectroscopy and mass spectrometry.

Absorption spectroscopy detection methods employ ultraviolet or visible light, utilizing the property that many molecules are capable of absorbing certain frequencies of light. The degree of absorbance for a molecule is generally directly proportional to the concentration of that molecule in solution at concentrations in the range of 10^{-2} to 10^{-6} M. Because most absorption spectroscopic methods are very robust and relatively inexpensive, they are commonly

used for quantitative analysis in forensic drug testing laboratories. One of the limitations of absorption spectroscopy, however, is that two analytes with overlapping absorption spectra and with similar elution times will be difficult to differentiate. In addition, the presence of chemical and/or spectral interferences can cause erroneous detector responses resulting in quantitation errors.

In mass spectrometry (MS), following the extraction and separation process the analytes in the sample are serially injected into the mass spectrometer for identification. While many different types of mass spectrometers are commercially available, in the type most commonly used in forensic drug testing laboratories analytes are bombarded with a beam of electrons, which causes the molecules to become ionized. While some of these ions will remain intact, many will fragment into smaller ions and neutral fragments. The original ionized precursor molecules and the product fragments are then separated in electric or magnetic fields based on their mass to charge ratio and then serially passed into a detector that measures the abundance of each ion. A plot of the abundances of the precursor and productions versus their mass:charge ratios is referred to as the compound's *mass spectrum* (Fig. 57.1). The highest molecular weight peak in a spectrum will usually represent the parent molecule minus a single electron (ionized), and is referred to as the *molecular ion*. The mass spectrum of the analyte is compared to a computerized database of mass spectra referred to as a *library* or an *authenticated standard* of a known compound. Because the fragmentation pathways for many molecules are well characterized and extremely reproducible, unambiguous identification of a compound can be achieved. Even analytes with the same nominal mass can be differentiated, because they usually produce very different fragmentation ions. Because the abundance of the ions is directly proportional to the concentration of the analyte in the solution, extremely accurate quantitation is possible using MS methods. One of the disadvantages of mass spectrometry is that it requires a highly trained analyst to develop the methods and interpret the data. Nevertheless, because of the high degree of specificity inherent in the results, mass spectrometry has become the de facto standard method for drug identification in forensic drug testing programs.

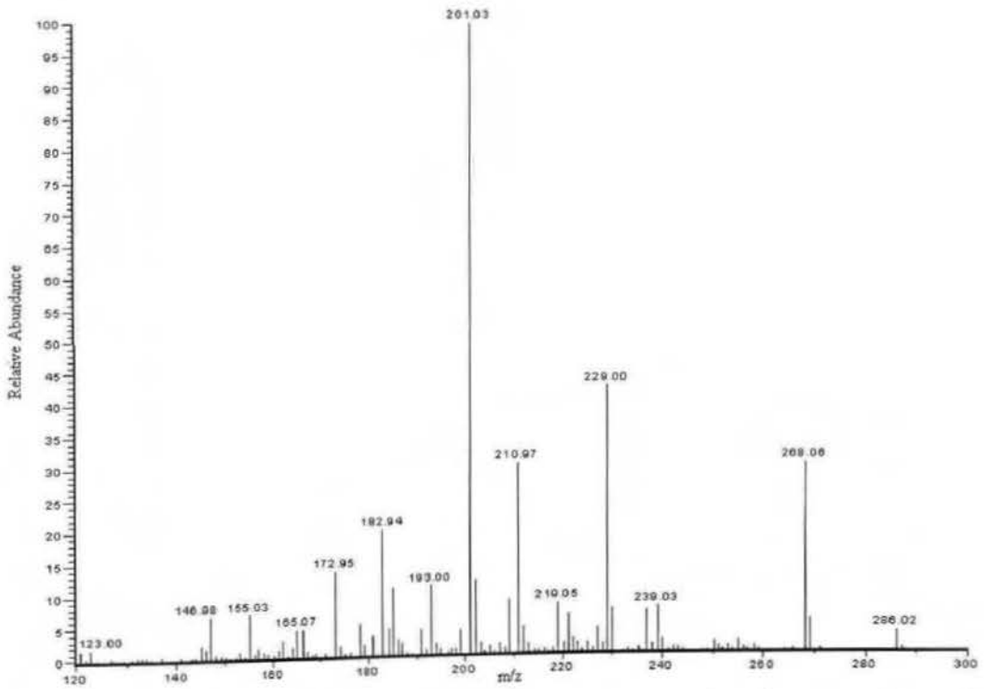

FIG. 57.1 Mass spectrum of morphine obtained by liquid chromatography mass spectrometry. Sample concentration was 50 pg/ml and the flow rate was 0.2 ml/min. Thirty-two scans were signal-averaged to produce the resultant mass spectrum.

SAMPLING, SCREENING, AND CONFIRMATION IN THE RACING LABORATORY

Sample Type and Collection. Drug and medication rules are generally enforced by the collection and testing of blood and urine samples from animals performing in athletic competitions. Sample collecting procedures must take into consideration both scientific and legal issuees. An important legal aspect of the process is chain-of-custody documentation, which is a tamper-resistant paper or electronic trail indicating where the sample has been and who has had custody of it at all times. For this reason the actual drug testing process begins when a sample is collected. In addition, because many modern mass spectrometric techniques can detect quantities of drugs or medications in the picogram to femtogram range, special care must be taken by the sampling personnel to prevent contamination from environmental sources during the collection process. Only clean sample collection vessels should be used, and personnel should wear the appropriate attire, such as disposable gloves, and should refrain from eating, drinking, and smoking during the process. Once collected, the samples are sealed with tamperproof evidence tape and secured in locked containers or coolers for transport to the testing laboratory. To prevent degradation of the samples, nonfrozen samples should be kept cold and shipped overnight. Otherwise the samples should be frozen and kept frozen until immediately prior to analysis.

Urine is the primary bodily fluid used for drug testing in most programs because it is relatively easy to obtain, and because most drugs and their metabolites are present in urine in higher concentrations than in blood. Generally, urine samples are collected from the animals following competitive events. In some programs blood, plasma, or serum samples are also collected, although this is done more commonly in horses than dogs. Plasma or serum samples are primarily used to regulate authorized or permitted medications, such as NSAIDs, where maximum serum/plasma concentrations have been adopted by the regulatory agency.

Occasionally other bodily fluids or tissues are collected for drug analysis. For example, in the past decade interest in the analysis of hair for drug detection has increased in forensic sciences. However, not all drugs administered to the horse will be incorporated into growing hair. In addition, when a drug is detected in hair it can be difficult to determine when the animal was actually exposed to the compound. For example, a sample of a horse's mane positive for the bronchodilating agent clenbuterol could be the result of an administration 6 or more months previously. For this reason, the usefulness of hair analysis and the legal and ethical ramifications of proceeding with regulatory action against an owner or trainer based on a positive hair test, remain to be determined. Saliva samples have also been tested for the presence of unauthorized medications. The principal value of testing saliva samples is the ability to detect agents recently administered by the oral route due to residual contamination of the mouth and pharyngeal area. Saliva is collected by swabbing the animal's mouth with a cotton gauze held in forceps. One of the principal disadvantages of saliva testing is that it is difficult to obtain a useful volume of fluid.

Testing Scheme Overview. Over the years, the drug testing process has evolved into a two-step procedure. When the samples arrive at the laboratory, small aliquots of each are subjected to multiple screening tests. In North America, thin layer chromatography (TLC), enzyme-linked immunosorbent assays (ELISAs) and instrumental techniques employing mass spectrometry are the most common methods used for sample screening. If the results of all the screening tests are negative, the sample is declared negative and no further action is taken. However, if the results of one or more of the screening tests are suspicious, the sample undergoes a second round of testing to confirm the presence of, and definitively identify, the substance. The results of the confirmation test must be able to withstand legal challenge and intense scientific scrutiny, making the identification of the compound by mass spectrometry essential. Although gas chromatography-mass spectrometry (GC-MS) has been the most commonly used method of confirmation, liquid chromatography-mass spectrometry (LC-MS) is rapidly becoming the method of choice in most forensic drug testing laboratories.

Screening Methods. The ideal screening test should be rapid, sensitive, and inexpensive. Specificity is not a necessity because the results are only preliminary and will be confirmed in a second round of testing that is highly specific. TLC has been used in forensic drug testing laboratories for over five decades and it remains one of the most common screening methods used in North America despite numerous disadvantages. For example, TLC methods require large volumes of both sample and solvent, they involve subjective interpretation of the results by the chromatographer, and their sensitivity is often not

adequate to detect many of the more potent drugs in use today. The TLC limit of detection (LOD), which is the lowest concentration of a drug that can be reliably detected by an analytical method, is usually in the range of 100 nanograms per milliliter (ng/ml) or parts per billion (ppb) for most analytes. TLC remains in use primarily because of its simplicity (technicians can be trained in a few weeks), dependability (complex instrumentation is not required), and capacity to simultaneously detect a wide range of substances in a single analysis.

ELISA testing is an integral component of most screening programs in forensic drug analysis, primarily because of its simplicity and sensitivity. The majority of laboratories use ELISA in conjunction with TLC or instrumental methods. In its simplest form the method has three primary components: an antibody specific for the drug or class of drugs, drug molecules labeled with an enzyme conjugate, and a substrate that will produce a measurable color change when the enzyme conjugate binds to the antibody. Drug molecules in the sample compete with enzyme-labeled drug molecules for binding sites on the antibodies. Enzyme-labeled drug bound to the antibody will react with the added substrate to produce a color change in the solution. Therefore, when unlabeled drug molecules are present in the sample, there is a decrease in color due to the competitive binding and this change can be measured by optical spectroscopy.

As mentioned previously, one of the advantages of the use of ELISA testing is its superior sensitivity. The LODs for most ELISAs are in the range of 1–10 ng/ml. ELISAs are generally designed to be very specific, detecting either an individual drug or a class of drugs that are structurally similar. Because there are a limited number of commercially available ELISA tests kits, however, the breadth of coverage that can be provided by these kits is limited. Most programs combine ELISA testing with other screening methods in order to increase the number of drugs that can be detected. Because they are an immune-based test, there is always the potential for nonspecific cross-reactions to occur. Therefore, like TLC, the results of ELISA tests are only presumptive and confirmation of those test results using a method with a higher degree of specificity is required for definitive identification.

In recent years, screening tests have been developed using GC/MS and LC/MS methods. As their names imply, these instrumentally based methods utilize either gas or liquid chromatography to separate any compounds of interest in a sample, which are then serially injected into the mass spectrometer for identification. In general these methods are equal to or more sensitive than ELISA testing, with LODs commonly in the range of 0.01–1 ng/ml. However, in a manner more similar to TLC analysis, they can detect a wide range of substances simultaneously in a single analysis. The primary limitations to these instrumentally based screening approaches are the initial costs of the instruments as well as the need for highly trained analysts, making the initial implementation of these methods expensive.

Confirmation Methods. If one or more of the screening tests gives results suggestive of the presence of a nonauthorized drug or medication, the sample undergoes a second round of testing, the purpose of which is to definitively confirm the presence and identity of the drug. The method used for confirmation must be highly specific and sensitive. The two most common methods used are GC/MS and LC/MS. Confirmational analysis is usually performed on only one sample at a time, as the extraction, separation, and detection steps are labor-intensive and may require one or more days of sample preparation. Traditionally the process has been only qualitative in nature, as the presence alone of a nonpermitted substance is considered a violation by most drug and medication rules, regardless of the amount in the sample. However, because improvements in analytical methods have resulted in the detection of smaller and smaller amounts of drugs, quantitative information can be useful in differentiating residues of therapeutic agents administered days or even weeks before the race from pharmacologically significant concentrations more indicative of race-day administrations.

REFEREE SAMPLE ANALYSIS.

As described above, before a reputable laboratory reports that a sample contains an unauthorized drug or an overage of an authorized medication, the sample has undergone multiple screening and confirmation tests using several different analytical methods. Nevertheless, a split or referee sample analysis is permitted by many drug and medication rules. In the split sample process, an aliquot or small portion of the original sample is reanalyzed at a second laboratory to verify the positive test. The purpose of the split sample analysis is to verify the results of the original laboratory and, in so doing, guard against laboratory mistakes or contamination of the original sample during the collection process. If the second laboratory does not confirm the presence of the

unauthorized substance found by the primary laboratory, no regulatory action is taken.

There are several variations in split sample analysis programs. For example, under FEI regulations a split sample analysis is automatically conducted by a second FEI-associated laboratory following any finding of a violation of its drug and medication rule (FEI Veterinary Regulations 2005). Should the second analysis fail to confirm the original finding, however, the rule does not stipulate whether regulatory actions will or will not be taken. The USEF recently implemented a program that allows for collection of a split sample and testing of that sample at a second referee laboratory (USEF 2005 General Rules).

FACTORS AFFECTING WITHDRAWAL TIMES

Veterinary practitioners often want to know withdrawal times or how long before an event or race they should discontinue treatment with a particular medication in order to avoid having an animal test positive for that agent. Unfortunately, it is very difficult for laboratories to generate accurate withdrawal times for therapeutic medications because many different factors can affect how long a drug remains detectable after administration. Probably the most important factor is the sensitivity of the testing method used by the laboratory. As discussed previously, the LODs for different analytical methods vary widely. For example, in general, TLC is much less sensitive than instrumental or ELISA analysis. Therefore, the withdrawal time for a medication tested by ELISA in one laboratory would be significantly longer than the withdrawal time determined by another laboratory using TLC analysis as its testing method. Even if the same method of analysis is used, differences in sample preparation can result in higher or lower analyte recoveries that can ultimately affect withdrawal time.

Many other factors outside of the laboratory may also affect withdrawal times. For example, the higher the administered dose, generally the longer the withdrawal time. The route of drug administration is also important. Intravenous administration generally results in the shortest withdrawal time compared to oral or other parenteral forms of dosing, such as intramuscular or subcutaneous. In addition, some drugs, such as clenbuterol and isoxsuprine, accumulate in the body with repeated dosing, and drug residues can persist in urine samples for 30 days or longer after the medications are withdrawn. There can also be large variations in the clearance rates of many medications among different horses. Because of all of these factors, in order to generate an accurate withdrawal time each laboratory may need to administer the medication in question at the highest dose commonly used for a prolonged period of time to a large number of horses. The laboratory must then collect and analyze samples from these horses using the same methods that they would use to screen their regulatory samples. Due to time constraints and financial limitations few laboratories have completed this process with more than a handful of medications.

THRESHOLDS, REPORTING LEVELS, AND CUTOFFS

As analytical chemistry methodology has improved, the smallest amount of a drug or medication that can be detected in bodily fluids has progressively decreased. Currently the LOD in urine for most substances of concern are in the low ng/ml range. As a result of this sensitive testing the use of drugs and medications in equine sports is considered by many to be well controlled. The side effect of this sensitive testing, however, can be the detection of substances that were not purposely administered to the horse. In some situations these agents are contaminants in the horse's environment. For example, theobromine can be found in cocoa husks, and scopolamine and atropine occur naturally in many plants in the genus *Datura*. In addition, it is now recognized that some substances thought to be exogenous synthetic agents are actually endogenous, albeit usually produced only in very small amounts. For example, both hydrocortisone and nandrolone are now recognized as occurring naturally in animals. In addition, as previously discussed, some medications can be detected in urine days or even weeks following the last administration.

As a result of the sensitive testing and the recognition that some substances may be endogenous to the horse or contaminants in its environment, almost every organizational body that regulates equestrian activities has adopted thresholds or cutoffs for a number of substances. Horses may compete in sanctioned events with the presence of these substances in their tissues, bodily fluids, or excreta, provided the concentration of the substance does not exceed the predetermined threshold value. Table 57.1 lists

a number of thresholds accepted by many regulatory agencies.

SUMMARY

Drug testing programs are implemented in order to enforce drug and medication rules. Most programs consist of a two-part testing process that utilizes urine as the primary sample type. All samples are tested in a preliminary screening process, and any samples with suspicious results undergo an additional round of confirmatory testing. Veterinarians need to be aware of the drug and medication rules under which their clients compete, and because detection periods have not been determined for many therapeutic substances they should allow for extended withdrawal times in order to avoid inadvertent positive tests.

ADVERSE DRUG REACTIONS

VICTORIA HAMPSHIRE AND MARGARITA A. BROWN

Method 1433
Algorithms 1433
Strengths of ADE Reporting Systems 1435
Limitations of ADE Reporting Systems 1435
Trends in Pharmacovigilance at FDA CVM 1435

Veterinarians are overwhelmingly successful in the use of pharmaceuticals to prevent and treat disease. Occasionally, veterinarians and animal owners observe adverse drug reactions. These may be associated with failures in the safety and efficacy of commercially marketed drugs. To this end, regulators in most western countries have developed and refined adverse drug event reporting systems. The stakeholders in this process are animal owners, veterinarians, drug sponsors, and regulators. Adverse drug event reporting has been a growing aspect of veterinary medicine, and practitioners are increasingly concerned with issues of informed consent.[4,5,10,11,15,16,21,31] The process of monitoring for drug risks and conveying ways to optimize benefit and minimize risk is called *pharmacovigilance*. The World Health Organization (WHO) defines pharmacovigilance as the science and activities relating to the detection, assessment, understanding, and prevention of adverse effects or any other drug-related problems.[30]

For most of the history of modern veterinary medicine, drugs approved for human use have been prescribed in an extralabel manner (that is, the indication for treatment of the subject species is not on the label). Since the United States Food and Drug Administration (FDA) established a veterinary bureau and subsequently since the formation of a Center for Veterinary Medicine (CVM) in 1984, growing numbers of drugs are specifically approved by FDA for use in animals. These approvals are based on review and assessment of carefully designed animal studies that specifically address safety and efficacy in the target species. For drugs that are approved for use in animals used for human food, a human food safety assessment is also done as delineated in the Code of Federal Regulations, Analytical Methods for Residues (21CFR§514.1 9b [7]).[25] Similarly, the United States Department of Agriculture regulates veterinary biologics, including vaccines (Virus-Serum-Toxin Act, Chapter 5)[26] The United States Environmental Protection Agency (EPA) regulates pesticides, such as topical flea and tick products (Federal Insecticide, Fungicide and Rodenticide Act, Section 3).[27] This chapter focuses on the regulation of postapproval animal drug risk information by the FDA CVM, with attention to the key aspects of the reporting process and basic methods of adverse drug event assessment that will be useful to veterinary students, academicians, and practicing veterinarians.

When a new drug is approved for veterinary use, it is given a new animal drug application number (NADA number) by which the postapproval information can be

archived. The labeling includes the primary container label, package inserts, packaging of any secondary containers, and any accompanying consumer information that was required at product launch. The labeling contains information about side effects, precautions, warnings, and contraindications that were discovered in preapproval studies. Labeling may also include promotion and advertising materials and client education sheets.

A marketed drug product may expand the number of times a drug is administered from what was observed in a relatively small number of animals utilized for preapproval studies. In the veterinary world, average clinical studies range from 30 or 40 in the target animal safety studies to 300 or 400 in clinical efficacy studies.[8] After approval, the number of doses sold can reach a treatment subpopulation within the estimated 62 million owned dogs and 76 million owned cats that exist in America.[1,28] There is no reliable nonproprietary data for exact numbers of prescriptions administered to dogs or cats. However, depending on the popularity of a new drug and the prevalence of a commonly diagnosed condition, such as arthritis, one can easily see the potential growth from several hundred animals dosed to several million. Thus, clinical manifestations that are too infrequent to be detected in relatively small preapproval studies begin to emerge in this period. Additionally, conditions of use that were not predicted in the preapproval period and other confounding factors, such as the possibility of targeted use in a particular age group, may influence the emergence of new clinical manifestations. The purpose of veterinary adverse drug event monitoring is to assess the frequency, similarity, and severity of such signs so that regulators can consider the possibility of drug association.

In the United States, postapproval monitoring for adverse drug events, ineffectiveness, and product defects falls under regulations promulgated in the Code of Federal Regulations. 21CFR§514.3 describes the reporting requirements to veterinary drug companies and contains important definitions:

An *adverse drug experience (ADE)* is any adverse event associated with the use of a new animal drug, whether or not considered to be drug-related, and whether or not the new animal drug was used in accordance with the approved labeling (i.e., used according to label directions or used in an extralabel manner, including but not limited to different route of administration, different species, different indications, or other than labeled dosage). Adverse drug experience includes, but is not limited to

1. An adverse event occurring in animals in the course of the use of an animal drug product by a veterinarian or by a livestock producer or other animal owner or caretaker.
2. Failure of a new animal drug to produce its expected pharmacological or clinical effect (lack of expected effectiveness).
3. An adverse event occurring in humans from exposure during manufacture, testing, handling, or use of a new animal drug.

The term *adverse drug event* is often used interchangeably with *adverse drug experience*. The regulations also distinguish *serious* ADEs as "an adverse event that is fatal, or life threatening, or requires professional intervention, or causes an abortion, or stillbirth, or infertility, or congenital anomaly, or prolonged or permanent disability, or disfigurement."

The definition of an *unexpected* adverse drug experience is "an adverse event that is not listed in the current labeling for the new drug and includes any event that may be symptomatically and pathophysiologically related to an event listed on the labeling, but differs from the event because of greater severity or specificity."

In the United States, the reporting of suspect veterinary drug reactions is initiated as a passive, or voluntary, process. This is important because most experts estimate that only a fraction of the real occurrences of adverse events are reported.[3,9,18,22,23,24] An adverse event may occur whether or not a drug is used according to its label, and regardless of regulatory labeling for that species as "FDA approved." Extralabel use should not be a deterrent to reporting an adverse event. The condition of use is important to CVM in evaluating what might be future supplemental claims, or in assisting CVM in noting conditions of use that should be placed as warnings or precautionary statements on a modified label.

Sponsors of new animal drug applications must report timely information regarding drug side effects after approval. Once a veterinary drug firm becomes aware of a voluntary report (either from the veterinarian or animal owner) there is a legal requirement for the firm to report serious and unexpected signs (those signs not presently on the label as side effects) to FDA CVM within 15 working days and to follow up on outstanding or unresolved cases, regardless of any opinion of causality. Other reports are submitted in the semiannual or annual reports that sponsors send to FDA CVM. Current regulations require that

the sponsor submit a summary report every 6 months for the first 2 years of marketing and annually thereafter.

Nearly all the reports that FDA CVM receives come directly from the drug sponsor on FDA CVM forms that contain key data elements describing the reaction and the context of the reaction.[7] Approximately 1% of reports come directly to FDA CVM from the animal owner or veterinarian and bypass the sponsor and/or request confidentiality from the sponsor.[6]

METHOD

FDA CVM monitors the frequency, severity, and similarity of clinical signs reported as adverse drug events. The *frequency* of an ADE clinical sign or syndrome is the number of times it or any other sign or syndrome is reported to the FDA CVM. The *severity* of the reaction or event includes the evaluation of individual reports that contain one or more clinical signs associated with death or serious clinical pathology that could be reasonably expected to end in death or serious debilitation (such as blindness, deafness, etc.) if intervention was not provided in a timely or aggressive manner. The *similarity* of the reactions or events refers to the situation where the reports in the database for a single drug are similar in onset, severity, and clinical signs.

If the frequency, severity, and/or clinical similarity of reports reach a level of concern that is observably or interpretively (as judged by the majority of the reviewers) occurring more than clinically expected in a population of similar size, age, and health status, the generated signal must be examined in greater depth, even if it represents a small number of reports.[17]

Identification of a signal generated for a particular sign or syndrome may result in a label change. Significant changes to the label are supplied in the form of a "Dear Doctor" letter mailed to veterinary practitioners across the nation, alerting veterinarians to an increase in frequency, similarity, or severity of drug-associated signs. In some cases there may be a recall or withdrawal of the drug. Clinicians should acquaint themselves and office staff with the appearance of these critical communiqués so that they are not discarded unread.

ALGORITHMS. FDA CVM utilizes a modified Kramer algorithm to assess whether an observed ADE is drug-related (Fig. 58.1). The algorithm has standardized criteria to facilitate an objective review process.[2,1,14]

There are six axes or criteria that are used together with an accompanying questionnaire and provide guidance. The basic tenet is to assess the occurrence of a clinical sign as a causally related clinical sign. Thus, the causal relationship is based on established knowledge—previous documentation of the clinical sign, alternative explanations for the clinical sign, timing of events, dosage given, diminution of the clinical sign when the influence of the drug passes (dechallenge), and reappearance of the clinical sign when the drug is given again (rechallenge).[17]

The algorithm is applied to each clinical manifestation in an adverse event report. The scores for each axis of the algorithm are summed to arrive at a causality assessment score for each clinical sign. General categories of drug-related association are

Remotely
Possibly
Probably
Definitely

All clinical manifestations with causality assessment scores of Possibly, Probably, or Definitely drug-related are included in the monthly update of the cumulative summary on the FDA CVM website.

Since the inception of the FDA CVM's ADE system, the development of new types of drugs has required closer attention to its application.[11,12,13] Take as an example the macrocyclic lactone heartworm preventives, which are given monthly or at even longer intervals. Since these drugs are reapplied at such long intervals, it can take a while for an association to be realized if an adverse drug event occurs.[12] Consider this analogy: clinical manifestations from agents such as *Campylobacter* and *Salmonella* can take days to appear, but most people blame their most recent meal for their gastrointestinal upset. Similarly, recurrence of the adverse event may not be recognized until after several rechallenges due to the length of time between applications.

It can be very difficult to determine the appropriate designation for dechallenge with a drug that can remain in the body for a month or longer. Typically, toxicologists use seven terminal half-lives as a timeframe for calculating drug disappearance where 99% of the drug is eliminated from the body.[19] Although for the most part events are expected to occur during times of peak serum concentration, reviewers should also consider chronic syndromes

Elements of Adverse Clinical Manifestation (CM) Algorithm

1. **Previous Experience With Drug:**
   - **+1** CM generally recognized to occur in this species at the dosage received.
   - **0** CM is not generally recognized to occur in this species at the dosage received but has been previously reported in veterinary and/or human medicine.

     Drug has limited accumulated clinical experience (time and/or quantity marketed).
   - **−1** CM previously unreported and drug has substantial accumulated clinical experience (time and/or quantity marketed).
2. **Alternative Etiologic Candidates:**
   - **+2** There is **no** good candidate or no change in a candidate which can explain the CM, exclusive of drug administration.
   - **0** An alternative candidate(s) exists, but not a good one(s) which can well explain the CM.

     CM commonly occurs spontaneously in this type of patient and situation, usually in the absence of any recognizable alternative candidate(s).
   - **−1** There is a good candidate or a change in a candidate which can well explain the CM, exclusive of drug administration.
3. **Timing of Events:**
   - **+1** Timing was consistent and as expected for this type of CM to this drug.
   - **0** Do not know what timing to expect.
   - **−2** Timing was inconsistent for this type of CM to this drug.
4. **Evidence of Overdose:**
   - **+1** CM is clearly a dose-related type of manifestation, **and** there is unequivocal evidence that the amount of drug received was an overdose for this animal.
   - **0** CM is not a dose-related type of manifestation **or** there is no evidence of an overdose.
5. **Dechallenge:**
   - **+1** CM diminished or disappeared after discontinuation of suspect drug or administration of **a specific** antidote.

     CM is known to be dose-related, and CM diminished or disappeared after dosage reduction.
   - **0** Dechallenge difficult, impossible, or inappropriate to assess.

     A non-specific agent or maneuver (non-antidotal) was administered that was directed against the CM and that usually produced the degree and rate of improvement observed in the case.

     CM characteristically transient and episodic, and there is no established pattern episodes (regardless of what occurs after discontinuing the drug).

     CM known to be dose-related, and CM did not diminish or disappear after dosage was reduced.
   - **−1** CM did **not** diminich or disappear after discontinuation of suspect drug.

     CM improved without dechallenge **and** the improvement **cannot** be attributed to the development of tolerance.
6. **Rechallenge:**
   - **+1** CM unequivocally recurred or exacerbated after rechallenge.
   - **0** There was no rechallenge attempted.

     A non-specific agent or maneuver (non-antidotal) was administered that obscured the response of the CM.

     CM failed to recur or exacerbate on rechallenge, **but** the dosage or duration of drug administration on rechallenge was substantially less than that suspected of causing the original CM.

     Recurrence or exacerbation of CM was impossible to assess because it was progressing or was at a level of severity that any further increase would be difficult to appreciate.
   - **−1** CM failed to recur or exacerbate on rechallenge.

FIG. 58.1 Elements of adverse clinical manifestation (CM) algorithm.

that might emerge from residual drug or drug product, such as cachexia or neoplasia. Such syndromes might be attributed to the "background" frequency of disease occurrence and could easily be missed.

The effect on the algorithm in these situations is to skew the summed causality assessment lower (to the level of "Possibly" or "Remotely" drug-related), since it is difficult to assign a positive number to represent a strong associa-

tion in time, recognition of rechallenge, or a definite result of dechallenge. This means that the signal of an emerging adverse event could be overlooked. This will be an ongoing consideration as new types of drugs are developed.

STRENGTHS OF ADE REPORTING SYSTEMS

Strengths of the ADE reporting systems include

1. ADE reporting provides a cost-effective way to study the safety and effectiveness of drugs in large, heterogeneous animal populations, compared to the animals in preapproval studies; thus, signals may be evaluated with greater correlation to context of use.[22]
2. The FDA CVM can monitor early risk signals and maintain ongoing surveillance.

Signals generated by evaluation of ADE reports can be used to generate hypotheses and can serve as the foundation for postapproval safety studies by the manufacturer.[20]

LIMITATIONS OF ADE REPORTING SYSTEMS

Limitations of the ADE reporting systems include

1. *Underreporting.* Spontaneously reported ADEs represent only a small portion of the number of ADEs that have actually occurred, resulting in an underestimate of the number of suspected ADEs.
2. *Lack of accurate exposure data.* In most cases in veterinary medicine, precise information related to doses sold and/or administered is not available. For this reason, it is not always possible to calculate the number of dogs affected by the drug compared to the number that actually received the drug (incidence). Likewise, it is usually not possible to calculate the number of those suspected to have reacted to the drug compared to the number of those suspect drug reactions that were actually reported to CVM (reporting rates).
3. *Report quality is often lacking.* Reports relying solely on contact with the animal owner often lack medical information such as laboratory test values, concomitant medications administered, and preexisting medical conditions. Attempts to collect information from veterinarians may be incomplete due to reliance on lay staff to complete the report form. Sometimes the attending veterinarian is too busy to discuss the case. Follow-up information about the outcome of the event may be lost when owners change veterinarians, move, or simply never bring the animal back for reexamination.
4. *Potential bias.* Media coverage, including direct-to-consumer advertising, and internet access have greatly increased consumer awareness in general. If a product receives media attention or becomes the subject of an internet website, there may be a flurry of reports from the public. The number of ADEs submitted for a drug is at its highest by the end of the first 2 years of its marketing.[29] Drug manufacturers with sophisticated pharmacovigilance programs are more likely to provide greater numbers of timely and accurate ADE reports than those without these systems. Another source of bias may be the failure to recognize a problem in a product due to a high level of comfort with its use, such as with a product that has been marketed for years or a new product perceived as having no side effects. Still another source could be failure to recognize a timely association of the event with a drug that has a sustained or chronic effect.

Still, despite these limitations, CVM and other FDA centers have found pharmacovigilance a valuable tool for communicating drug risk to the health professional and consumer.[10,17,20]

TRENDS IN PHARMACOVIGILANCE AT FDA CVM. Currently, the FDA CVM receives more than 30,000 ADE reports each year. There has been a steady increase from the approximately 4,500 received at the inception of the current ADE program in 1997. Figure 58.2 demonstrates the growth in adverse experience reporting to CVM over time.

The ADE reports sent to the CVM primarily represent adverse events occurring in the U.S.A., but may include foreign reports if the suspect product carries the same label used in the U.S. This means that adverse events are not reported for the same product that carries a different brand name in another country, although such events may be known to the regulatory authority of that country. As a result, a single report of a serious adverse event may seem insignificant in one country but, if it were known that similar events had been reported in other countries, this "isolated" event might be viewed with more importance.

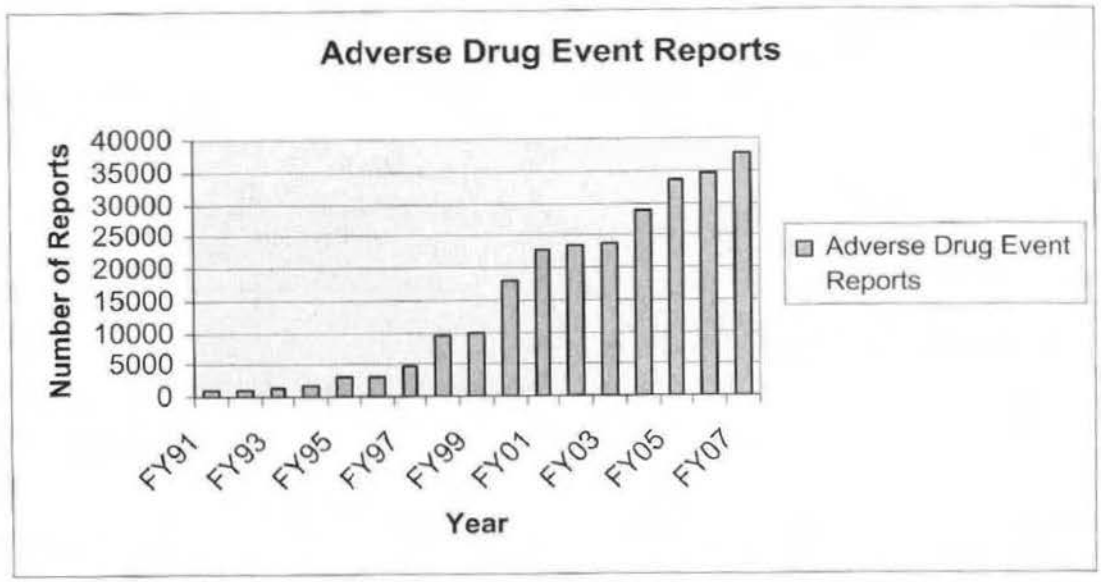

FIG. 58.2 The number of veterinary adverse drug events filed with the U.S. Food and Drug Administration Center for Veterinary Medicine by fiscal year.

The number of veterinary adverse drug events in a foreign country also depends on such factors as the market size of the drug in that country, consumer awareness and tendency to report, and existence of an established reporting program.

The effort to allow such important information to reach the countries in which the same product is marketed (albeit under different names) is being addressed by the Expert Working Group for Pharmacovigilance of the International Cooperation on Harmonization of Technical Requirements for Registration of Veterinary Medicinal Products (VICH). Regulators from global regions and representatives from industry and observer countries are arriving at agreements that will allow some expedited reports of adverse events to be sent to all participating countries.

Standardization of information submitted by VICH regions will help to maximize the quality of the adverse event reports, providing more complete data for analysis.

Paper submissions of adverse events are bulky and labor-intensive to process and store. As international sharing of information progresses, electronic submissions will be increasingly important. An electronic submissions system common to the FDA CVM and the major pharmaceutical companies will minimize the clerical effort of receiving, tracking, entering, and analyzing adverse event information; this is already in the testing phase and should be established within the next year. Web-based forms are being investigated for ease of submission that should make reporting more practical for today's busy professional. The integrated result of the informed client, the attentive clinician, the detailed adverse event report, and vigilant surveillance activity by pharmaceutical firms and regulatory authorities should result in timely, user-friendly web postings of accumulated ADE information as well as rapid identification and correction of emerging safety issues.

DOSAGE FORMS AND VETERINARY FEED DIRECTIVES

JIM E. RIVIERE AND GEOF W. SMITH

Pharmacokinetic Considerations and Controlled-Drug Delivery 1439
Palatability and Ease of Drug Administration 1441
Veterinary Feed Additives 1442
Site-Directed Therapy 1444

One of the primary differences between human and veterinary pharmacology is the wide range of dosage forms available to the veterinarian that occurs as a direct consequence of significant differences in the way drugs are administered to animals and humans. These differences are a consequence of obvious dissimilarity in anatomy and physiology, but also are a direct consequence of variations in behavior, husbandry practices, and inability to verbally communicate with animal versus human patients. Additionally, as discussed in Chapter 61, some animals are raised for human food production and thus drug delivery strategies that result in so-called injection-site residues may not be acceptable solely due to possible human consumption of the delivery device or its residues. Different dosage forms are employed for three main reasons: ease of administration and thus compliance, controlled rate of drug delivery, and husbandry constraints in treating populations of animals in a production environment.

The focus of this chapter is to introduce the reader to the wide variety of dosage forms encountered in veterinary medicine. Specifics on most of these formulations can be found in the individual therapeutic chapters or the introductory chapters on pharmacokinetics and ADME.

PHARMACOKINETIC CONSIDERATIONS AND CONTROLLED-DRUG DELIVERY

By far, the dosage form has the greatest influence on the rate and extent of absorption of drugs. The physiology behind these factors was discussed in Chapter 2 and their resulting effects on a drug's plasma concentration-time profile were presented in Chapter 3. The development and impact of these formulations has been extensively reviewed elsewhere (Hardee and Baggot 1998; Baggot 2002; Martinez et al. 2002). When the absorption characteristics of a drug formulation become rate limiting, and flip-flop pharmacokinetics becomes operative, the shape of the drug's concentration-time profile, and thus pharmacologic effect, is in control of the formulation and not the animal's ability to clear the drug. Secondly, innovations in drug delivery allow existing drugs to be more effectively used and provide extension of the commercial life of the product for a manufacturer.

The classic example of the effect of formulation is seen with the plasma concentration-time profiles of potassium, procaine, and benzathine penicillin G (Fig. 59.1). The formulation strategy is to complex the active drug (e.g., penicillin G) with a moiety that delays its release to the

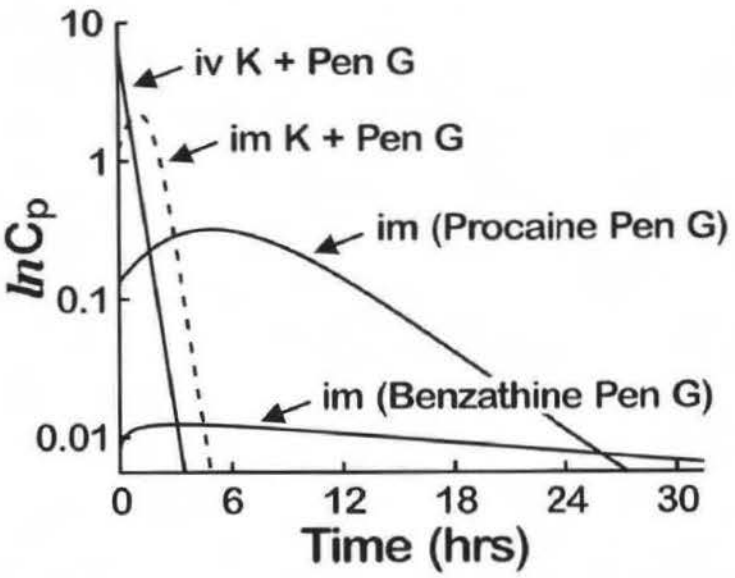

FIG. 59.1 Effects of formulation and route of administration on the plasma concentration versus time profiles of penicillin G.

surrounding capillary beds by modulating the drug's solubility. A pharmaceutics text should be consulted for the chemistry of these processes. The result is that the rate of release of the compound from the dosing formulation becomes slower than that of the drug's elimination, making it rate limiting.

The potential problems with these strategies are twofold. If one considers antimicrobial therapy, for bacteria with very high therapeutic thresholds (e.g., minimum inhibitory concentrations, MICs), the prolonged release formulations may never provide effective therapeutic drug concentrations. Second, such so-called "depot" preparations in food animals may result in persistent drug concentrations in tissues, thereby prolonging the withdrawal time (see Chapter 61). Drug depots at injection sites may persist much longer than effective blood concentrations and may be easily detected at slaughter. One must exhibit care to differentiate drug tissue concentrations at injection sites from those achieved after absorption and systemic distribution (Sanquer et al. 2006).

This scenario also nicely illustrates the reason that knowledge of both the extent and rate of drug absorption are needed to adequately describe the absorption of a drug and underscores why determination of drug bioequivalence (e.g., dosage form interchangeability) requires assessing both metrics related to rate (peak, time to peak) and extent (AUC) of drug absorption. The importance of these factors was also discussed in Chapter 3 under dosage regimen construction.

Approved dosages are very dependent upon the formulation of the drug utilized, a factor that must be considered when using any drug in a veterinary patient. This approach has recently been taken advantage of to develop other once-daily dosing of drugs such as antibiotics in veterinary species, the increased dosing interval being due either to the use of drugs with inherently long half-lives or depot release characteristics. These formulations stress the necessity of knowing the dosage form used when conducting any pharmacokinetic analysis as it may modulate the rate-controlling factor in drug disposition. In many cases, this can be detected only from intravenous pharmacokinetic experiments.

The development of depot preparations has received a great deal of attention by pharmaceutical industries. Some contraceptives in humans achieve monthly dosing intervals through injection in the subcutaneous tissue of insoluble tablets, which results in very slow drug release; the best example is the use of levonorgestrel implanted capsules (Norplant®). Similar strategies have been employed in veterinary medicine for the administration of growth promotants. These include estradiol formulated in rubber implants (Compudose®), progesterone and estradiol pellets (Implant-C®), and zeranol (Ralgro®). Newer approaches include use of biodegradable gels that may be injected as a liquid through a syringe; these gels form a slowly degrading solid once in the tissue. Temperature-sensitive thermogels can also be used to control release of drug once in the body at physiological temperatures. A great deal of new technology is being developed for such formulations that promises more sophisticated dosage forms in the future.

Oral drug dosage forms achieve control of release through modulation of the surface area of dissolving drug particles, through the size of particles that alter their gastrointestinal transit time, or through the use of multiple layers in the formulation that control the rate and extent of drug release and dissolution. The simplest example is to coat a drug to prevent its dissolution in the acid environment of the stomach. These formulations are specifically designed for specific species, due to differences in gastrointestinal content and motility, as well as issues that include palatability. Capsules can be designed that initially release a bolus of readily soluble drug that functions as a loading dose into the animal. This is then followed by slower release of drug that maintains effective levels. For some compounds, only local delivery is needed to the gastroin-

testinal tract (e.g., certain antiparasitics), and the formulation can be designed for such activity. Work has occurred in humans to specifically deliver drug to the colon for localized effect. Again, it must be stressed that many of these controlled-release dosage formulations are specifically designed for species-specific anatomical (size of pyloris), biochemical (cellulose based for nonruminants), and/or physiological (pH, transit time) factors that prevent easy use in other species.

A truly unique aspect of dosage form not seen in human medicine are those employed in ruminants that take advantage of the observation that heavy materials sink in the rumen and are not passed further along the digestive tract. This has resulted in the design of mechanical dosage devices that infuse drug into the rumen for specific durations. Some materials are formulated to be flocculent and float in gastrointestinal contents allowing controlled passage though the stomach. Finally, slow-release osmotic pumps may be implanted in animals to achieve controlled drug infusions.

A major variable concerning parenteral injections relates to the physiology of the injection site. For a drug to be adequately absorbed from a depot preparation, there must be access to the perfusing capillaries and an adequate rate of tissue perfusion. A major source of variability is the muscle into which intramuscular injections are made. Studies have elegantly demonstrated in horses that if the injection is made between the fascial tissue bundles of a muscle group, less systemic absorption will occur than if the injection is in the muscle mass. Similarly, if the muscle group, or more likely, the SC injection site, has poor blood perfusion, less absorption may occur. If the injection results in a local tissue reaction, subsequent inflammation and fibrosis may "wall off" the drug formulation preventing absorption. Changes in ambient temperature, with compensatory changes in skin blood perfusion, may modulate absorption rate. There are numerous variables in these processes, and it is often only through the use of careful pharmacokinetic analyses that their influence on drug absorption cause can be ascertained.

Topical dosage forms include gels and patches that control diffusion from the dosage form to be rate limiting for dermal absorption. These products have been discussed in Chapter 2 and are fully reviewed elsewhere (Riviere and Papich 2001). The advantage of dermal over oral or parenteral controlled-released approaches is that the topical gel or patch can be removed should cessation of dosing be required. Transdermal fentanyl patches for analgesia in dogs has been a particularly successful story for using human patches. However, these cannot be easily transferred between species as the rate-limiting barrier may be species- and site-specific. As of this time, specific patches for animals have not been marketed.

In contrast, there are numerous topical spot-on, pour-on, collars, dip, and shampoo formulations for topical pesticides, often focusing on flea control. Some of these have resulted in once-monthly dose administration and increased owner compliance. These preparations are fully covered in Chapters 44 and 48 of the present text. In addition to these unique pour-on applications, large-animal veterinary medicine also employs ear-tags and dust-bags that allow topical drug delivery in cattle and swine in a rate- and dose-controlled fashion.

PALATABILITY AND EASE OF DRUG ADMINISTRATION

Another factor relatively unique to veterinary medicine relates to the ease of drug administration to animals that might present danger to the individual administering the drug. This has resulted in formulating drugs in dosage vehicles that are palatable and will be easily eaten by the animal, but made of ingredients that do not alter drug absorption properties. A great deal of information is available from the pet food and vitamin industry that provides quantitative approaches to assess factors such as taste preferences and palatability (Ahmed et al. 2002; Thombre 2004). This has resulted in the development of chewable drug formulations as well as flavor ingredients that mask bitter taste or odors that animals refuse to eat. In contrast to human medicine, where sight and verbal cues may allow administering distasteful drugs to adults, animals rely on senses of taste and smell to determine whether a drug-containing formulation will be consumed. Other approaches to oral drug administration under consideration include use of dissolvable films and oral sprays for targeting the buccal cavity of patients. These are particularly being developed for cats where owners often have difficulty in administering other oral drug formulations.

A final approach that is relatively unique to veterinary medicine includes the direct administration of drug into drinking water, into lick-tanks, or on feed for use in large production settings (e.g., cattle, swine, poultry). An important distinction with this continuous form of drug administration is that, unlike the bolus effect seen with individual

liquid dosing or rapidly dissolving tablets, absorption may not be first-order. If administration is constant in water or feed, absorption may be zero-order and have pharmacokinetic behavior resembling an infusion. Finally, drugs may be administered in medicated blocks, which results in ease of administration but little control of individual animal dosage.

VETERINARY FEED ADDITIVES

One strategy for administering drugs to animals that is unique to veterinary medicine is oral dosing via feed. This is often necessary due to the need to treat a large number of animals in a production environment. Unlike individual animal dosing, this approach does not assure that a specific dose of drug reaches each animal, since drug dosage is now a function of food consumption. As mentioned above, issues of palatability and odor also must be taken into consideration.

The legal control of feed additives is also different than other drug formulations. The Veterinary Feed Directive (VFD) refers to a relatively new category of medicated feeds created by the Animal Drug Availability Act of 1996. Prior to this time, the Food and Drug Administration (FDA) had only two options for regulating the distribution of animal drugs: over-the-counter or prescription. The primary purpose of the VFD was to provide an alternative to these categories for certain therapeutic drugs that are mixed in feed. A VFD drug still ensures the participation of a veterinarian, but it allows producers to acquire medicated feeds through traditional manufacturers without involving a pharmacist or having to follow state pharmacy laws.

In 1996 the Center for Veterinary Medicine (CVM) of the FDA expressed a greater need for control over the use of certain antimicrobial agents in medicated feeds. Initially it was suggested to mandate all new therapeutic agents approved for use in feed be for use by prescription only. However, having additive drugs approved as prescription-only was unacceptable to the animal agriculture and feed industry. Requiring these drugs to be for use by prescription only would have turned feed mills into drug stores because they would be forced to mix a new batch of feed each time a prescription was written. Studies done by the American Feed Industry Association (AFIA) in the 1990s estimated the average feed costs in the swine industry would have risen from $36 to $100 per ton because of additional costs associated with special ordering and the need to mix only small volumes of feed at once. These prescription drugs would also fall under the direction of most state pharmacy regulations, which would further complicate the ability to manufacture and distribute medicated feed.

The VFD was therefore created to be an alternative to the traditional prescription classification. It places a much greater emphasis on professional control as compared to over-the-counter medications while still allowing agricultural producers to obtain medicated feeds efficiently and cost effectively. This classification applies only to drugs that are newly approved as VFD medicated feeds. As of 2006, the two drugs that have been approved in this category are tilmicosin (Pulmotil®), which is approved for control of swine respiratory disease associated with *Actinobacillus pleuropneumoniae*, and *Pasteurella multocida* and florfenicol (Aquaflor®), which is indicated for the control of mortality in catfish due to enteric septicemia associated with *Edwardsiella ictaluri*. As with other medicated feeds, the extralabel use of any VFD drugs is prohibited.

The initial requirement of using a VFD medicated feed is a valid veterinarian-client-patient relationship. As defined by the American Veterinary Medical Association (AVMA), this relationship exists when

1. The veterinarian has the responsibility for making medical judgment regarding the health of the animal(s) and the need for medical treatment, and the client has agreed to follow the instructions of the veterinarian.
2. There is sufficient knowledge of the animal(s) by the veterinarian to initiate at least a general or preliminary diagnosis of the medical condition of the animal(s). This means the veterinarian has recently seen and is personally acquainted with the keeping and care of all the animal(s), and/or by medically appropriate and timely visits to the premises where the animals are kept.
3. The practicing veterinarian is readily available, or has arranged for emergency coverage, for follow-up in case of adverse reactions or failure of the therapeutic regimen to solve the problem.

Once a veterinarian has made an initial diagnosis, he/she can issue a signed VFD on a preprinted, multipart form. The veterinarian gives the form to the producer, who then orders the medicated feed from the feed supplier. A VFD feed may not be distributed to a producer without a signed VFD form. Three groups are involved:

1. The person or firm supplying a VFD drug to a producer must receive and retain a copy of the signed VFD form issued by the veterinarian.
2. Licensed feed manufacturers and distributors who ship VFD feed to a downstream distributor or retailer for inventory must receive and retain a copy of written acknowledgement stating that the VFD feed will be further distributed only in accordance with FDA requirements.
3. All distributors and retailers who do not hold a feed mill license must notify the FDA within 30 days of their initial VFD feed shipment.

The form for Veterinary Feed Directive products should be provided to the veterinarian by the manufacturer of the specific therapeutic agent (Fig. 59.2). This form must be completed by the veterinarian and should normally include the following information:

1. The name, address, and telephone number of the producer
2. The species, location, number of, and description of animals being treated
3. The date(s) of treatment (if different from the date on the VFD form)
4. The name of the drug to be used, the concentration of the drug to be included in the feed, and the amount of feed to be manufactured
5. The directions for mixing and feeding (including dilution) and duration of treatment, including appropriate withdrawal times. The expiration date of the feed

ELANCO Pulmotil

PULMOTIL® (tilmicosin) Veterinary Feed Directive

Client	See More Swine	Veterinarian	Jim Smith
Address	123 Pig Lane	Address	Hog and Dog Veterinary Services
	Sample City, NC 20060		2625 N Loop Drive
			Sample City, NC 20060
Phone #	919-539-8177	Phone #	919-123-4567
Fax #		Fax #	919-123-4678

Swine to be treated (number and location):
Count: 2500 Group Name: Barn 2

Mix into Type C Medicated Feed to provide:

181 g/ton	272 g/ton	363 g/ton
☐	☒	☐

Warning: Feeds containing tilmicosin must be withdrawn 7 days prior to slaughter.

Feeding Directions: Feed continuously as the sole ration for 21 days beginning approximately 7 days before an expected outbreak of swine respiratory disease.

Special Instructions: Feed for 21 days/18 tons of feed

Expiration Date: 11/22/2006 (Month/Day/Year (Not to exceed 90 days))

Amount of final (Type C) feed 18.0 tons

Veterinarian's Signature: Sample DVM Date: 8/22/2006

License Number and State: 00000 North Carolina

FIG. 59.2 Sample Veterinary Feed Directive form for tilmicosin (reprinted with permission from Elanco Animal Health).

7. The veterinarian's name, address, license number, state of licensing, and signature

The form is the most significant component of using VFD approved medications. A VFD order cannot be issued by telephone. If the form cannot be hand-delivered, it can be faxed or sent via an email attachment; however, the original form must be received by the distributor within 5 working days. VFD forms have to be retained for a minimum of 2 years by all three parties involved (the veterinarian, the producer, and the feed mill) and should be available for review by the FDA.

Only vendors with a valid feed mill license are authorized to store VFD products, which means that a producer is not allowed to keep a surplus of medicated feed on the farm. However licensed veterinarians are allowed to act as distributors of VFD feeds by notifying the FDA once, in writing, 30 days before the first anticipated distribution of medicated feed.

SITE-DIRECTED THERAPY

The final consideration related to veterinary dosage forms are those drugs specifically designed for local effects. These include intramammary and intrauterine formulations, and ophthalmic and otic drugs. Examples of these are discussed under the individual drug sections and special therapy chapters of this text.

USP'S ROLE IN VETERINARY PHARMACOLOGY AND EVIDENCE-BASED INFORMATION

CORY LANGSTON, STEFAN SCHUBER, AND IAN F. DEVEAU

***USP* and Its Compendia**	**1445**
***USP* and FDA**	**1446**
***USP* Evidence-Based Pharmacotherapy**	**1447**
Introduction	**1447**
The Veterinary Pharmaceutical Information Monograph Creation Process	**1447**
Drawbacks to the USP Monograph Creation Process	**1450**

The *United States Pharmacopeia (USP)* is a nonprofit organization that few veterinary practitioners are familiar with; yet it plays important roles in maintaining drug quality and promoting the proper use of medications. There are two sections to this chapter, the first, "*USP* and Its Compendia," explains the history of the organization, its continuing mission, and its publications. The second section, "*USP* Evidence-Based Pharmacotherapy," details the evidence-based approaches used by *USP* in creating its veterinary drug information monographs and how these are increasingly finding utility by veterinarians, particularly relative to extralabel drug use.

USP AND ITS COMPENDIA

As stated in the preface to the first *USP* of 1820, *USP*'s mission was and continues to be

> . . . to select from among substances which possess medicinal power, those, the utility of which is most fully established and best understood and to form from them preparations and compositions, in which their powers may be exerted to the greatest advantage. It should likewise distinguish those articles by convenient and definite names, such as may prevent trouble or uncertainty in the intercourse of physicians and apothecaries.[1]

There are many important words in this brief text, but the first two (*to select*) are among the most important. *USP* was not intended to be simply a listing of all available drugs but rather a selection of the *best* drugs, which came to be termed *official drugs*. The first *USP* of 1820 also provided a list of the *Materia Medica* of the time (". . . simple medicines, together with some prepared medicines, which are kept in the shop of the apothecary, but not necessarily prepared by him") and a third list of secondary drugs—"the claims of which [were] of a more uncertain kind." These three categories duplicate remarkably the items now available in a modern pharmacy: 1) the best drugs (now mostly manufactured and FDA-approved, including safe and effective OTC products usually marketed subject to FDA and *USP* monographs), 2) a secondary list (some dietary supplements), and 3) routine items of health care not requiring preparation on the part of the pharmacist. The first *USP* in principle was thus based on the idea of a national formulary composed of the best drugs, drawing them out of a sea of nostrums of uncertain safety, efficacy, and quality.

After *USP*'s first convention in 1820, the selection of the best or official drugs for subsequent editions of *USP* was directed by the Committee on Scope (now the Council of Experts). Historically, physicians held a majority on the Committee of Revision, and pharmacists constituted a minority. This dichotomy at times sparked debate between physicians and pharmacists about appropriate admissions of the best drugs to *USP*. For example, during the 19th century, physicians but not pharmacists resisted the inclusion of hydroalcoholic patent medicines of dubious provenance and value that entered commerce around the Civil War. As a general approach, the Committee of Revision tended to select single-entity therapeutics for inclusion in *USP*, advancing the science of therapeutics from use of crude mixtures to pure moieties.[2] In a development that in many ways parallels that of *USP*, pharmacists increasingly relied on the American Pharmaceutical Association's *National Formulary* (*NF*), first published in 1888. The early *NF* attempted to provide standardized recipes for compounded preparations—in fact, the full title of the first *NF* was *The National Formulary of Unofficinal Preparations*, the word *unofficinal* alluding to the acts of compounding and dispensing of prescriptions from ingredients (many of which were included in *USP*) and standard preparations made and kept by pharmacists.[3]

In 1985, *USP* ended the Committee on Scope (as it came to be known) with the preparation of *USP XXI*, which became official in 1985.[4] This occurred for good reason: *USP* no longer selected the best drugs for the U.S. marketplace. During the 20th century, FDA had taken on the task of approving all new drugs in the U.S. based on a determination of both safety and efficacy relative to benefit. These then were the best drugs. *USP*'s role became one of providing public quality monographs for these drugs, which also includes monographs for a small number of pre-1938 "grandfathered" drugs (i.e., certain drugs that were marketed before the passage of the 1938 Federal Food, Drug, and Cosmetic Act; see below). As a result of the long and illustrious scientific history of work by dedicated compendial scientists, government regulators and policymakers, pharmaceutical manufacturers, compounding professionals, and many others, a robust set of good-quality drugs now is available to practitioners and patients in the U.S.

***USP* AND FDA.** Spurred by stories of U.S. soldiers dying because of substandard drugs during the Mexican War (1846–1848), the U.S. government recognized *USP* and some European pharmacopeias in the 1848 Drug Import Act,[5] which sought to control the quality of drugs moving in commerce at the time. *USP* was officially incorporated as a nonprofit organization in Washington, D.C., in 1900. Six years later the Federal Food and Drugs Act of 1906, signed by President Theodore Roosevelt, declared that drugs were adulterated if they differed "from the standard of strength, quality, or purity, as determined by the test set down in the *United States Pharmacopeia* or *National Formulary* . . .".[6] In 1938, 105 people died of diethylene glycol poisoning after consuming Massengill's Elixir Sulfanilamide.[7] In response, that same year Congress passed the Federal Food, Drug, and Cosmetic (FD&C) Act, which preserved and strengthened the recognition of *USP* in federal law, prevented the Secretary of Agriculture (now the Secretary of Health and Human Services) from unilaterally amending *USP* tests or methods of assay, and recognized *USP* packaging and labeling requirements as federal requirements.[8]

In 1974 *USP* acquired *NF* and since 1975 has published the two compendia as one volume, *USP–NF*. Publication now occurs annually with two *Supplements*, reflective of continuing advances in new therapies and in the science of metrology. From provisions in the 1938 FD&C Act, *USP* and *NF* are designated official compendia of the U.S. and are recognized as well in other national and international laws for enforcement and other purposes.[9] *USP*'s volunteer bodies consist of convention delegates who meet at 5-year intervals, an 11-member Board of Trustees, and the Council of Experts, the standards-setting arm of the organization. In its 2000–2005 cycle, the Council of Experts was composed of the chairs of 31 Expert Committees that created standards for *USP–NF*. An additional 28 Expert Committees created value-added content for the *USP–Drug Information* (*USP–DI*) series[10] and an additional three (Safe Medication Use, Information Development and Dissemination, and Therapeutic Decision-Making) focused on special topics. The chairs of the Council are responsible for electing membership of each Expert Committee, which numbers usually between 5 and 20 members. All are assisted by a staff of approximately 400 in *USP*'s Rockville, MD, offices.

USP reengaged in the provision of drug information in 1970 with publication of the *USP–DI* series (*Volume I: Drug Information for the Health Care Professional, USP–DI Volume II: Advice for the Patient*, and *Volume III: Approved Drug Products and Legal Requirements*), which provided

value-added information (off-label uses, safety, dosing, and other information) to supplement FDA-approved labeling. In 1998, *USP* sold rights to *Volumes I* and *II* to Thomson Publishing Company, retaining editorial control for value-added content. However, the agreement between *USP* and Thomson was that Thomson would abandon the publication of veterinary drug information monographs, allowing *USP* to seek other venues for publication.

USP EVIDENCE-BASED PHARMACOTHERAPY

INTRODUCTION. Veterinarians traditionally obtain their knowledge from subject-matter experts via lectures, textbook chapters, journal articles, web resources, or personal consultations. Although this approach will always have a place in teaching medicine, obtaining knowledge from a single expert has potential drawbacks: experts may have their own biases, unevaluated dogmas may be perpetuated, and opinions may differ among experts. Most importantly, when relying solely on expert opinion clinicians have no basis on which to make their own determinations about the best approach for their particular patients.

In the 1990s a paradigm shift began in human medicine that concentrated less on authority-based expertise and instead emphasized the critical review of the scientific literature. This approach became known as evidence-based medicine (EBM). EBM has been defined as the "conscientious, explicit, and judicious use of current best evidence in making decisions about the care of individual patients. This means integrating individual clinical expertise with the best available external clinical evidence from systematic research."[11] To those unfamiliar with EBM, it might seem that this approach offers nothing new. Although it is true that the literature has been used to guide medical decisions for as long as we can remember, EBM formalizes that process and filters the literature so that clinicians are aware of the evidence that influences their decisions and the strength of that evidence. It should be pointed out that EBM does not ignore expert opinion altogether; it does, however, relegate its importance to a much lower level of influence than other recognized resources.

Because an exhaustive analysis of the literature can be quite time consuming, physicians rely on what are commonly known as "systematic reviews" instead of performing their own EBM synopses. "Systematic reviews comprehensively examine the literature, seeking to identify and synthesize all relevant information to formulate the best approach to diagnosis or treatment."[12] An example of a systematic review conducted in human medicine might include a topic such as "What is the role of estrogen exposure and the risk of breast cancer?"[13]

EBM is well entrenched in human medicine and many resources exist for the physician. Databases devoted exclusively to systematic reviews in human medicine include the *Cochrane Collaboration* and the *British Medical Journal's Clinical Evidence Compendium*. The extent to which this approach has been adopted is further demonstrated in that a search of the *PubMed* online database for articles containing the words "Systematic review" in their title produced 4,178 articles. This abundance of literature is not, however, the case with evidence-based veterinary medicine (EBVM). A similar *PubMed* search restricted to contain the word *veterinary* in the title, abstract, or key words produced only 6 journal articles.

An exception to this paucity of EBVM is the veterinary drug information monographs published by the *United States Pharmacopeia (USP)*. The method whereby these monographs are produced is unique in veterinary medicine because it incorporates evidence-based approaches, but interpretation of that evidence takes place via consensus of the members of the Veterinary Medicine Information Expert Committee with an opportunity for public review and comments before the information is authorized by the *USP*. Over the years since its inception, this committee has been composed of 8 to 15 veterinary pharmacologists, clinical pharmacologists, pharmacists, and species experts. The *USP* veterinary drug information monographs are at present freely available to the public at the *USP* website www.usp.org/audiences/veterinary/monographs/registration.html (complimentary registration required).

A hard-copy publication, the Veterinary Pharmacopeia, is under development by *USP* and will contain the information monographs along with additional pharmaceutical information of veterinary importance.

THE VETERINARY PHARMACEUTICAL INFORMATION MONOGRAPH CREATION PROCESS. The process of monograph creation begins with a *USP* staff veterinarian obtaining information available on the drugs for review, including U.S. and Canadian label information, FDA Freedom of Information documents, foreign drug labels, and journal articles. Careful attention is paid

to species-specific information. This information is then arranged into a specified format containing commonly used brand names, category of drug, indications, regulatory considerations, chemistry, pharmacology/pharmacokinetics (i.e., mechanism of action/effect, absorption, distribution, protein binding, biotransformation, elimination), precautions to consider, side/adverse effects, overdose treatment, client consultation, and veterinary dosing information.

Many sections, such as chemistry and regulatory considerations, are noncontentious and are merely formatted to fit the monograph layout. Any pharmacokinetic information gathered is added, regardless of species. Dosage recommendations, label and extralabel, are based on Expert Committee consensus. When an extralabel dosage recommendation is made for a food animal, the Food Animal Residue Avoidance Database provides an associated recommended withdrawal time. The indications section, however, requires the greatest effort and is the section to which the EBVM approach is most obviously applied.

For all extralabel indications and for any label indication that is viewed as contentious by an Expert Committee member, evidence tables are generated relative to that indication. Each table contains the citation information, the type of study (e.g., case report[s], clinical trial, disease model, in vitro study, meta-analysis, pharmacokinetic study without surrogate endpoints, pharmacokinetic study with surrogate endpoints), whether treatments were randomized, type of control used (e.g., positive, negative, uncontrolled), and the type of masking used (e.g., single-masked, double-masked, nonmasked). A synopsis of the methods used, doses and duration of therapy studied, results, author conclusions, and limitations noted by *USP* staff are included. This is repeated for each item of litera-

Title: Efficacy of Doxycycline, Azithromycin, or Trovafloxacin for Treatment of Experimental Rocky Mountain Spotted Fever in Dogs

Breitschwerdt, EB, Papich, MG, Hegarty, BC, Gilger, B, Hancock, SI and Davidson, MG. Efficacy of Doxycycline, Azithromycin, or Trovafloxacin for Treatment of Experimental Rocky Mountain Spotted Fever in Dogs. *Antimicrobial Agents and Chemotherapy*, Vol, 43, no 4, April 1999. (813–821).

Author Year (Ref.) Sponsor(s)	Design Methods Goal	Dose Duration N	Results Conclusions	Limitations of Study/DID Staff Comment
Breit-schwerdt, EB Papich, MG Hegarty, BC Gilger, B Hancock, SI Davidson, MG 1999	**Design:** -in vivo study -R, C **Methods:** -Vero cell culture-grown *R rickettsii* were inoculated into egg yolk sacs to produce an infective inocubim. A Guinea pig model was used to optimize the inoculum given to the test dogs -Sixteen 4- to 5-month-old female laboratory-raised beagles were randomly divided into	**Dose:** -Group 1 served as untreated controls -Groups 2 through 4 received doxycycline hyclate (5 mg/kg of body weight given orally, at 12-h intervals), azithromycin (3 mg/kg orally, once daily), or trovafloxacin (5 mg/kg orally, at 12-h intervals), respectively. **Duration:** -began on PID 5 and continued for 7 days for doxycycline and trovafloxacin, and for 3	**Results:** -All dogs were febrile and positive for circulting rickettsiae in blood as detected by tissue culture and/or PCR by PID 5, at which time treatments were begun for the three treatment groups. Compared to the infection control group, treatment groups experienced a statistically significant improvement in attitudinal scores ($P = 0.0003$) by 48 h after the initiation of treatments. Following the initiation of antimicrobial therapy, rectal temperatures nonmalized after 12 h in	Short duration of azithromycin treatment may have decreased the efficacy of the drug.

FIG. 60.1 Example evidence table.

ture relevant to the proposed indication for that drug. A portion of an example evidence table is given in Figure 60.1.

The available information about the indications, all of which are species-specific, is placed into one of three categories. "Accepted" indications are those that have substantial data supporting them and are in common use. The majority of these indications are labeled indications, but extralabel indications also are included if they rise to the required level of evidence. The next indications category is "Potentially effective" (analogous to "Acceptance not established" in earlier published monographs). These are indications with moderate evidence to support a particular use. Last, an indication may be deemed "Unaccepted," meaning the drug should not be used for a given purpose. This latter categorization is most often applied to older drugs that have been rendered obsolete by newer treatments. In addition, beginning in 2005 all new monographs and periodic revisions of older monographs include evidence ratings for each indication. Each rating is composed of one overall Evidence Quality indicator and one or more Evidence Type indicators (see Table 60.1 and Figure 60.2). The monograph identifies into which of the three categories an indication falls, combined with the drug product's evidence ratings, thereby providing an evidentiary basis to support an indicated use.

The initial draft, evidence tables, references, and specific questions or problems obvious to the staff are sent to Expert Committee members, ad hoc reviewers with selected expertise, and manufacturers of the drug under review.

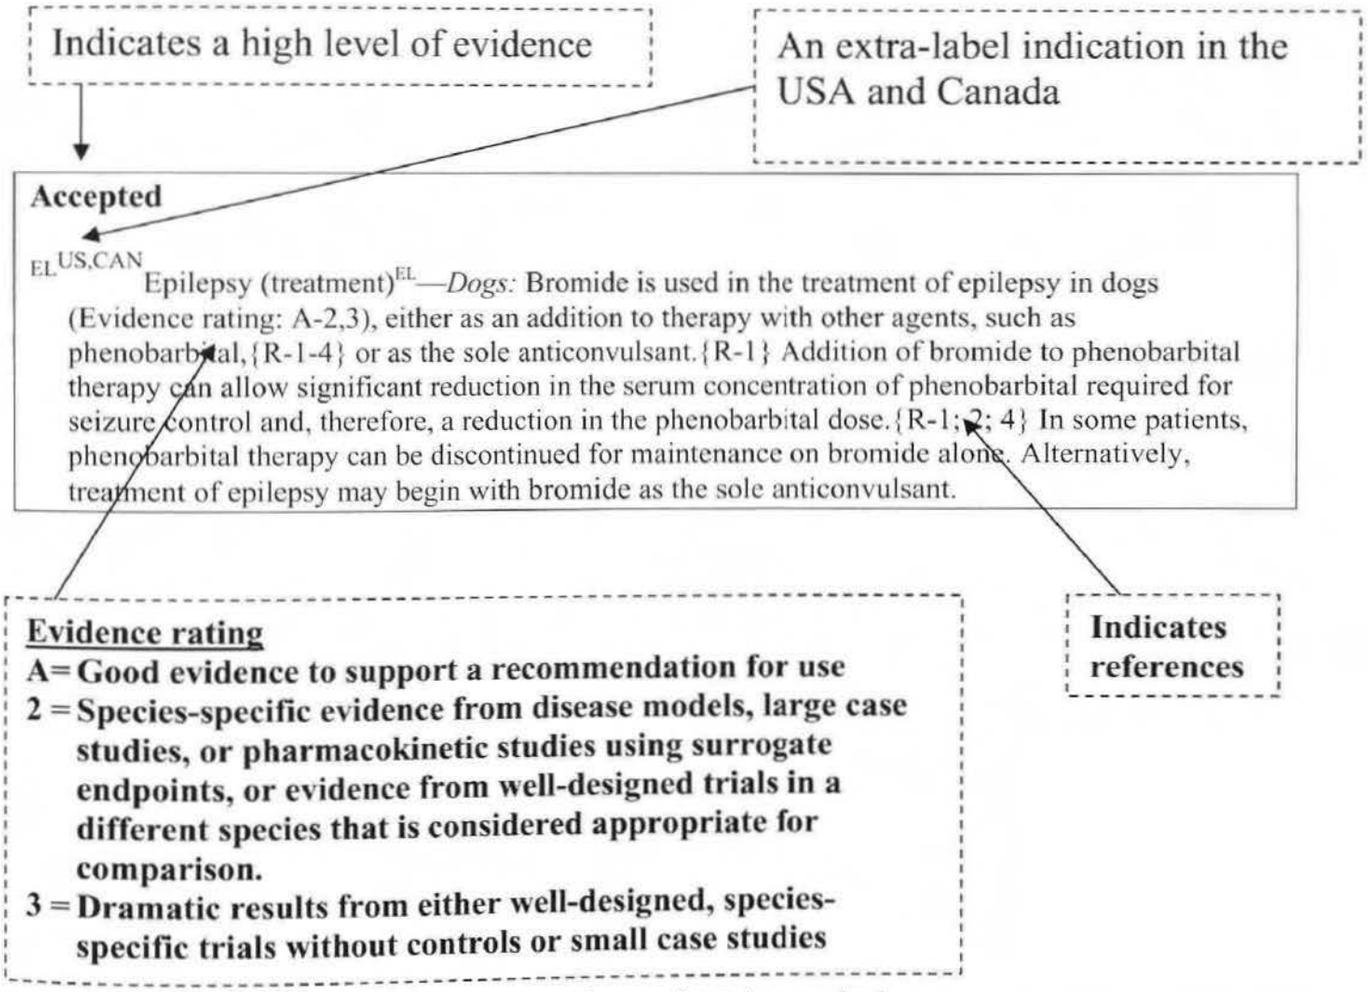

FIG. 60.2 How to read a USP indication (the same nomenclature applies to dosage sections).

TABLE 60.1 Evidence ratings

Evidence Quality

A. Good evidence to support a recommendation for use
B. Moderate evidence to support a recommendation for use
C. Insufficient evidence to support a recommendation for use
D. Moderate evidence to support a recommendation against use
E. Good evidence to support a recommendation against use

Evidence Type

1. Species-specific evidence from at least one large randomized and controlled trial (RCT) or multiple small RCTs
2. Species-specific evidence from a small RCT, disease models, large case studies, or pharmacokinetic studies using surrogate endpoints or evidence from well-designed trials in a different species that is considered appropriate for comparison.
3. Dramatic results from either well-designed, species-specific trials without controls or small case studies.
4. Pharmacokinetic studies without surrogate endpoints
5. In vitro studies
6. Opinions of respected authorities on the basis of clinical experience or reports of expert committees.

Comments and concerns are then addressed in revised monographs and ballots. Monograph revision and Expert Committee review continue as many times as needed by means of an iterative process until a consensus is reached. Before the monograph is finalized it is listed for public review on *USP*'s website, during which time copies of draft text are made available on request to all interested parties for review and comment. Following public review the monograph is finalized, becomes a part of *USP*'s authorized text, and is published (Fig. 60.3). Monographs undergo periodic updates at 2- to 4-year intervals or more often, if needed. At present, *USP* monographs are the only drug information source in veterinary medicine undergoing such extensive evidence-based evaluation coupled with expert panel review, a process by which the scientific credibility of the information is maintained.

- The incorporation of extra-label and label indications and dosages for all domestic species.
- The inclusion of slaughter and milk withdrawals when extra-label drug use in food animals is considered an acceptable option for therapy. (Withdrawal times provided by FARAD for the specified conditions noted.)
- The inclusion of information for U.S. and Canadian veterinary drugs.
- The grouping of indications into three categories. The "Accepted" category indicates that clear evidence exists to support use of the drug for a particular purpose. "Potentially effective" (formerly "Acceptance not established") indicates that use of the drug for an indication may be worthy of consideration if superior therapies do not exist, but the evidence is either scant or subject to concern based on experimental design. If a use is viewed as ineffective or has been replaced by clearly superior therapies, the indication is deemed "Unaccepted." These categorizations are applied to label and extra-label uses.
- The inclusion of evidence levels (flags) in newer and revised monographs for each indication.
- The use of evidence tables to address controversial issues, particularly relative to extra-label drug use.
- The U.S. Food and Drug Administration and product manufacturers are included in the review cycle. (Although comments made by FDA are considered, those opinions are nonbinding on USP. The information contained in these monographs should not be considered an endorsement or "acceptance" by FDA regarding a given use or dosage.)
- The review of each monograph by the USP Veterinary Medicine Drug Information Expert Committee. This committee consists of 10 to 15 volunteers recognized as experts in pharmacology, internal medicine, or species discipline.

FIG. 60.3 Unique features of a USP Drug Information Monograph.

DRAWBACKS TO THE *USP* MONOGRAPH CREATION PROCESS. The same process that creates the *USP* information monographs, which may be the best compilation of drug information in veterinary medicine, also creates its drawbacks. Because *USP* information monographs seek to be the most comprehensive single source of veterinary information about a drug, the vast amount of information can be overwhelming to new users. Because of this information overload, users experience a learning curve while they gain experience in knowing how to quickly find the information needed.

When the *USP* Veterinary Medicine Expert Committee was first formed, its members made an attempt to create the monographs. Unfortunately, the use of volunteer experts produced a limited number of monographs that displayed variable quality. The addition of a full-time *USP*

staff veterinarian to create the draft monographs resulted in a dramatic improvement in both quality and quantity of monographs produced. Because of the amount of information that must be amassed and filtered, evidence tables created, and the multiple reviews involved, a tremendous amount of time is required to produce a monograph. This effort coupled with the time required to revise older monographs every 2 to 4 years limits the number of new monographs that can be produced in a year.

Perhaps the most serious drawback to the *USP* approach to monograph creation is the cost involved. Though the committee members volunteer their services, the overhead for *USP* staff salaries, meetings, and publications can be quite large. Hard-copy publication costs are why evidence tables are for internal use rather than being released with the monograph. Nevertheless, work continues to address new families of pharmaceuticals while updating existing monographs.

For those who are familiar with the monographs created by *USP* there is little doubt that they represent the most complete source of veterinary pharmaceutical information and the only evidence-based resource. The degree to which the veterinary profession will embrace and volunteer to support and enhance these efforts will determine the future of the program.

CHEMICAL RESIDUES IN TISSUES OF FOOD ANIMALS

JIM E. RIVIERE AND STEPHEN F. SUNDLOF

The Concern over Residues in Food	**1453**	**Pharmacokinetics and Residues**	**1457**
Regulation of Drug Residues in Animals	**1455**	**Drugs Prohibited from Extralabel Use**	**1460**
The Veterinarian and Extralabel Drug Use	**1456**	**Residue Prevention**	**1460**

Most of this textbook has focused on describing the pharmacodynamics and pharmacokinetics of drugs in animals. In both human medical and companion-animal veterinary practice, the primary concern in drug selection and use is the therapeutic end point, whether or not the drug is efficacious against the disease being treated. Doses are usually administered at label recommendations, and if greater than label doses are administered, only potential toxicity is of concern. While this line of reasoning is also true to a large degree in food-animal production, veterinarians and producers involved in the treatment of disease in food animals bear the additional concern of the persistence of drug residues in the edible tissues after the disease process has been treated. Adulteration of the food supply with antimicrobial agents, pesticides, environmental contaminants, and other chemicals has been a growing source of concern to the general public and special-interest groups in recent years.

The importance of chemical residues in the edible tissues of food-producing animals has been thoroughly reviewed elsewhere (Sundlof 1989; Riviere 1991, 1992a; Van Dresser and Wilcke 1989; Mercer 1990; Kindred and Hubbert 1993; Bevill 1989). The purpose of this chapter is to acquaint the veterinarian with the legal and regulatory issues concerning the control of drug and other chemical residues in the United States, and to review some of the pharmacokinetic parameters used to determine withdrawal times for drugs and other chemicals in food animals. The primary parameter used by veterinarians to prevent violative tissue residues is the length of the withdrawal time, or the time required for a drug to be depleted from the animal before the animal's meat can be marketed for human consumption. In dairy practice, this is the milk discard time. Recently, government regulation and control have necessitated more stringent adherence to withdrawal times, and on-site monitoring for many drugs has been instituted. This may have an economic impact on production costs. Unlike in previous editions of this text, withdrawal times will not be tabulated, because they are subject to constant regulatory revision. Extensive tables of tissue depletion pharmacokinetic data are published elsewhere (Craigmill et al. 2006).

THE CONCERN OVER RESIDUES IN FOOD

A great deal of concern has been demonstrated over the last 40 years about the presence of chemical adulterants or residues, mainly antimicrobials and pesticides, in the meat,

poultry, and milk supplies of the United States. By definition, a chemical residue is either the parent compound or metabolite of that parent compound that may accumulate, deposit, or otherwise be stored within the cells, tissues, organs, or edible products (e.g., milk, eggs) of an animal following its use to prevent, control, or treat animal disease, or to enhance production. Residues can also result from unintentional administration of drugs, or food additives. Finally, accidental exposure to chemicals in the environment can also result in tissue residues.

Concerns over food residues are economic as well as public health related. For example, the contamination of milk with antibiotics, most commonly penicillin, can affect starter cultures used to make fermented milk products such as cheeses, buttermilk, sour cream, etc., which can result in economic losses to those processors. From a public-health viewpoint, both the U.S. government and producer associations have taken active roles in minimizing antibiotic residues in meats and milk. Penicillin, for example, is known to induce allergic reactions in some sensitive people, and therefore, penicillin-tainted milk poses a health risk for these individuals. Similarly, chloramphenicol has been reported to induce blood dyscrasias that may lead to death; hence, its use in food-producing animals has been prohibited by the Food and Drug Administration (FDA). The FDA has also prohibited the use of nitrofurans in food-producing animals (excluding the topical routes for administration) because studies have shown them to be carcinogenic. Not only therapeutic drugs but pesticides create residue problems. Most pesticides are administered topically, allowing some amount of percutaneous absorption and sequestration in edible tissues. Lindane has been detected in the fat deposits of sheep dipped in a 0.0125% lindane emulsion 12 weeks after topical exposure (Collett and Harrison 1963). Other studies have shown lindane residues in sheep, goats (Jackson et al. 1959), and lactating cows (Oehler et al. 1969). In addition to lindane, many common pesticides (organochlorines, organophosphates, botanicals, pyrethrins, etc.) and herbicides used in agriculture today that are applied topically have been shown to produce residues in food-producing animals. Environmental contaminants (e.g., heavy metals, PCB, dioxins, mycotoxins) are also of major concern today. Tissue residue violations detected by governmental monitoring programs have been summarized by Sundlof (1989). More information on xenobiotics in food-producing animals is available in Riviere (1992a). Both public-health and economic concerns have been the major driving forces in the United States and in other countries behind the search for ways to minimize the threat of residue contamination of the public food supply.

Contamination of the food supply with chemical residues is rarely an intentional act and usually results either from failure to observe the correct meat withdrawal or milk discard time for a drug after it has been used to treat a disease process in food animals or from accidental contamination of feed by chemicals or drugs. A study by Van Dresser and Wilcke (1989) provides some interesting insight on drug residue problems in food-producing animals. In that study, streptomycin, penicillin, sulfamethazine, and oxytetracycline were the four most common antibiotics found in tissues, with sulfamethazine being the most commonly found sulfonamide in animal tissues. Long-acting formulations of these drugs (i.e., penicillin and oxytetracycline) had the highest association with violative residues in the animals involved in the study. Injectable drugs were more likely to be associated with residue problems than were feed additives and boluses. Most of these residues were found in veal calves, cows, and market barrows and gilts. The most frequently cited reason for violative residues was failure to observe the correct withdrawal time for the drug. Failure to observe the correct withdrawal time was cited as the most common reason for violative drug residue levels in a study performed by the FDA in the 1970s (Bevill 1984) and continued to be the most common cause of residue violations in the 1990s. Interestingly, in this study the producer was found to be the responsible party in 80% of the cases investigated for violative levels of drug found in edible tissues (when the responsible party could be identified); unapproved drug use (extralabel drugs) is not considered a major cause of drug residues in animals. Ways to prevent drug residues will be discussed later in this chapter.

The FDA and Environmental Protection Agency (EPA) establish tolerances for a drug, pesticide, or other chemical in the relevant tissues of the food-producing animals. The tolerance is the tissue concentration below which a marker residue for the drug or chemical must fall in the target tissue before that animal's edible tissues(s) (meat, milk, or eggs) are considered safe for human consumption (Riviere 1991). The marker residue may be the parent compound, or a metabolite, and reflects a known relationship to the total residues of the drug or chemical (parent and all metabolites). The target tissue is an edible tissue, frequently liver or kidney which, when the compound has depleted

below the tolerance, assures that all edible tissues are safe for human consumption. Tolerances for different tissues are considered legal end points for which drug withdrawal times are established. Tolerances are established based on assessment of potential hazard of consumption to humans, a topic extensively reviewed elsewhere (Gehring et al. 2006). Oral toxicity studies are conducted in animals leading to the determination of an acceptable daily intake (ADI) for the compound in the human diet. These studies consider the compound's carcinogenic potential, systemic, reproductive, and developmental toxicity, and incorporate various safety factors. Recently, the potential for an antimicrobial compound to induce resistance in bacteria is also factored in. A safe concentration for human consumption is calculated using an equation which accounts for the amount of a specific food consumed by a person representing a high-consuming population (e.g., 19-year-old males) so that a safe concentration of the drug in this food (e.g., meat, milk, eggs) can be established. Various safety factors and statistical considerations are built into these determinations, and a tolerance for this drug in the specific tissue is established where appropriate and published. For example, safety factors reflect the duration of exposure and the nature of the toxic effects associated with the chemical. A teratogen requires a larger safety factor than a nonteratogen, and ADIs based on a short-term subchronic study use a larger safety factor than ADIs based on chronic studies. The tolerance is for a specific drug or chemical entity and reflects both the inherent toxicity of the chemical as well as assumptions about the human consumption of the tissue for which the tolerance is established. Tolerances are determined for the active ingredient (the drug substance or its metabolite) and are not established for the specific formulation of the commercial drug product. A full discussion of this process has recently been reviewed (Baynes et al. 1999) and can be found in toxicology or risk assessment texts. It is important for the veterinarian to realize that the end point for determining withdrawal times, the tolerance, is a combined scientific and legal concept and therefore *is* ultimately controlled by regulatory and not medical practices.

The actual withdrawal time appearing on a drug label is also a function of the experimental design that the manufacturer used in the research studies submitted to the FDA for approval. Thus, although the science governing the withdrawal time is based on the pharmacokinetic principles discussed below, the withdrawal time is actually determined based on experimental data. Generally, a drug is administered to healthy animals, groups of the animals are slaughtered at sequential time intervals, and their edible tissues are analyzed for drug concentrations. The withdrawal time is the time from cessation of treatment to the time it takes for the residues of the drug to deplete below the safe concentration. A statistical method is used to determine the time at which the marker residue depletes to the tolerance in the target tissue. The method determines the time, rounded to the next whole day, at which the upper bound of the marker residue tissue concentration is below the established tolerance in the target tissue (where the upper bound is statistically determined to represent with 95% confidence the 99th percentile of the population). Withdrawal times for the FDA-approved drugs for use in food animals are only valid for the specified species, dose, route, and frequency of administration. They are also specific to the manufacturer's product and formulation; thus, a drug substance (the active ingredient) may have different withdrawal times when present in differently formulated drug products. An analogous process occurs in establishing milk discard times and in determining the withdrawal times for drugs administered to egg-laying poultry (although presently, all drugs approved in the U.S. for use in laying hens have a 0-day withdrawal).

REGULATION OF DRUG RESIDUES IN ANIMALS

Producers, veterinarians, and other persons involved with chemicals and food-animal production should be acquainted with a few terms and the agencies involved in drug residue control in order to better understand the drug residue problem and how withdrawal times are determined.

The use of drugs in veterinary medicine especially in food-producing animals is closely regulated in the United States by the FDA under the Department of Health and Human Services. The FDA is charged, through the Federal Food, Drug and Cosmetic Act, with regulating the use of drugs in humans and in animals as well as requiring that the safety and efficacy of a drug be established before the product can be approved for use in animals, including those drugs added to animal feeds. The FDA also regulates human biologics, medical devices, drugs, and food safety. The FDA's Center for Veterinary Medicine (FDA-CVM) is responsible for the regulation of drugs, medical devices,

and feeds intended for animals. The FDA is charged with the responsibility for establishing withdrawal times for drugs and the tolerances of drugs. The FDA and the EPA share responsibility for establishing tolerances for pesticide residues in animal-derived foods.

Whereas the FDA establishes safety guidelines for drug use in food animals, it is the responsibility of the USDA to enforce the standards established by the FDA and the EPA. The USDA, through authorization by the Federal Meat Inspection Act and the Poultry Inspection Act, inspects meat and poultry for sale through interstate commerce. The USDA is also authorized to test the tissues of food-producing animals through provisions in the Federal Insecticide, Fungicide and Rodenticide Act to determine whether violative levels of residues of chemicals and drugs are present. The Food Safety Inspection Service (FSIS), a division of the USDA, monitors these tissues through the National Residue Program (NRP) and identifies problems with drug and chemical residues. The NRP has been in existance for over 25 years and has concentrated on individual as well as population sampling for monitoring and surveying possible residue problems in slaughter animals. In 1992, the NRP estimated they would collect some 350,000 specimens that year to analyze for antimicrobial and pesticide residues (Kindred and Hubbert 1993). The FSIS is the largest safety inspection force in the federal government (Norcross and Post 1990).

The FSIS uses several rapid tests for determining contamination of animal products. Among these are the Swab Test on Premises (STOP) for antibiotic and sulfonamide residues, the Overnight Rapid Beef Identification Test (ORBIT) for species identification of meat, the Calf Antibiotic and Sulfa Test (CAST), the Sulfa-on-Site (SOS), and a variety of Enzyme-Linked Immunosorbant Assays (ELISAs) (Norcross and Post 1990). Rapid screening tests for residues have been summarized (Sundlof 1989). Milk in bulk tanks and from individual animals is assayed for antibiotic residues using various testing strategies: Penzyme III (SmithKline Beecham Animal Health), Spot Test (Cambridge Biotech Corp.), Charm Tests (Charm Sciences, Inc.), and Delvo tests (Gist-Brocades Food Ingredients, Inc.), to name only a few. This area is difficult to adequately summarize because rapid advances in analytical screening methodologies have led to the rapid development of new tests.

Other federal government agencies have defined roles in regulating the sale and use of drugs in animals, including the Drug Enforcement Agency (a division of the Department of Justice), the Animal and Plant Health Inspection Service (a part of the USDA), the EPA (mainly for pesticides), and the Department of Transportation. On a state level, the Department of Public Safety, Department of Health, the Animal Health Commission, Boards of Veterinary Medical Licensing, and Pharmacy Boards all have some regulatory influence over the use of drugs in food-producing as well as companion animals.

THE VETERINARIAN AND EXTRALABEL DRUG USE. The FDA approves new animal drugs for specific indications in a particular species or subclass of animals (e.g., dairy cattle, weanling pigs, etc.). Occasionally, veterinarians may encounter diseases or conditions in animals for which there are no FDA approved drugs. Under such circumstances, veterinarians often administer drugs that are not approved for use in food animals or they administer approved drugs in nonapproved ways, practices commonly referred to as "extralabel" usage. Extralabel drug use is defined as the use of a drug in a manner that is inconsistent with its FDA-approved labeling, a practice that, until 1994, was technically illegal. Recognizing that the Food, Drug and Cosmetic Act (FD&C) placed veterinarians in an untenable position of having to choose between providing for relief of animal suffering or complying with the law, the U.S. Congress passed the Animal Medicinal Drug Use Clarification Act (AMDUCA) in 1994. AMDUCA amended the FD&C Act to allow veterinarians under specific conditions to prescribe and administer drugs in an extralabel manner. Table 61.1 lists drugs specifically prohibited from extralabel use in food animals. Under AMDUCA, veterinarians may resort to the extralabel use of approved animal and human pharmaceuticals provided that the following conditions are met:

1. There is no approved new animal drug that is labeled for the intended use and that contains the same active ingredient which is in the required dosage form and concentration, except where a veterinarian finds, within the context of a valid veterinarian-client-patient relationship, that the approved new animal drug is clinically ineffective for its intended use.
2. Prior to prescribing or dispensing an approved new animal or human drug for an extralabel use in food animals, the veterinarian must
   - Make a careful diagnosis and evaluation of the conditions for which the drug is to be used;

TABLE 61.1 Drugs prohibited from extralabel use in food animals

Chloramphenicol
Clenbuterol
Diethylstilbestrol (DES)
Dipyrone*
Gentian Violet
Nitroimidazoles (including dimetridazole, metronidazole, and ipronidazole)
Nitrofurans (including nitrofurazone and furazolidone; topical use prohibited as well)
Phenylbutazone use in adult dairy cattle
Sulfonamide drugs in lactating cows**
Fluoroquinolones*
Glycopeptides

*Prohibition does not apply to approved uses.

**Prohibition does not apply to approved uses of sulfadimethoxine, sulfabromomethazine, and sulfaethoxypyridazine.

- Establish a substantially extended withdrawal period prior to marketing of milk, meat, eggs, or other edible products supported by appropriate scientific information, if applicable;
- Institute procedures to assure that the identity of the treated animal or animals is carefully maintained; and
- Take appropriate measures to assure that assigned timeframes for withdrawal are met and no illegal drug residues occur in any food-producing animal subjected to extralabel treatment.

The following additional conditions must be met for a permitted extralabel use of in food-producing animals of an approved *human* drug, or of an animal drug approved only for use in animals not intended for human consumption:

1. Such use must be accomplished in accordance with an appropriate medical rationale.
2. If scientific information on the human food safety aspect of the use of the drug in food-producing animals is not available, the veterinarian must take appropriate measures to assure that the animal and its food products will not enter the human food supply.
3. Extralabel use of an approved human drug in a food-producing animal is not permitted if an animal drug approved for use in food-producing animals can be used in an extralabel manner for the particular use.

Implicit in these regulations are that the veterinarian makes every effort to first use an approved drug at an approved dosage, that an individual veterinarian-client-patient relationship exists between the producer and the veterinarian, that proper animal identification and documentation be maintained, and that the veterinarian makes every effort to determine an extended withdrawal time for this usage (e.g., consult with a databank such as the Food Animal Residue Avoidance Databank, FARAD), which the producer must adhere to. The regulation prohibits extralabel use for routine production purposes, routine disease prevention, or as feed additives.

PHARMACOKINETICS AND RESIDUES

Pharmacokinetics is the science of quantitating the change in drug concentration in the body over time as a function of the administered dose. Although this discipline has been covered in Chapters 2 and 3 of this text and elsewhere (Riviere 1992b, 1999), it is important to review some principles here since it serves as the basis for understanding withdrawal times.

How a drug or combination of drugs behaves in the body after administration not only is important from a therapeutic point of view but is of paramount importance to the producer and veterinarian in order to prevent residues in the edible tissues after the disease process has been resolved and the animal is slaughtered. For therapeutic usefulness and drug residue determinations, a known amount of drug is administered to a healthy animal. Serum concentration data are collected and mathematical models are created so that the overall disposition of the drug in the body can be evaluated in relation to absorption, distribution, metabolism, and elimination. Parameters for these models are estimated by fitting regression lines to the observed serum concentration versus time profiles, an example of which was shown in Chapter 3, Figure 3.15.

The slopes of the three lines shown in Figure 3.15, when plotted on a semilogarithmic plot, represent distribution (λ_1), short-term elimination (λ_2), and long-term elimination (λ_3) from the body. The λ_1 (or α) and λ_2 (or β) phases of the serum concentration versus time profile are the only phases that are usually present when serum concentrations are monitored over a short period of time after dosing and are typically used to predict therapeutic drug concentrations. When serum concentrations are monitored for longer periods of time after drug administration using more sensitive assay methods, however, the λ_3 (or γ) phase of elimination appears for certain compounds. This can be

present for several days or several months after the last administered dose depending on the drug's physicochemical properties, the amount of drug administered, and the species in which it was administered. This λ_3 phase reflects drug disposition in the so-called "deep compartments." Alternatively, for prolonged-action depot preparations (e.g., benzathine penicillin), this terminal phase may actually reflect the rate-limiting absorption phase ("flip-flop" phase). For purposes of determining withdrawal times of drugs that may be used in food-producing animals, we will focus our discussion on the terminal phase of drug elimination to determine the half-life ($t_{1/2}$) of the drug in the body, since this is the measurement that is relevant in determining drug withdrawal times.

In the actual research studies conducted to determine a withdrawal time, it is the half-life of drug in the specific tissue that is of paramount importance. This information is not available to the veterinarian. Additionally, tissue pharmacokinetics are exceedingly complex, and a discussion here of terminal half-lives will be sufficient to illustrate the concepts involved. For more in-depth information on the clinical application of pharmacokinetics and how pharmacokinetic parameters can affect clinical parameters, readers should consult Chapters 3 and 51 of this textbook.

The half-life of the drug or chemical in the body is the primary biological measurement used to determine withdrawal times of drugs and chemicals in food-producing animals; however, this parameter can be influenced by many biological factors. The $t_{1/2}$ of a drug by definition is the time is takes for 50% of the drug in the animal to be eliminated from the body and is based on the terminal slope of the elimination curve used to determine the withdrawal time of a drug. The $t_{1/2}$ is calculated using the equation

$$t_{1/2} = \ln 2/\text{slope or } t_{1/2} = 0.693/\text{slope}$$

If the concentration of a drug in the muscle of a food animal after dosing is 100 parts per million (ppm), then the time it takes for the concentration in the muscle to decrease to 50 ppm would be the biological half-life of the drug in the muscle. Extrapolated out, the amount of drug in the muscle after 10 half-lives would be 0.1 ppm, or, put in other terms, 99.9% of the drug would have been eliminated from the muscle after 10 half-lives. If the dose is doubled and the beginning concentration in the muscle is now 200 ppm, only 1 additional half-life would be required to reach the 0.1 ppm concentration. On the other hand, if the half-life of the drug in the muscle is doubled, perhaps due to a disease state, then the elimination half-life would also double, thereby increasing the risk of violative drug residues in the edible tissues of that animal.

As stated above, the elimination half-life can be influenced by many biological factors. The half-life of a drug or chemical in the body is influenced by how well it distributes in the body and how quickly it is eliminated from the body. The physicochemical properties of a drug can influence its disposition in the body—in particular, how well it distributes into certain tissues, whether or not it penetrates intracellularly, or whether it permeates the blood-brain barrier. The volume of distribution (V_d) is the quantitative estimate of the extent of the distribution of the drug in the body and can therefore directly influence the $t_{1/2}$ of the drug. It is a proportionality constant relating the concentration of drug in the serum to the total amount of drug in the body. For an intravenous injection of a drug, the equation for calculating V_d is

$$V_d = \text{amount of drug in the body}/\text{serum drug concentration}$$

It is important to point out that the V_d, typically reported in l/kg, does not actually refer to any specific physiologic space or body area; rather, it gives a good indication of how well a drug in general distributes throughout the body. A drug that has a large V_d typically has good tissue distribution throughout the body (e.g., tetracyclines), while a drug with a small V_d has less penetration into the body tissues as whole, perhaps being confined to the extracellular spaces due to one or more of its physicochemical properties (not lipid soluble, fixed charge). While V_d may give an indication of the overall distribution of a drug, some drugs may not be uniformly distributed throughout the body. In this case, a drug may seek specific cells or organs or be bound to tissue macromolecules, resulting in a large V_d measurement and yet a relatively poor overall distribution in a majority of the body's tissues. Some drugs may have prolonged withdrawal times due to a large V_d.

In addition to V_d, the clearance (Cl) of the drug also plays an important part in determining the withdrawal time of the drug. Clearance quantitates the efficiency of the elimination processes and is defined as the rate of drug elimination from the body relative to the concentration of drug in the serum by the equation

$$Cl = \text{rate of elimination}/\text{serum drug concentration}$$

Drugs that have a slow rate of elimination from the body will tend to have protracted half-lives, while those that are eliminated quickly will have shorter half-lives.

The $t_{1/2}$ is dependent on two functions: V_d and Cl. By combining terms, an equation can be derived that reflects the influence of V_d and Cl on the $t_{1/2}$ of a drug:

$$t_{1/2} = \ln 2 V_d / Cl \text{ or } t_{1/2} = 0.693\, V_d / Cl$$

Several physiologic events can occur to change V_d or Cl and can therefore influence the $t_{1/2}$ of the drug in the body. For example, if renal function is impaired, the drug's clearance may be reduced and the $t_{1/2}$ prolonged by several hours or several days, in turn prolonging the withdrawal time of the drug. If the animal's fluid balance changes, the V_d may change accordingly. Factors such as the age, nutritional status, percentage of body fat, species, presence of other drugs, extent of protein binding can all have a significant role in determining the V_d and Cl and hence the $t_{1/2}$ of any drug introduced into the body. For more information on the pharmacokinetics, readers are encouraged to consult Chapters 2 and 3.

Recent work has used physiologically based pharmacokinetic modeling (similar to Fig. 3.18) to develop models that incorporate tissue compartment measurements into their structure (Craigmill 2003; Buur et al. 2005, 2006). These models also allow direct incorporation of statistical estimates of population variability in all processes impacting on residue depletion to be included in the modeling. Their downside is that significant data are required for their solution.

The pharmacokinetic behavior and efficacy of the drug or chemical used to treat a disease process are of major concern early on in the successful management of herd health in food animals. For residue control in food-animal species, the primary purpose of knowing the pharmacokinetic behavior of the drug (i.e., the terminal elimination half-life) is to determine the withdrawal time to avoid residue accumulation in those tissues consumed by humans. A knowledge of what physiological processes affect the half-life is thus essential to determine when a withdrawal time might need to be modified due to disease-induced prolongation of the withdrawal time.

Theoretically, if a tissue tolerance and the dose of drug were known, pharmacokinetic techniques could be used to calculate an individual withdrawal time. For an oral drug, this requires knowing the fraction of the dose administered which is absorbed into the body (e.g., bioavailability). This amount, divided by the V_d, is the initial concentration of drug in the body (C^0). If one were to assume that the loss of drug from the body were only dependent upon the terminal withdrawal time, then adjusting equation 3.10 by solving for T as the withdrawal time, and substituting K as 1.44 $t_{1/2}$, the following relationship can be derived as

$$\text{withdrawal time} = 1.44 \ln\left(C^0/\text{tolerance}\right)\left(t_{1/2}\right).$$

Of course, this is an oversimplification. In reality, this equation would work if C^0 were the concentration of drug in the target tissue at the end of drug administration, as this amount is dependent upon the λ_2-phase elimination processes. Complex pharmacokinetic models can be used to calculate this number. Then the above equation would be valid. Officially established withdrawal times must take into account all interanimal variability, and thus statistical processing of these data establishes the withdrawal time for the worst-case scenario.

The above equation is useful to gain a perspective on what the withdrawal time is relative to the terminal half-life. Assume that for most antibiotics a "therapeutic" concentration is 10 μg/ml and the tissue tolerance is 0.01 ppm (0.01 μg/ml). One also must assume homogeneous distribution of the drug throughout the body. Thus, withdrawal time equals 1.44 [ln (10/0.01)] $t_{1/2}$, or 9.94 $t_{1/2}$. A withdrawal time for this drug would be equal to 10 half-lives. If the drug has a short half-life (e.g., penicillin), the withdrawal time is short. However, if the drug has a prolonged tissue half-life (e.g., an aminoglycoside), the withdrawal time could exceed a year in the target tissue. Similarly, a drug with a very low tissue tolerance has a longer withdrawal time because ln (C^0/tolerance) is now greater. If a drug is metabolized, the metabolite may determine the withdrawal time ("marker residue") since its half-life is rate limiting.

This "rule of 10" can be derived by assuming that 10 half-lives are required to eliminate 99.9% of an administered dose, as discussed earlier in this section. An examination of half-lives and withdrawal times for a number of approved pharmaceutics confirms this relation as being very conservative relative to human food safety endpoints (Gehring et al. 2004). In fact, these so-called "half-life multipliers" of 4–5 were often sufficient since the target tolerance for drugs with minimal adverse effects was not at very low concentrations reflective of complete drug elimination. Using a divisor of 5 could actually be considered even more conservative since the additional time added to the withdrawal time would be longer.

This relationship is important to consider when one administers an increased dose of drug. If the dose is doubled, withdrawal time should just be increased by a single half-life. In the above example, the calculation would 1.44 ln (20/0.01), or 10.94 half-lives, which confirms this concept. However, if a disease process changed the half-life by either increasing volume of distribution or decreasing clearance (e.g., kidney disease) causing the half-life to double, withdrawal time should be doubled. This phenomenon supports the observation that seriously ill animals with altered pharmacokinetics deserve increased attention to ensure complete drug withdrawal. It is also important to note that withdrawal time is determined in healthy animals, and thus serious disease conditions may cause residues even when the approved dose and official withdrawal time are used. *It is critical for a veterinarian to have a conceptual understanding of this relationship between withdrawal time and half-life before doses are modified in food-producing animals.* When such a withdrawal time is calculated, the animal should be checked with the appropriate rapid screening test.

For lactating dairy cows and goats, the identical principles apply to determining the milk discard times. The milk discard or withholding time is the time after drug administration when the milk cannot be used for human consumption. This is determined by administering the drug and collecting and analyzing milk until drug concentrations are below the milk tolerance established for that drug. Like withdrawal times, the discard time is product and species-dependent. In this case, it is based on the half-life of the drug in the milk. If one knows the concentration of the drug in the milk at the end of drug administration, the milk half-life, and the milk tolerance, the above equation can be used to precisely calculate withdrawal. This has been particularly useful when valuable dairy cows have been accidentally exposed to pesticides (e.g., heptachlor) and pharmacokinetic data were used to determine milk discard times since approved withdrawal times do not exist. In this case, the relevant parameter is the half-life of drug in milk. All of the principles discussed above relative to meat withdrawal apply. The half-life in milk is a function of how the drug is excreted into the milk after systemic administration (or oral or interuterine) or is retained in the udder after intramammary infusion. For example, basic drugs such as erythromycin have longer discard times than acidic drugs such as penicillin because the former tend to distribute more readily into milk due to the pH partitioning phenomenon. Similarly, lipophilic drugs will tend to have longer milk discard times. Discard times are different for these different routes of administration. One must be sure that a drug used as dry cow therapy is not inadvertently administered to a lactating cow, because the residue concerns are different since most dry cow formulations are long-acting preparations.

DRUGS PROHIBITED FROM EXTRALABEL USE

Certain drugs are prohibited from extralabel use in food animals under AMDUCA (Table 61.1). The FDA may prohibit the extralabel use of an approved new animal or human drug or class of drugs in food animals if FDA determines that the extralabel use of the drug or class of drugs presents a risk to the public health, or an acceptable analytical method needs to be established but such method has not been established. A prohibition may be a general ban on the extralabel use of the drug or class of drugs or may be limited to a specific species, indication, dosage form, route of administration, or combination of factors.

RESIDUE PREVENTION

Although public awareness of the drug residue problem in food is high and several governmental agencies spend large amounts of time attempting to control this problem, residues in animal tissues are still an important concern today. The responsibility for residue control and prevention cannot lie solely within a governmental agency; rather, the responsibility must be shared by the government, producers, veterinarians, teachers and academicians, marketing associations, and other interested parties, who must strive for both healthy and efficiently grown animals as well as a safe food supply. Several approaches can be taken to achieve this goal.

The first step in residue prevention is to make individuals and organizations aware of the problem through education. Education of laypersons can be accomplished through a variety of mechanisms: available open lay and veterinary medical literature, computer databases, consultations with veterinary medical personnel, or the efforts of national organizations. A number of national producer organizations have firm initiatives in place to prevent harmful residues in food-producing animals, including dairy (Adams 1993), beef (Wilkes 1993), pork (Lautner 1993), and veal (Wilson and Dietrich 1993) organizations. Awareness has

also been raised concerning some species of companion animals (Macomber 1993; Kay 1993).

Failure to observe the correct withdrawal time of a drug was the leading cause of tissue residue violations in two studies (Van Dresser and Wilckie 1989; Bevill 1984). Once the importance of residue control in the U.S. food supply is made clear and the importance of observing the correct legal withdrawal times for the drugs used in food-producing animals is understood, the incidence of tissue residue violations will (theoretically) decrease dramatically. Many have reported on other possible ways to reduce or prevent residues from occurring in food animals (Gehring et al. 2006; Riviere 1991; Marteniuk et al. 1988; Sundlof 1989; Kindred and Hubbert 1993; Mercer 1990). Rapid screening test technology has advanced significantly in the past few years and has been used to detect low levels of residue contamination in slaughtered animals in a quick manner. As these tests become more sensitive and more widely used, animals with residue contamination can be isolated and removed before reaching the end consumer, further decreasing the residue problem.

Several rapid screening tests are available. They are powerful tools for the veterinarian using a drug in an extralabel manner or in a seriously diseased animal. Once the veterinarian establishes a putative withdrawal time using the principles discussed above, the animal should be tested with the appropriate rapid screening assay to ensure that the prediction is accurate. If a residue is detected, a prolonged withdrawal time should be recommended until a negative screening value is observed. If this practice is followed, the veterinarian will have done everything possible to ensure a residue-free product.

FARAD is a USDA-supported computerized databank of scientific and regulatory information, established in 1982 and reauthorized by the U.S. Congress in 1998, that can assist the veterinarian, producer, or other individuals in making rational choices in preventing drug and pesticide residues in food animals. It is a collaboration of North Carolina State University, University of California at Davis, and University of Florida at Gainesville. FARAD contains information on veterinary drug registration information; current label information; foreign registration and safety data; tolerances for drugs and pesticides for tissues, eggs, and milk; withdrawal information; physicochemical properties; pharmacokinetic and toxicokinetic information; residue test information; bibliographic citations; and other information useful in preventing drug residues in food animals. The database is regularly updated to provide users with the most current information available. FARAD is easily accessed by voice telephone (888-USFARAD), fax, and electronic mail at two regional access centers (North Carolina State University and University of California Davis). By contacting an access center, users can obtain any of the current information listed above. FARAD services are free to clientele. FARAD also publishes periodic updates on extralabel drug withdrawal time estimates and other issues as a regular feature in the *Journal of the American Veterinary Medical Association* (FARAD DIGESTS). The program's website (www.farad.org) should be consulted for orientation to its services and current access information. More information on FARAD is available elsewhere (Riviere et al. 1986; Payne et al. 1999).

Other sources of drug information pertaining to residues in food animals are also available. The FARAD pharmacokinetic data have been published in book form (Craigmill et al. 2006). The Food and Agriculture Organization (FAO) and World Health Association (WHO) Joint Expert Committee on Food Additives (JECFA) has evaluated several drugs and has published monographs that list toxicity, metabolism, acceptable daily intakes, maximum residue levels permitted for different tissues, and biological fate of drugs in food-producing animals. The *United States Pharmacopoeia* (USP) also publishes monographs (similar to the monographs for human drugs) that go into more depth about expanded (extralabel) pharmaceutical usage and pharmacokinetic variables that can alter withdrawal times in food-producing animals (Sundlof 1993).

The prevention of harmful residues in the edible tissues of our food-producing animals is the responsibility of many producers, veterinarians, professional and layperson associations, and governmental agencies. All of these groups must continue to strive to regulate and utilize the drugs used to prevent or cure animal diseases in a responsible manner in order to prevent the accumulation of harmful amounts of residues in the food supply.

  antihistamines for, 421
  histamine release, 413–14
Anastrozole, for cancer treatment, 1225

Androgens, 718t, 730–32
anabolic steroids, 730–31
benign prostatic hypertrophy, 731, 731f
finasteride, 731–32, 731f
testosterone, 730, 730f
Anemia
amphotericin B and, 1019
griseofulvin and, 1015
novobiocin and, 969
rifampin and, 971
Anesthesia, NSAIDs and, 482
Anesthesiology
anesthetic classification, 199–202, 199t
general, 200–202, 201f
local and regional, 200, 200t
anesthetic use, 198–99, 198f
clinical anesthesia basics, 202–6, 202t
anesthetic period, 205, 205t
postanesthetic period, 205–6, 206t
preanesthetic period, 202–5, 203t
principles of, 197–208, 197t
response to anesthesia, 206–8, 207f, 207t, 208f, 208t
Anesthetics
atropine with, 175
body fluids, electrolytes, and acid-base balance, 643
bretylium with, 595
classification of, 199–202, 199t
general, 200–202, 201f
local and regional, 200, 200t
clinical basics, 202–6, 202t
anesthetic period, 205, 205t
postanesthetic period, 205–6, 206t
preanesthetic period, 202–5, 203t
epinephrine with, 136–38
inhalation, 229–53
administration properties, 233–34
drug kinetics properties, 234–35
overdose, 404
overview of, 229–31, 230f, 230t
pharmacodynamics of, 241–53, 242f, 243f, 244f
pharmacokinetics of, 235–41, 236f, 237f, 238f, 238t, 239f, 240t
physicochemical characteristics of, 231–33, 231t, 232f, 233t
trace concentrations of, 253
injectable, 265–96
barbiturates, 267–75
disadvantages of, 267
dissociatives, 279–81
indications for, 266
properties for, 267
propofol, 275–79
local, 381–97, 382f
agents, 392–95
formulation of, 388–89
future outlook of, 397
interactions with, 391–92
mechanisms of, 381–83
metabolism of, 387–88
regulatory issues of, 392
stability of, 392
structure and chemistry of, 383–87, 385t–386t, 387t
topical use of, 395–96
toxicity of, 389–92, 390f
using, 396–97
neuromuscular blocking agents and, 211
opioids as, 311
response to, 206–8, 207f, 207t, 208f, 208t
use of, 198–99, 198f
Angiotensin, 429–33
cardiovascular effects of, 432
formation of, 431–32, 431f
pharmacology of, 432–33
renin release, 430–31, 430f
Angiotensin-converting enzyme (ACE), 431
inhibitors of, 433, 559–62
adverse effects of, 561
captopril and enalapril, 559–62
for chronic renal failure, 562
interactions with, 561–62
mineralocorticoid receptor antagonists and, 666
other agents, 562
Angular limb deformities in foals, tetracycline antibiotics for, 908
Anhydrous absorption ointments, 1290
Animal Drug Availability Act of 1996 (ADAA), 1360–61, 1370
Animal Drug User Fee Act of 2003 (ADUFA), 1361–62
Animal Medicinal Drug Use Clarification Act of 1994 (AMDUCA), 47, 1335–36, 1360, 1369–70, 1408, 1408t, 1409t

Autonomic nervous system
  autonomic drugs, 120t, 121
    parasympathomimetic agents, 157–65, 158f
  function of, 102–8
    central integration of, 108
    information transmission, 107–8, 107f
    interrelationships in, 102, 105
    organ responses to, 105–7, 105t–106t
  G proteins and cyclic nucleotides, 119f, 120–21
  neurohumoral transmission, 108–10
    adrenergic, 110–13
    cholinergic, 113–14
    definition of, 107
    general concepts of, 108–9
    physiologic events, 109–10
  nitric oxide, 115–19
  organization of, 101–2
    parasympathetic, 102, 104f
    sympathetic, 102, 103f

putative neurohumoral substances, 115
receptor sites, 114
Avermectins
approved status of, 1190t
available preparations of, 1132–33, 1134t
chemistry of, 1190
ecotoxicological impact of, 1140
efficacy of, 1191–92
general pharmacology of, 1119–22, 1120f, 1121f
mechanism of action, 1122–23, 1123f, 1186t
pharmacodynamics of, 1127–30, 1128f, 1129f
pharmacokinetics of, 1123–27, 1190–91
drug and host-related factors affecting, 1135–38, 1136t, 1137f, 1138f
exchange between bloodstream and target tissues, 1123–26, 1124f, 1125f
metabolism, excretion, and transport of, 1126–27
resistance to, 1132
safety/toxicity of, 1192, 1192t
therapeutic uses of, 1130–32
tissue residues and withdrawal times of, 1138–39
Avian influenza, disinfectants for, 831–32
Axonal conduction, 109, 109f
5-Azacytidine, for cancer treatment, 1217–18
Azalides, 1146t–1148t, 1173
Azamethonium, 177–78
Azaperone, 365–66, 366f, 368
Azapetine, 146–48, 147f
Azathioprine, 1241–42
adverse effects of, 1242
cat problems with, 1242
clinical use of, 1241–42
mechanism of action of, 1241, 1241f
toxicity of, 1242
Azithromycin, 954–55, 962–63, 1146t–1148t, 1173
clinical use of, 963
safety of, 963
Azlocillin, 874–75
Azole antifungals, 1014f, 1019–31, 1019f, 1020t
amphotericin B with, 1017
fluconazole, 1023–24
interactions with, 1020, 1021t
itraconazole, 1019f, 1020t, 1024–29, 1027t–1028t
ketoconazole, 1019f, 1020–23, 1020t
mechanism of action, 1019–20
other drugs, 1031
posaconazole, 1019f, 1020t, 1030–31
voriconazole, 1019f, 1020t, 1029–30, 1030f

Bacitracin, 968
Bacteria, drug absorption and, 18–19
Bacterial septicemia, with diarrhea, 1265
Barbiturates, 267–75
adverse effects/contraindications, 273
classification of, 267–68, 267f, 268f, 268t
dose, 273, 273t
duration of action, 274
history of, 267
indications, 272
as injected euthanizing agents, 404
interactions with, 275
mechanism of action, 268–69
metabolism of, 272–73
methohexital, 270
overdose/acute toxicity, 275
pentobarbital, 269
pharmacokinetics of, 272
phenobarbital, 270
physiologic effects of, 270–72
products, 275
species differences, 274
for status epilepticus, 506
thiamylal, 269
thiopental, 269
thyrotropin and, 705–6
Barbituric acid, 267, 267f
Baricity, for local anesthetics, 388
Bartonella henselae, ectoparasiticides for, 1181
Basic pharmacology, 9
BBB. *See* Blood-brain barrier
Behavior drugs, 509–33
drug classes, 515–33
antidepressants, 521–22
antipsychotics, 516–17
anxiolytics, 517–21, 517f
atypical antidepressants, 529
miscellaneous drugs, 531–33
monoamine oxidase inhibitors, 529–31
nonbenzodiazepine hypnotics, 521
SSRIs, 525–29, 527f
TCAs, 522–25, 522f, 522f
drug combinations, 532
introduction to, 509–10
neurotransmitters, 513–15
acetylcholine, 515
dopamine, 514
gamma amino butyric acid, 515
norepinephrine, 514
serotonin, 514–15
pharmacokinetics of, 510–13, 511t–512t
treatment success with, 533
Benazepril, 562
Benign prostatic hypertrophy (BPH), 731, 731f
Benzenesulfonamides, 1102f, 1108–9, 1108f

Benzimidazoles (BZD), 1054–76, 1102f, 1109–13, 1110f, 1111f, 1112f
  administration routes of, 1070–71
  albendazole, 1069, 1146t–1148t, 1155, 1155f
  as antiprotozoan drugs, 1146t–1148t, 1154–56, 1155f
  chemistry of, 1054, 1055f
  disposition kinetics and efficacy of, 1071–74, 1073f
  distribution to parasite location, 1063–65, 1064f, 1065f
  drug transfer into target parasite, 1067–68, 1067f
  febantel, 1146t–1148t, 1155–56
  fenbendazole, 1069–70, 1146t–1148t, 1155, 1155f
  flubendazole, 1070
  formulations of, 1070–71, 1074–75
  mebendazole, 1070
  mechanism of action of, 1054–56
  metabolism of
    hepatic and extrahepatic oxidative, 1058–61, 1059f, 1060f
    reductive, in gastrointestinal tract, 1061–63, 1061f
  oxfendazole, 1070
  oxibendazole, 1070
  pharmacokinetics of, 1056, 1056f
    in nonruminants, 1065–67
    in ruminants, 1056–65, 1059f, 1060f, 1061f, 1064f, 1065f
  ricobendazole, 1069
  thiabendazole, 1068–69
  withdrawal times, safety, and toxicity of, 1075–76
Benznidazole, 1146t–1148t, 1151f, 1153
Benzocaine, 395
  physicochemical and pharmacodynamic characteristics of, 383–84, 387, 387t
Benzodiazepine antagonists, 362–65
  adverse effects/contraindications for, 364
  classification of, 362–63
  history of, 362
  indications for, 363
  interactions with, 364
  mechanism of action, 363
  overdose/acute toxicity with, 364
  pharmacodynamic effects of, 363, 518
  pharmacokinetic properties of, 363–64, 519
  products, 364–65
Benzodiazepines, 203–4, 356–62, 499–500, 517–21, 517f
  adverse effects/contraindications of, 361
  classification, 356–57
  doses for, 361–62
  history, 356
  indications for, 357
  interactions with, 362
  mechanism of action, 357
  overdose/acute toxicity with, 362
  pharmacodynamic effects of, 357–58
  pharmacokinetic properties of, 359–60, 360t
  products, 362
  species differences with, 361
  structure of, 356f
  use of, 518
Benzothiadiazines, 662–63
Benzoyl peroxide, for dermatopharmacology, 1288
Benzoylphenyl urea compounds, 1198
Beraprost, 570
Bethanechol, 160, 161t, 163
  clinical uses of, 164
  as gastrointestinal prokinetic drug, 1254
  pharmacologic effects of, 163–64
bGH. *See* Bovine somatotropin
Bicarbonate, regulation of, 622–23, 622t, 623f
Bier Block, 396
Biguanides, as antiseptics, 823
Bile acids, 1270, 1270t
Bile flow, 44–45, 45t
Biliary drug elimination, 43–45
  bile formation, 43–44, 43f
  biliary drug transport, 44–45, 45t
Bioavailability
  assessment of, 1401–3, 1402t

regulatory discretion for extralabel use, 1408
regulatory requirements for, 1407–8
unapproved drugs available, 1416
VFD. *See* Veterinary Feed Directive
VICH. *See* International Conference on Harmonisation of Technical Requirements for Registration of Veterinary Medicinal Products
Vidarabine, 1035
Villi, in drug absorption, 18, 18f
Vinblastine sulfate
for cancer treatment, 1219
toxicity of, 1208
Vinca alkaloids, cancer treatment and, 1219
Vincristine sulfate
for cancer treatment, 1219
toxicity of, 1208
Vinorelbine, for cancer treatment, 1219
VIP. *See* Vasoactive intestinal polypeptide
Virbagen omega, 1042
Virginiamycin, 971
Vitamin K antagonists, 684–85, 685t
absorption and metabolism of, 684–85
administration of, 685
chemistry and action of, 684, 685t
clinical use of, 685
interactions with, 685
Vitamin K, for hemostasis, 680–81
chemistry and mechanism of action, 680–81, 680f
clinical use of, 681
Volume of distribution (Vd), 513
of one-compartment open model, 51–52, 51f
of two-compartment open model, 58–59, 58f
Vomiting
amphotericin B and, 1019
carboplatin and, 1215
cisplatin and, 1215
cyclosporine and, 1238
doxorubicin and, 1222
ketoconazole and, 1022–23
methimazole with, 762–63
neurotransmitters involved in, 1247–48, 1248t
novobiocin and, 968
rifampin and, 969
von Willebrand factor (vWf), 674
Voriconazole, 1019f, 1020t, 1029–30, 1030f
adverse effects of, 1030
clinical use of, 1029–30
vWf. *See* von Willebrand factor

Warfarin, 684–85
Water
disorders of balance of, 612–13, 613t
glucocorticoids and, 780
homeostasis of, 608–10, 610f
renal regulation of excretion of, 610–12, 611f
Water-oil emulsion ointments, 1290
Water-soluble ointments, 1290
Waxman Hatch Act, 1384
WHO. *See* World Health Organization
Withdrawal time
calculation of, 47–48, 1338–41, 1339t
allometric scaling, 1340
future directions, 1340–41
pharmacokinetic studies, 1338–40, 1339t
species grouping, 1340
food animals and, 1455, 1460–61
in performance animals, 1428
World Health Organization (WHO), 1388–89, 1461

Xanthines, as antihistamine, 417
Xenon, 230f, 230t, 231
administration properties of, 233–34
anesthetic dose, 240–41, 240t
Xylazine, 341–42, 342t, 347t, 348, 348f

Yohimbine, 353, 353f, 354t
Young animals, fluoroquinolone administration to, 1000–1
problems with, 1003–4

Zafirlukast, respiratory system and, 1306–7
Zaleplon, 521
Zidovudine, 1038
Zileuton, respiratory system and, 1306
Zolazepam, 357, 359, 359f, 360t
Zolpidem, 521
Zonisamide, 503–4
adverse effects of, 504
clinical use of, 504
pharmacokinetics of, 503–4
Zoological pharmacology, 1343–50
allometry in, 1349–50
invertebrates, 1344
vertebrates, 1344–48, 1346f, 1347f, 1348f
